ABSTRACT

Bats are among the most diverse animals on the planet and harbor numerous bacterial,

viral, and eukaryotic symbionts. The interplay between bacterial community composition

and parasitism in bats is not well understood and may have important implications for

studies of similar systems. Here we present a comprehensive survey of dipteran and

haemosporidian parasites, and characterize the gut, oral, and skin microbiota of

Afrotropical bats. We identify significant correlations between bacterial community

composition of the skin and dipteran ectoparasite prevalence across four major bat

lineages, as well as links between the oral microbiome and malarial parasitism, suggesting

a potential mechanism for host selection and vector-borne disease transmission in bats.

Mirroring recent studies of host-microbiome co-speciation in mammals, we find a weak

correlation between chiropteran phylogenetic distances and bacterial community

dissimilarity across the three anatomical sites, suggesting that host environment is more

important than shared ancestry in shaping the composition of associated bacterial

communities.

Keywords: microbiome, malaria, vector-borne disease, Afrotropics, Chiroptera

SIGNIFICANCE

Animals rely on bacterial symbionts for numerous biological functions, such as digestion

and immune system development. Increasing evidence suggests that host-associated

microbes may play a role in mediating parasite burden. This study is the first to provide a

comprehensive survey of bacterial symbionts from multiple anatomical sites across a

broad taxonomic range of Afrotropical bats, demonstrating significant associations

between the bat microbiome and parasite prevalence. This study provides a framework for

future approaches to systems biology of host-symbiont interactions across broad

taxonomic scales, which will allow for the recognition of the interdependence between

microbial symbionts and vertebrate health in the study of wild organisms and their

natural history.

70   \body

72   INTRODUCTION

74   Humans and other animals rely on bacterial symbionts for numerous biological

functions, such as digestion and immune system development (1, 2). Many studies have

found significant associations between host phylogeny (shared common ancestry) and

bacterial community composition (3, 4), while others have identified spatiotemporal

variables as significant drivers of host-microbe associations over the course of individual

lifespans (5-7). The influence of microbes on their hosts may be context dependent, such

that the presence of a particular microbe may be beneficial under one set of ecological

conditions and harmful under another. Thus, patterns of association between vertebrates

and bacterial symbionts provide a unique lens through which to explore evolutionary and

ecological phenomena.

84   Recognition of the interdependence between microbial symbionts and vertebrate

health has led to a growing paradigm shift in the study of wild organisms and their

natural history. Vertebrate species not only exhibit inherent life history characteristics,

but serve as hosts to myriad bacteria, archaea, viruses, fungi, and eukaryotic organisms

that abound in their environments. Many relationships between eukaryotic parasites and

hosts have ancient origins, and the same may be true for host-microbial associations.

Indeed, it is possible that bacterial symbionts of vertebrate hosts interact with eukaryotic

parasites, viruses, or fungal symbionts in ways that could ultimately shape host evolution

(8). For example, evidence from human and anthropophilic mosquito interactions

suggests that the skin microbiome can influence vector feeding preference, thereby

affecting transmission patterns of mosquito-borne pathogens (such as WNV, yellow

fever, dengue, malaria, etc.), and ultimately imposing selective pressures on human

populations - indeed, positive selection of malaria-protective genes can be seen in the

human genome (9). Despite the potential significance of such interactions between hosts,

microbes, and pathogen-transmitting vectors, they have not been well studied in most

wild vertebrate systems.

Bats (Mammalia: Chiroptera) are an important system for comparison of the

relative contributions of evolutionary and ecological factors driving host-symbiont

associations. In addition to being one of the most speciose orders of mammals (second

only to the order Rodentia), bats frequently live in large colonies, are long-lived, and

volant, granting them access to a wide geographic range relative to their non-volant

mammalian counterparts. The associations of diverse eukaryotic parasites (e.g. dipteran

insects, haemosporidia, helminths) within numerous bat lineages have been well-

characterized (10-13). Furthermore, bats have received increasing attention due to their

role as putative vectors of human pathogens (*e.g.* Ebola, Marburg, SARS (14, 15)).

Indeed, numerous serological surveys have supported the role of Afrotropical bats as

reservoirs for a number of viruses (16-18). Taken together, these features make bats an

appealing and tractable model for studying the interaction of bacterial symbionts and

non-bacterial parasites and pathogens.

In this study, we conduct the first broad-scale study of Afrotropical bat-associated

microbes. We test associations between bacterial community composition in the

gastrointestinal tract, skin, and oral cavities from nine families and nineteen genera of

bats. We pair this information with host-parasite associations between bats and

ectoparasites in the superfamily Hippoboscoidea (obligate hematophagous dipteran

insects), and haemosporidian (malarial) parasites putatively vectored by these

hippoboscoid insects. Using a combination of machine learning, network theory, and

negative binomial distribution models, we test the hypothesis that host-associated

bacterial communities predict prevalence of parasitism by obligate dipteran and malarial

parasites.

RESULTS

1) Ectoparasite and malarial parasite prevalence among Afrotropical bats

Sampling was conducted across 20 sites in Kenya and Uganda from July-August

of 2016. Sites ranged from sea level to ~2500m in elevation (Fig. 1; Table S1). We

collected gut, oral, and skin samples for bacterial community characterization from a total

of 495 individual bats, comprising 9 families, 19 genera, and 28 recognized species. Bat

families with the greatest representation included Hipposideridae (n = 80), Miniopteridae

(n = 116), Rhinolophidae (n = 88), and Pteropodidae (n = 106). All host and parasite

vouchers are accessioned at the Field Museum of Natural History (Chicago, IL, USA)

(Table S2). Miniopterid bats experienced the highest prevalence of both ectoparasitism

(*M. minor*, 89%) and malarial parasitism (*M. minor*, 67%) (Table 1). Bats with similarly

high ectoparasite prevalence at the host species level included *Rhinolophus eloquens* (79%

prevalence), *Stenonycteris lanosus* (62%), and *Triaenops afer* (60%). Unlike miniopterid

bats, these bat species did not harbor any detectable malarial parasites (Table 1).

2) Bacterial richness of bat skin drastically exceeds that of gut or oral communities

Across all samples, 51,136 Exact Sequence Variants (ESVs) were identified using

Deblur (19). Gut microbial communities exhibited the lowest overall diversity (9,804

ESVs), followed by oral (13,629 ESVs), and skin (46,904 ESVs), the latter being

significantly greater than gut or oral ($p < 2.2e\text{-}16$, Kruskal-Wallis; Bonferroni corrected

p-value $p < 1e\text{-}113$, Dunn's test) (Fig. 2A). Aggregate mean observed ESVs by host

genus were 70, 93, and 531 for gut, oral, and skin samples, respectively (Table 2). As with

observed ESV richness counts, the Shannon index of bat skin microbial communities was

significantly greater than that of either gut or oral microbiota ($p < 2.2e\text{-}16$, Kruskal-

Wallis; Bonferroni corrected p-value $p < 1e\text{-}119$, Dunn's Test) (Fig. 2B). Based on

weighted UniFrac distances, measures of intraspecific beta dispersion revealed a

continuum of dissimilarities across all host species (Fig. 3). Mean beta dispersion among

anatomical sites differed significantly ($p < 1.2e\text{-}7$, Kruskal-Wallis; Bonferroni corrected

p-value $p < 0.01$, Dunn's Test). Meausres of intraspecific beta dispersion among

unweighted UniFrac and Bray-Curtis distances also showed a continuum of

dissimilarities across host species, and exhibited significant differences in mean beta

dispersion across anatomical sites (Fig. S1).

3) Microbial communities significantly correlate with geographic locality, anatomical site,

and host taxonomy, but not host phylogeny

Permutational analysis of variance (PERMANOVA) identified geographic

locality, host taxonomy, and anatomical sampling site (gut, oral, skin) as significant

factors explaining variation in three independent measures of microbial beta diversity

(Bray-Curtis, unweighted UniFrac, and weighted UniFrac) ($p < 0.001$, ADONIS) (Table

4). Secondary analysis of sites by elevation revealed that bats at higher elevations tended

to host increased alpha diversity across gut, oral, and skin microbiomes ($p < 2e\text{-}16$, linear

regression) (Fig. S2). In general, gut microbiota were dominated by Proteobacteria

(Enterobacteraceae) and Firmicutes (Bacillaceae). Oral microbiota were dominated by

Proteobacteria (Neisseriaceae, Pasteurellaceae). The oral microbiota of several insect bat

families (Miniopteridae, Nycteridae, Rhinolophidae) were enriched for Firmicutes in the

Mycoplasmataceae family, while the oral microbiota of fruit bats (Pteropodidae) were

enriched for Firmicutes in the Streptococaccea family. Similar to gut and oral microbiota,

skin also showed a high relative abundance of Proteobacteria (Moraxellaceae,

Enterobacteraceae) and Firmicutes (Bacillaceae), with a pronounced increase in relative

abundance of Actinobacteria and Bacteroidetes (Fig. 4).

Linear regression analyses of host phylogenetic distances and microbial

community dissimilarity (unweighted UniFrac (uf) and weighted UniFrac (wuf)

distances) revealed weak correlations for gut (uf: $R^2 = 0.013$, $p < 0.05$; wuf: $R^2 = 0.002$, p

$= 0.752$; $R^2 = 0.0007$, $p = 0.2643$; $R^2 = 0.0015$, $p = 0.522$), oral ($R^2 = 0.009$; $p < 0.05$), and

skin ($R^2 = 0.024$; $p < 0.005$) microbiota and host evolutionary relatedness (Fig. S3).

4) The microbiome is associated with parasitism in African bats

To test for significant associations between bacterial communities and eukaryotic

parasites (obligate ectoparasitic dipteran insects, and obligate endoparasitic malarial

parasites), we employed a combination of machine learning techniques, network analyses,

and negative binomial distribution models (see methods). PERMANOVA analysis

identified ectoparasite status and malarial infection status as significant predictors of

bacterial beta diversity dissimilarity among skin and oral microbiota, respectively ($p <$

0.001, ADONIS). Tests of three independent measures of beta diversity (weighted

UniFrac, unweighted UniFrac, and Bray-Curtis) produced congruent results, with the

exception of oral microbiome, which was not significantly predictive of malarial infection

based on unweighted UniFrac analysis (Table 3).

Supervised machine learning analyses (random forests; see methods) produced

models that could classify the anatomical source of microbial communities and the host

genus of gut, oral, and skin microbial samples with reasonable accuracy (ratio of baseline

to observed classification error ≥2; *i.e.* random forest models performed at least twice as

well as random). Random forest models also performed well when classifying ectoparasite

status based on skin bacterial community composition, but less well for classification of

malarial status based on oral bacterial community composition (Table 5).

Following the application of statistical and machine learning approaches, we

employed network analyses to characterize the co-occurrence topology of microbial

communities (in terms of the relative abundance of co-occurring ESVs) across the skin

microbiota of our four most well-sampled bat families (Hipposideridae (n = 80),

Miniopteridae (n = 116), Rhinolophida (n = 88), and Pteropodidae (n = 106)). Network

analyses produced strikingly consistent results, revealing a significant decrease in cluster

size (p < 0.05, Mann-Whitney-Wilcoxon rank sum test) and median node degree (p <

0.05, t test), as well as reduced network connectivity for parasitized bats from three of the

four bat families examined (Fig. 5; Fig. S4).

5) Bacterial taxa on skin correlated with presence or absence of obligate dipteran
ectoparasites

      Negative binomial distribution (*e.g.* DESeq) models applied to skin microbiota in

four well-sampled bat families (Hipposideridae, Miniopteridae, Rhinolophidae,

Pteropodidae) identified a number of ESVs that were significantly associated with either

ectoparasitized or non-ectoparasitized bats (Fig. 6). Overall, we identified 89 and 24

ESVs significantly associated with parasitized and non-parasitized bats, respectively

(Table S3). Bacterial classes with the greatest representation among significant results

were Actinobacteria (16 families), Gammaproteobacteria (11 families), Bacilli (5

families), and Alphaproteobacteria (3 families). ESVs significantly enriched in parasitized

bats from at least three out of four bat families included Mycobacteraceae

(Actinobacteria), and Xanthomonadaceae (Gammaproteobacteria). ESVs significantly

enriched in parasitized bats from at least two out of four bat families included

Hyphomicrobiaceae (Alphaproteobacteria), Alcaligenaceae (Betaproteobacteria),

Moraxellaceae (Gammaproteobacteria), Planococcaceae (Bacilli), Flavobacteraceae

(Flavobacteria), Halobacteraceae (Halobacteria), and Chitinophagaceae (Saprospirae)

(Fig. 6).

DISCUSSION

The bacterial diversity we observed among gut, oral, and skin microbiota of bats

fall within ranges similarly observed in other vertebrate groups (3, 20-23). Although few

studies have simultaneously compared gut, oral, and skin microbiota from the same

individuals, our data refelct an apparent trend in the literature of skin bacterial diversity

among vertebrates significantly outnumbering gut or oral bacterial diversity (24-27). Our

data corroborate the findings of Nishida and Ochman (3), revealing no relationship

between chiropteran phylogeny and gut bacterial community dissimilarity. We found the

same absence of phylogenetic signal among oral and skin microbial communities. As

suggested in other studies of volant vertebrates (bats and birds), convergent adaptations

driven by the evolution of flight may be influencing the nature and composition of

microbial communities in both bats and birds (28-30).

Microbial community specificity can be assessed as a function of intraspecific

variation in dissimilarity (beta dispersion), where low dispersion suggests a tight and

perhaps co-evolutionary link between hosts and symbionts, whereas high dispersion

suggests more random associations between hosts and symbionts (31). Measures of beta

dispersion among bats revealed a continuum for all three anatomical sites, with oral

bacterial commuities showing lower levels of beta dispersion (for weighted UniFrac

distances) than gut or skin communities (Fig. 3). This continuum suggests a possible

gradient of host-symbiont specificity across different bat species that may be influenced

by evolutionary history or host ecology. Given that we found no association between

bacterial community dissimilarity and host phylogenetic distance, variation in beta

dispersion is more likely a reflection of host ecology than evolutionary history.

Similar to recent studies in North American bats (32), we found sampling locality

to be a significant factor influencing skin, gut and oral microbial composition (Table 4).

Furthermore, we observed an apparent trend in increasing Shannon diversity and

observed ESV richness along an elevational gradient that was most pronounced for skin

microbiota (Fig. S2). A positive correlation between bacterial richness and elevation has

been observed in studies of amphibian skin (33) and montane soil, and this pattern may

be the result of climatological and other abiotic factors (*e.g.* pH) found along elevational

gradients (34, 35).

We found the general composition of gut microbiota in East African bats to be

similar to that of Neotropical bats, with Proteobacteria being the dominant bacterial

phylum present (36). Regardless of diet (insectivorous or frugivorous), the distal bat gut is

dominated by bacteria in the family Enterobacteriaceae (Phylum: Proteobacteria), though

fruit bats do have an increased relative abundance of bacteria in the family Clostridiaceae

(Phylum: Firmicutes) relative to insectivorous bats. In their study of neotropical bats,

Phillips et al. (37) noted an increased relative abundance of Lactobacillales in frugivorous

bats, and we note a similar pattern among pteropodid fruit bats in this study, which

exhibited a slightly higher proportion of Streptococcaceae (Order: Lactobacillales)

relative to insectivorous bats. Overall, the domination of the chiropteran gut by

Proteobacteria differs markedly from other mammalian gut microbiomes, which are

generally dominated by Firmicutes (21, 38, 39).

Among most bat families, the oral microbiome was dominated by Pasteurellaceae

(Phylum: Proteobacteria), and in some cases a high relative abundance of bacteria in the

families Mycoplasmataceae (in nycterids), Neisseriaceae (in vespertilionids and

rhinonycterids), and Streptococcaceae (in pteropodids) was also observed. Although the

oral microbiome has received less attention than that of the gut, several studies have

found diverse Pasteurellaceae and Neiserria lineages present in the oral microbiota of

animals, including domestic cats (20) and marine mammals (40). Pasteurellaceae lineages

have also recently been documented in the oral microbiota of Tasmanian devils (23, 41).

In humans, Pasteurallaceae (genera *Haemophilus* and *Aggregatibacter*) and Neisseriaceae

(genera *Neisseria*, *Kingella*, and *Eikenella*) play an important role in the formation

supragingival plaque (22). Though these bacterial groups are present in lower proportions

in other animals relative to bats, their presence in a broad range of host taxa suggest a

conserved evolutionary niche.

Our analysis identified links between ectoparasitism, malarial parasitism, and

bacterial communities on the skin and in oral cavities, respectively. Network analyses

identified consistent, stable, and species-rich clusters of bacteria on the skin of non-

ectoparasitized bats, compared to relatively disconnected and apparently transient bacteria

on the skin of bats harboring ectoparasites. This result mirrors that found in human-

mosquito interactions, in which individuals with lower bacterial diversity on the skin are

significantly more attractive to blood-seeking mosquitoes than individuals with higher

diversity (42). In humans, skin bacteria play a known role in attracting mosquitoes via

their production of volatile organic compounds (VOCs), and studies have shown that

variation in skin microbial community composition can increase or decrease human

attractiveness to blood-seeking mosquitoes (42-44). Similar mechanisms may be at play

in the bat-ectoparasite system, particularly given the phylogenetic proximity of

hippobscoid bat parasites to mosquitoes.

Several bacterial families exhibited significant associations with presence of

ectoparasitism in bats based on DESeq analyses. Bacteria found across multiple host

families included (but were not limited to) Alcaligenaceae, Chitinophagaceae,

Flavobacteriaceae, Moraxellaceae, Mycobacteriaceae (*Mycobacterium* spp.), and

Xanthomonadaceae. In many cases, these bacterial families were associated with

parasitism in some bat families, and absence of parasitism in others, suggesting a

potential mechanism by which ectoparasites might be distinguishing between "correct"

and "incorrect" hosts. As suggested by human-mosquito interaction studies (42, 43, 45),

bacteria positively associated with increased rates of blood-feeding dipteran host selection

may be producing VOCs on which the insects rely to identify their hosts. Bacteria that

are negatively associated with such insects may be consuming the products of the former,

or may be producing VOCs of their own that mask those of the former (suggested by

Verhulst et al. (42)). To better understand the mechanisms underlying these correlations

in wild populations, future experiments should consider including sampling of VOCs *in*

vivo.

PERMANOVA analyses identified associations between the oral microbiome

and malarial parasite prevalence among bats in the family Miniopteridae, although these

associations were less robust than those of the skin bacteria and ectoparasitism. Upon

further exploration of this potential association, we identified a single bacterial ESV in

the genus *Actinobacillus* (99% similar to *A. porcinus* based on NCBI blastn search) as

significantly reduced in malaria-free bats (baseMean 7.61, -24.2 log2FoldChange, p =

1.7E-20). Network analyses indicated no significant differences in connectivity or node

degree distribution (results not shown). Because no other bat groups experienced rates of

malarial parasitism adequate for statistical analyses, we were unable to explore this

relationship further. Future studies that incorporate greater sampling of malaria-positive

species may reveal more robust microbial associations, as have been documented in

numerous experiments with controlled rodent and human malaria infections (45-47).

Although we cannot ascertain causality of differences in the microbial

composition of skin in this study, our results support the hypothesis that these differences

may provide a mechanism by which ectoparasites can locate or distinguish hosts.

Alternatively, observed differences in microbial composition could result from microbial

transfer from parasites to hosts. Given the known effect of locality and apparent absence

of host phylogenetic signal in microbial community composition of skin, one possible

explanation is that local environmental variables play a greater role in determining host-

bacteria associations in bats. Indeed, in North America, multiple bat species have been

found to share many bacterial genera with soil and plant material (32). Thus, local

conditions and bacterial composition of bat roosts are likely playing an important role in

driving the composition of skin bacteria, and via mechanisms similar to the camouflage

hypothesis, could subsequently influence which individuals become parasitized.

METHODS

1) Sampling

Sampling for this study was conducted from the eastern coast of Kenya to the northern

border of Uganda during August-October 2016 (Fig. 1; Table S1, S2). Eight families

and nineteen genera of bats (order: Chiroptera) were collected as part of bird and small

mammal biodiversity inventories. All sampling was conducted in accordance with the

Field Museum of Natural History IACUC and voucher specimens are accessioned at the

Field Museum of Natural History (Table S2). Blood samples were collected and screened

for haemosporidia and haemosporidian taxonomy was assigned using previously described

molecular methods (13). Following blood sampling, ectoparasites were removed with

forceps and placed directly into 95% EtOH; ectoparasites taxonomy was assigned based

on morphological features. For the purposes of analysis with microbiome data,

ectoparasite and malarial status were each scored separately as 1 (present) or 0 (absent).

Gut, skin, and oral samples were taken for each bat for microbial analyses. Gut samples

consisted of fecal material collected directly from the distal end of the colon using

sterilized tools, and preserved on Whatman® FTA® cards for microbiome analyses. For

oral microbiome analyses, we preserved both buccal swabs in lN_2 and tongue biopsies in

95% ethanol (EtOH). Comparison of ESV diversity obtained from paired subsets of each

sample type revealed greater diversity recovered from tongue biopsies (data not shown);

tongues were therefore used for characterization of oral microbiomes in this study. Lastly,

skin samples from five regions of the body (ear, wing membrane, tail membrane, chest,

back) were collected and pooled in 95% EtOH using sterile Integra® Miltex® 5mm

biopsy punches. The goal of sampling from five body regions was to maximize bacterial

diversity recovered from the external skin surface of each individual. We based our

storage media selections on the recent study by Song et al. (48). Host sequencing and

phylogenetic methods are described in Fig. S2.

2) Microbiome sequencing, characterization, and parasite association

DNA extractions were performed on gut, tongue, and skin samples using the MoBio

PowerSoil 96 Well Soil DNA Isolation Kit (Catalog No. 12955-4, MoBio, Carlsbad,

CA, USA). We used the standard 515f and 806r primers (49-51) to amplify the V4

region of the 16S rRNA gene, using mitochondrial blockers to reduce amplification of

host mitochondrial DNA. Sequencing was performed using paired-end 150 base reads

on an Illumina HiSeq sequencing platform. Following standard demultiplexing and

quality filtering using the Quantative Insights Into Microbial Ecology pipeline

(QIIME2) (52) and vsearch8.1 (53), ESVs were identified using the Deblur method (19)

and taxonomy was assigned using the Greengenes Database (May 2013 release;

http://greengenes.lbl.gov). Libraries containing fewer than 1000 reads were removed

from further analyses. Negative controls all contained fewer than 1000 reads and were

filtered at this step. We did not rarefy the data, based on the recommendations of

McMurdie and Holmes (54). Data were then subset for analyses according to sample

type, host genus, and locality (or some combination thereof). Site-specific analyses were

only performed for sites from which five or more individual bats were sampled. We

calculated alpha diversity for each sample type (gut, oral, skin) using the Shannon index,

and measured species richness based on actual observed diversity. Significance of differing

mean values for each diversity calculation was determined using the Kruskal-Wallis rank

sum test, followed by a post-hoc Dunn test with bonferroni corrected p-values. Three

measures of beta diversity (unweighted UniFrac, weighted UniFrac, and Bray-Curtis)

were calculated using relative abundances of each ESV (calculated as ESV read depth

over total read depth per library). Significant drivers of communitity similarity were

identified using the ADONIS test with Bonferroni correction for multiple comparisons

using the R package Phyloseq (55). Complete code for microbiome analyses can be found

at http://github.com/hollylutz/BatMP.

3) Machine learning and network analyses

A supervised machine learning approach was used to produce random forests (RF) for the

classification of different variables. RFs were constructed using 500 decision trees and

subsets of ESV data via the supervised_learning.py script implemented in QIIME (52).

We tested the ability of RFs to accurately classify 1) anatomical site (using all data), 2)

host genus (using gut, oral, or skin microbial data separately), 3) ecotparasite status (using

skin microbial data), and 4) malarial status (using oral microbial data). RF performance

was assessed by comparing the out-of-bag estimated error (OOB) with baseline (random)

error. If the ratio of OOB to baseline error was less than or equal to two, the model was

considered to perform reasonably well, as it performed at least twice as well as random

(56). To reconstruct microbial networks for skin and oral bacterial communities within

bat family groupings (which were further sub-divided into parasitized or non-

parasitized), we utilized the R package Sparse Inverse Covariance Estimation for

Ecological Association Inference (SPIEC-EASI) (57). All network datasets were filtered

to contain only ESVs that appeared in at least three individuals within each respective

dataset. Network results produced with SPIEC-EASI were summarized using the R

packages CAVnet (58) and igraph (59). Network stability was assessed by sequentially

removing network nodes (ordered by betweeness centrality and degree) and observing

natural connectivity (*i.e.* eigenvalue of the graph adjacency matrix) as nodes are removed.

To determine which, if any, bacterial ESVs were significantly associated with ectoparasite

or malarial prevalence, we performed analyses based on the negative binomial distribution

of ESVs relative abundance, utilizing the R package DESeq2 (60). False discovery rate

(FDR) was calculated using the Benjamini-Hochberg method (default method in

DESeq), and *p*-values were adjusted accordingly.

ACKNOWLEDGMENTS

We thank the Kenya Wildlife Service and the Uganda Wildlife Authority for permission

to conduct research in national parks. For logistical support and assistance in the field, we

thank Mike Bartonjo of the National Museums of Kenya, Phausia Kweyu of Karatina

University, Dr. Robert Kityo, Solomon Sebuliba, and Cissy Akoth of the Makerere

University Zoological Museum, Drs. Brian Amman, Jonathan Towner, and Rebecca

Tiller of the Centers for Disease Control and Prevention, and Lauren Lutz. We thank

Neil Gottel for his knowledge and assistance with laboratory processing of microbial

samples, and other members of the Gilbert Lab, including Alyson Yee, Cesar Cardona,

Thomas Kuntz, Drs. Bea Penalver, Melissa Dsouza, and Naseer Sangwan for the

assistance with bacterial 16s analyses.

FIGURE LEGENDS

Figure 1. Sampling localities and elevation, grouped by district. Colors correspond to

elevation, and white numbers and size of points correspond to number of bats collected.

Figure 2. Alpha diversity of Exact Sequence Variants (ESVs) by anatomical sites,

including (A) Observed richness, (B) Shannon index of diversity, (C) ESVs shared

between anatomical sites. Asterisks indicate significant differences between groups

(Dunn's Test, Bonferroni corrected p-value $p < 0.0001$).

Figure 3. Intraspecific variation across anatomical sites measured as beta dispersion of

weighted UniFrac distances. Dotted lines indicate mean dispersion for anatomical

groupings; numbers in parentheses indicate sample size per bat species. White and gray

boxes correspond to the chiropteran suborders Yangochiroptera (microbats) and

Yinpterochiroptera (fruits bats and kin), respectively.

Figure 4. (A) Relative abundance of top 6 bacterial phyla grouped by anatomical site,

with each bar corresponding to individual libraries. (B) Relative abundance of the most

prevelant eight bacterial families across all anatomical sites, grouped by bat family.

Phylogeny based on Teeling et al. (61).

Figure 5. (A) Distribution of skin microbial network clusters for parasitized and non-

parasitized bats, grouped by bat family (* indicates signifiance at $p < 0.005$, Kruskal-

Wallis) (B) Visualization of skin bacterial networks (based on Fruchterman-Reingold

algorithm); colored nodes correspond to unique clusters of co-occurring ESVs within

each network.

Figure 6. Log2fold change in relative abundance of skin-associated ESVs from the four

most-sampled bat families. ESVs shown were found to be significantly associated with

ectoparasite status in bats based on analysis of negative binomial distributions of relative

abundance (Banjamini-Hochberg FDR corrected p-value $p < 0.05$). Positive values

correspond to ESVs found to be enriched on parasitized bats, and negative values

correspond to ESVs found to be enriched on non-parasitized bats. Gray bars highlight

ESVs in bacterial families that were enriched in parasitized bats for three out of four bat

families.

Table 1. Bat sampling, ectoparasite prevalence (n_{ecto}), and malarial parasite prevalence (n_{haem}) and identification.

Bat family	Bat species	n_{bats}	n_{ecto} (%)	n_{haem} (%)

Figure S1. Measures of intraspecific beta dispersion among (A) unweighted UniFrac and (B) Bray-Curtis distances. Dotted gray line indicates mean beta dispersion for each anatomical group and dissimilarity measure.

Figure S2. Linear regression of (A) Shannon diveristy and (B) observed ESV richness of gut, oral, and skin microbiomes against elevation from which host was sampled (~0 - 2500 meters above sea level). R^2 and significance values are provided within each plot.

A

B

Figure S3.A Linear regression of patristic distances between microbial community dissimilarity (unweighted and weighted UniFrac) and phylogenetic distances between individual bat species sampled in this study.

Figure S3.B Maximum likelihood phylogeny of bat species. Phylogenetic distances were calculated as patristic distances based on maximum likelihood reconstruction of bat species-level phylogeny with 1000 bootstrap (bs) replicates. Closed circles > 95% bs support, open black circles > 90% bs support, open gray circles >75% bs support.

Methods: DNA was extracted from pectoral muscle tissue of bat specimens, and sequenced for mitochondrial Cytochrome-b (cyt-b) using the primer pair LGL 765F and LGL 766R to amplify the entire cyt-b gene (1, 2). PCR amplification and sequencing were carried out as in Demos et al. (3).The best-supported model of nucleotide substitution for cyt-b was determined using the BIC on the maximum-likelihood topology estimated independently for each model in jMODELTEST2 (4) on CIPRES Science Gateway v.3.1 (5). Maximum-likelihood estimates of cyt-b gene trees and concatenated gene trees were made using the program RAxML-HPC v.8 (6) on the CIPRES portal. We conducted analyses using the rapid bootstrapping algorithm and searched for best-scoring ML tree algorithm under the GTRGAMMA model with 1000 bootstrap replicates (references listed on next page).

Figure S4. Network Analyses - (A) Node degree dsitribution of parasitized and non-parasitized bats, grouped by family. (B) Network fragility plots, showing natural network connectivity with sequential removal of nodes ordered by betweenness and degree.
