Abstract:

Hepatitis B virus (HBV) is an important human pathogen belonging to the *Hepadnaviridae* family, *Orthohepadnavirus* genus. It infects over 240 million people globally. The reverse transcription during its genome replication leads to low fidelity DNA synthesis, which is the source of variability in the viral proteins. To investigate the variability quantitatively, we retrieved amino acid sequences of 5167 records of all available HBV genotypes (A-J) from the Genbank database. The amino acid sequences encoded by the open reading frames (ORF) S/C/P/X in the HBV genome were extracted and subjected to alignment respectively. We analyzed the variability of the lengths and the sequences of proteins as well as the frequencies of amino acids. Our study comprehensively characterized of the variability and conservation of HBV at the level of amino acids, especially for the structural proteins, hepatitis B surface antigens (HBsAg), to find out the potential sites critical for virus assembly and immune recognition. Interestingly, the preS1/S2 domains in HBsAg were variable at some positions of amino acid residues, which provides a potential mechanism of immune-escape for HBV, while the preS2 and S domains were conserved in the lengths of protein sequences. In the S domain, the cysteine residues and the secondary structures of the alpha-helix and beta-sheet were likely critical for the stable folding of the protein structure. The preC domain and C-terminal domain (CTD) of the core protein are highly conserved. And the polymerases HBpol and the HBx were highly variable at the amino acid level.

Hepatitis B virus; Amino acid; Sequence characterization; Variation; conservation;

Introduction

Hepatitis B virus (HBV) is one of important human pathogens that causes hepatitis. Over 240 million people are estimated to be infected with HBV. HBV belongs to the *Hepadnaviridae* family, *Orthohepadnavirus* genus. HBV has 3 forms of viral particles, 44nm-diameter infectious Dane particles and non-infectious 22nm-diameter spherical or tubular subviral particles (SVPs). Its genome is only about 3.2kb and contains 4 overlapping opening reading frames (ORFs) which encodes 7 structural or nonstructural proteins. Although HBV is a double-stranded DNA virus, it replicates the genome by an intermediate template of pregenome RNA and thus presents a high mutation rate and low fidelity (1).

There are 3 forms of hepatitis B surface antigens (HBsAg) in the virus envelope with some domains exposed to lumen or cytosol(2). They are large, middle and small HBsAg, respectively and share the same C-terminal domain but different N-terminal domains(3, 4). They form the components of both Dane particles as well as SVPs. The HBsAg can elicit strong protection reaction of individuals against HBV or induce immune tolerance through persistent expression(1, 5). Moreover, it's a good candidate as therapeutic vaccine but is not efficient enough.

It may provide better information about potential antiviral targets to analyze the variability of HBV at the level of amino acids rather than nucleotide. In this study, to investigate the difference of viral proteins sequences/domains, we reported the sequences variability of HBV strains(genotypes A-J). We also further characterize the features of HBsAg, which may help to understand its function.

Material and methods

HBV sequences acquisition and alignment

In November 2017, a total of 5167 HBV genome records with confirmed genotypes were retrieved from the Genbank Nucleotide Database of National Center for Biotechnology Information (NCBI). The whole dataset was divided into different categories according to areas, China, Southeast-Asia (SE-Asia, including Indonesia, Malaysia, Myanmar, South Korea, Thailand, Vietnam, Japan and Korea), America (including Argentina, Brazil, Canada, Chile, Colombia, Mexico, USA and Venezuela), Europe (including Belgium, France, Germany, Ireland, Italy, Luxembourg, Netherlands, Poland, Russia, Serbia, Spain, Sweden, Turkey and UK), and the other area (including India, Iran, Saudi Arabia and Syria). Then, the amino acid sequences of 4 HBV ORFs (S, C, P and X) were extracted according to their start and end sites and were then subjected to sequences alignment with Clustral Omega(6).

Subsequent analysis was focused on those functional sequences or domains annotations. The sequences labelled with "nonfunctional" or "truncated" were discarded. The final items for analysis were 3208 sequences of ORF C, 3064 sequences of ORF S, 3701 sequences of ORF P and 4265 sequences for ORF X. The domains for further analysis were the preS1 receptor binding domain (preS1-RBD) , the preS1 domain, the preS2 domain, the S domain, the preC domain,

the core protein assembly domain (core-AD, usually 149AAs) and the core protein C-terminal domain (core-CTD, also

known as the arginine-rich domain, ARD). The positions of the preS1-RBD is referred to the sequence previously

reported(7). The preS1/S2/S domains are encoded by ORF S, while the preC, core-AD and core-CTD are encoded by

ORF C.

Feature of HBV sequences and domains

We analyzed the variability of sequences from different aspects. All domains were extracted from aligned sequences.

Aligned sequences with only gaps across the domain were discarded in subsequent analysis. Hence, the left items are

the total number of sequences for calculation of the percentage of different indices mentioned below. Among all the

sequences or domains the most frequent one was defined as the predominant sequence, which represents the conserved

sequence. It was defined as unique sequences that those sequences or domains encodes the same protein but different to

each other at the level of amino acid. Similarly, the most frequent length of sequences or domains was defined as the

predominant one. The ratio of sequences with the predominant length suggests the length conservation of a sequence or

domain.

Statistics of the frequency of amino acids of each site in sequences

After sequences alignment, we computed the ratio of amino acids residues (including gaps) for each position as

below.

$$R_{amino\ acid} = \frac{N_{sequences\ with\ specified\ amino\ acid}}{N_{total\ sequences}}$$

The ratio was the the number of sequences with specified amino acid divided by the total number of available

sequences. We define the predominant amino acid residue as the one with the highest ratio at that site.

Prediction of the secondary structure of HBsAg

A representative sequence record (Accession number of its genome record: AM295797) was subjected to the

prediction of secondary structure of the large/middle/small HBsAg. The prediction was performed in PSIPRED website

(http://bioinf.cs.ucl.ac.uk/psipred/).

Analysis of similarities of pair-wise sequences

The pair-wise sequences similarity was calculated based on the aligned sequences. The similarity was defined as the

ratio of the number of positions with identical amino acid residues to the length of the sequences. The similarity profile

was shown as a histogram. Pearson correlation coefficient (R) was computed between two profiles using Python library

scipy. R>0.8 was regarded as correlation, while R>0.9 was regarded as high correlation.

Results

Amino acid sequences analysis

The geographical sources of the 5167 sequences of documented HBV strains are listed in Table 1. A total of 3657

items(70.8%) of them are from Asia, 42.2% of which are China strains, and 17.8% are Europe strains. It suggests that

China is still a major epidemic area.

We compared 4 features of HBV sequences, the ratio of the predominant sequence, the ratio of unique sequences, the

ratio of sequences with the predominant length and the number of sequence lengths (Fig. 1). These values can

characterized either the variability or the conservation of sequences or domains. The preC domain presented the highest

ratio of predominant sequence, indicating a highly conserved domain, followed by the core-CTD. The HBpol and large

HBsAg had the top two highest ratio of unique sequences.

The lengths of amino acid sequences or domains of HBV was variable.. The number of the lengths of small HBsAg

was the smallest (Fig. 1 and Fig. S1), while those of the HBpol was the largest. The preC domain and core-CTD were

next to small HBsAg, which revealed their lengths were conserved. The preS1/S2 domains and the HBcAg are the most

conserved. However, considering the length, the small and middle HBsAg, the preS1-RBD, the preS2 domain, the core-

AD and the HBx are the most conserved. It's probable that the length is critical for the assembly, so structural proteins,

especially the small HBsAg and the core-AD, were conserved except the preS1 region which functions as receptor

binding(7). Moreover, for the HBpol, the sequence length aren't critical. Some domains of the HBpol may provide the

flexibility of length for the function.

We analyzed different HBV proteins at the level of amino acid and found that only the predominant sequence of

HBcAg account for more than 20% of total sequences (Fig. 1). However, almost all of small HBsAg sequences are of

the same length. The preS2 is also highly conserved in length. While the preS1 is more variable. In comparison, the

HBpol was variable both in length and in amino acid sequence.

The predominant AAs in different sequences or domains

We analyzed the amino acid residues in 4 HBV ORFs. As a whole, it's interesting that some sites were much

conserved while some were much variable (Fig. 2). Frequencies of almost all predominant AAs were above 50%. AAs

in the ORF S were more variable. For those predominant AAs (>=0.950), there were only about ~20% sites in the preS1

domain and ~50% sites in the preS2 domain, while there were more than 60% sites in other sequences or domains,

especially near 70% sites in the HBpol. Even in the ORF C, there were more than 60% sites with predominant AAs

(>=0.950). The amino acid residues in the preS2 domain and the S domain were more variable than those in the core-

AD and the core-CTD. It indicates the surface antigen could be more variable and provides the base of immune escape.

Among all sites, L350 in the large HBsAg and H83 in the HBpol were the most conserved. No mutation was found at

those sites of all HBV strains in our study. It is probable a potential target for development of new anti-virus strategy.

Sequences variant

After sequences alignment, we could further obtain the profile of pair-wise similarity in a whole picture. To compare the similarity of sequences or domains in different areas, we extracted subsets data from different locations, especially China which is a very important area with high prevalence of HBV infection. It's surprising that different areas exhibit different profiles of pair-wise similarity (Fig. 3). Almost all pair-wise similarities were more than 80% except that some similarities of preS2 were around 60%. The profiles of both the preC domain and the core-CTD in different areas were highly similar. When these profiles were compared using the Pearson cross-correlation coefficient, the preS2 domain, the preC domain and the core-CTD show highly coefficient. However, the profiles of the preS1 domain, the S domain, the core-AD, the HBpol and the HBx were different among different areas.

Prediction of secondary structure of the HBsAg

The HBsAg component are important proteins in immune escape and persistence of immune tolerance. It's still known a little about the structure of it. From the prediction of its secondary structure, it's surprising that alpha-helix only exists in the S domain, while the preS1/S2 domain contains only coil (Fig. S3). While comparing the different amino acid frequencies of each sites in the HBsAg, we also found that cysteine residues also exist in the S domain. Considered the conserved length of S domain, we speculate that the stable of its structure is critical for the assembly of both SVPs and envelope of Dane particles. There were 40-46 amino acid residues in the N-terminal of preS1 critical for the receptor binding of HBV(7), so the flexibility in the preS1/S2 domain could provide the allosteric effect during the virus-host recognition.

The distribution of predominant amino acids in the HBsAg

For the HBsAg sequence, it's interesting that cysteine only exists in S domain (Fig. S2). While for HBcAg, another structural protein of virions, only 3 highly conserved cysteine residues exist in the core-CTD (Fig. S3). However, cysteine residues exist throughout sequences of the non-structural proteins, the HBpol and the HBx (Fig. S4 and Fig. S5). A special function of cysteine is to form intra- or inter-molecular disulfide bonds, which can stable the structure of proteins. Thus, it's postulated that these disulfide bonds keep the stability of the S domain in the envelope, while the preS1/S2 domain without any cysteine residues could provide highly flexible conformation to help binding to the host receptor.

It have been reported that 40-46 amino acid residues in the N-terminal of the preS1 domain is critical for binding to host receptor(7-9). We found that this domain is highly conserved. However, it's surprising that over 50% HBV genome records encodes the preS1 sequence with a N-terminal extension of RBD up to 11 amino acid residues (Fig. 4). It has never been reported that this sequence is associated with receptor binding. Its amino acid sites were also highly

conserved excepting Lys11 (Fig. 4).

Discussion

The amino acid sequence is close to the folding of proteins. It causes high variation that HBV genome replicates

through a process of reverse transcription. Thus, it's necessary to have a comprehensive investigation on the amino acid

sequences of HBV proteins, which could help finding the variability and conservation of domains close to the function

and the differences between different geographical strains.

Our study revealed the variability of HBV ORF S, C, P and X at the level of amino acid. It showed the sequence

variability both in length and in the amino acid sequences. These variability of virus proteins don't seem to hamper the

normal functions. The 4 ORFs of HBV are partially overlapping. When a mutation happens in a ORF, it also likely

happens in another one. It will effect either the function or the transcription of viral proteins. Hence, the conserved

regions in HBV genome are functionally important. However, it also reveals functional flexibility in high variable

regions.

Especially, the variability of the HBsAg at the level of amino acid provided many potential epitopes. This is the

potential mechanism exhausting the immunocytes or antibodies which recognize the HBsAg. It has been reported that

the HBsAg in tubular SVPs organizes regularly in crystalline-like pattern(10). As the C-terminal part of the HBsAg, the

S domain is transmembrane and folds as the protrusion on the periphery(2, 10). Moreover, there were a total of 12

highly conserved cysteine residues in the S domain, far more than those in the core-AD of HBcAg (Fig. S3 and Fig.

S4). It indicates that these cysteine residues were probably critical for the stable of protein structure, which could help

the protrusions on SVPs to arrange in a regular way. Even the cysteine residues in HBcAg are not necessary for the

disulfide bond(11). The core-CTD is located in the internal of HBV capsid, which helps enclosing the virus genome in

assembly(12). We postulate that those cysteine residues and the lengths of the S domain are much critical for the stable

of the HBsAg structure. Furthermore, the N-terminal extension of the preS1-RBD was also a highly conserved

sequence. It's probably associate with the function of receptor binding in some unknown way.

In conclusion, we studied the viral proteins of HBV at the level of amino acid. Quantitatively investigation reveals

the conservation and variability among different sequences and domains. It would be helpful to further study the variant

epitopes of the HBsAg in the immune escape and recognition of HBV and for the development of new vaccines and

antiviral drugs.
