**ABSTRACT** Connections between the structure of bacterial communities in suppressive soils 24 25 and potato resistance to common scab (CS) are not well understood. In this study, one resistant 26 and one susceptible cultivar were grown in a conducive and suppressive field to assess cultivar 27 resistance  $\times$  soil suppressiveness interactions. The resistant cultivar had a higher Mg content in periderm compare to susceptible cultivar, while suppressive soil had lower pH (5.3 vs 5.9), N, C, 28 P. Ca contents but higher Fe and S compared with the conducive soil. Bacteria and actinobacteria 29 30 numbers were higher in the conducive soil. Copy numbers of *txtB* gene (coding for a pathogenicity determinant) were similar in both soils but were higher in the conducive soil (for 31 32 periderm samples) and in the susceptible cultivar (for conducive soil samples). Taxonomic 33 microarray analysis and Illumina sequencing of 16S rRNA genes amplicon showed that bacterial community differed between resistant vs susceptible cultivar and to a lesser extend between 34 suppressive vs conducive soil. Bacteria participating in soil suppression belonged to 35 Pseudomonadaceae, Bradyrhizobiaceae, Acetobacteraceae and Paenibacillaceae, while resistant 36 cultivars selected a bacterial community resembling that of the suppressive soil, which was 37 38 enriched in *Nitrospirae* and *Acidobacteria*. Thus, the analysis of soil suppressiveness×cultivar resistance interactions enabled to gain new insight to CS control in the field. 39 40

#### 41 **IMPORTANCE**

It was demonstrated that potato cultivars susceptible and resistant to common scab select differing bacterial community and above that this trait is further modified in suppressive and conducive soil. Common scab severity was diminished by either resistant cultivar or suppressive soil but without additive effect between them. Out of the two factors, potato cultivar had a more significant influence on tuberosphere bacterial community composition than soil. Results highlighted the usefulness of both cultivar resistance and soil suppressiveness traits in

- 48 understanding and managing disease control of crops.
- 49

- 51 **KEYWORDS** Soil bacterial community, potato rhizosphere, *Actinobacteria*, *Streptomyces*,
- 52 thaxtomin

Suppressive soils were described as soils in which disease severity remains low, in spite of the presence of a pathogen, a susceptible host, and climatic conditions favorable for disease development (1, 2). Relatively few soils with suppressive character have been described in the world to date (3). They represent a unique model for studying plant disease control. It is of prime interest to conserve their functioning, and ultimately, these soils may help us to learn how to establish suppressive character of soil at other sites (4).

59 It is agreed that soil suppressiveness is related to soil health and crop productivity through physico-chemical conditions or microbial communities (5, 6). Yet, suppressiveness is difficult to 60 61 understand because in soil, (i) most physico-chemical factors are not independent from one 62 another, (ii) phytopathogenic taxa may display genetic and functional diversity, and (iii) microbial communities are composed of many taxonomic groups with unknown functions and 63 their structure is affected not only by soil but also by the plant host (4). Therefore, the assessment 64 of suppressive soils may necessitate to target potential interactions between all these ecological 65 factors. 66

67 Common scab (CS) of potatoes is a soil-borne disease caused by *Streptomyces* spp. that 68 produce thaxtomin phytotoxins, and for which suppressive soils were reported in the USA (6, 7). 69 In these systems, disease control is largely attributed to biological interactions (mostly 70 competition and antagonism) between plant-beneficial microbiota and pathogens mediated via 71 antibiotic production or enzymatic activities (4, 8). In one situation, nonpathogenic *Streptomyces* 72 spp. were correlated with CS suppressiveness (6), and it was also hypothesized that other 73 actinobacteria may be involved in this disease suppression (4).

In our previous investigations, two sites (Vyklantice and Zdirec) from the Czech Republic, where CS suppressive and conducive fields occur next to each other were studied both in field trials (9, 10) and pot experiments (11). The CS suppressive character of the fields differed

according to field location, presumably in relationship to local soil chemical properties (9). Potato cultivars susceptible and resistant to CS have different ecophysiologies, and they differ in chemical composition of the potato periderm, which may further influence microbial community structure (12). Therefore, our hypothesis was that pathogen control via plant-enriched taxa occurring in the tuberosphere was a trait associated with both the suppressive soil and cultivar.

82 CS-susceptible and resistant potato cultivars have not been compared yet in terms of their 83 respective interactions with the soil microbial community, so that was the focus of the current work. We wanted to assess the relative importance of suppressive soil and resistant cultivar as 84 85 ecological factors shaping bacterial community properties in CS disease suppression conditions, 86 and identify the corresponding bacterial taxa. We used a field set-up that included a combination of both disease suppressive vs conducive soils, and resistant vs susceptible cultivars. Bacterial 87 community structure in soil and potato tuberosphere was assessed by 16S rRNA taxonomic 88 microarray and Illumina sequencing, and these results were compared to CS severity observed on 89 tuber surface, quantity of thaxtomin biosynthetic genes *txtB*, quantities of total bacteria and 90 91 actinobacteria and soil and periderm chemical characteristics.

Currently, next generation sequencing is the preferred approach to study bacterial 92 communities. The method enables high throughput and financially-efficient description of 93 94 bacterial taxa present in a sample. However, the method has its drawbacks. In particular, it is not 95 highly quantitative so only a relative quantity of determined taxa can be assessed, and also it may 96 be difficult to separate sequencing errors from real diversity (13). In comparison, taxonomic 97 microarrays as a method for bacterial community assessments are more laborious (so are slower) and give results only for a selected group of taxa. However, these taxa can be purposefully 98 selected and aimed at determining particular characteristics of bacterial community, and 99 microarrays are semi quantitative (14), which makes microarrays a useful complement to 100

101 Illumina sequencing. In this work, we used a validated taxonomic microarray focusing on disease 102 suppressive soils and bacterial taxa possessing plant growth-promoting and antagonistic traits in 103 soil environments (15, 16), which was further extended with probes focusing on CS pathogens. 104 The microarray approach was combined with amplicon Illumina sequencing to obtain deeper 105 insight to relationships of bacterial communities in cultivar resistance and soil suppressiveness.

106

107 **RESULTS** 

108 Common scab severity and quantities of thaxtomin biosynthetic genes. In conducive soil H, severity of CS (resulting from natural field infestation) was significantly higher in 109 110 susceptible cultivar Agria than resistant cultivar Kariera (Fig. 1; ANOVA, p<0.001). In suppressive soil L, CS severity did not differ between the cultivars, and was as low as for the 111 112 resistant cultivar in conducive soil. The number of *txtB* gene copies was similar in both soils (Supplementary Tables S2A and S4A), while in periderm it was significantly higher (p=0.006) in 113 conducive than suppressive soil (Supplementary Tables S2B and S4B). The two cultivars grown 114 in the same soil had comparable quantities of txtB gene copies in their periderm, yet, the number 115 116 of *txtB* gene copies was significantly higher for susceptible cultivar Agria in conducive soil than in suppressive soil. In summary, CS control required resistant cultivar (independently of the soil) 117 or suppressive soil (for susceptible cultivar). 118

119 Chemical composition of tuberosphere soil and periderm. In tuberosphere, contents of 120 N, C, P, Ca, Fe and soil pH were significantly higher in conducive than suppressive soil 121 (ANOVA; all p<0.001), while S content was significantly higher in suppressive soil (ANOVA; 122 p<0.001). Ca content was significantly higher in bulk soil than in tuberosphere of both soils 123 (ANOVA; p<0.001; Supplementary Tables S3A and S4A). In periderm, N content was 124 significantly higher in both cultivars from suppressive soil (ANOVA; p<0.001), Ca content was

significantly higher in susceptible cultivar Agria in both soils (ANOVA; p=0.011), and Mg content was significantly higher in resistant cultivar Kariera in both soils (ANOVA; p<0.001). Fe content was significantly higher in conducive soil in both cultivars (ANOVA; p=0.035) and it was higher in the resistant cultivar in both soils (ANOVA; p=0.006; Supplementary Tables S3B and S4B).

In summary, CS control was connected either with lower content of N, C, P, Ca, Fe and lower soil pH in tuberosphere in suppressive soil, or with higher content of Mg in periderm of the resistant cultivar. In addition, S content was significantly higher in tuberosphere for the combination of suppressive soil x resistant cultivar.

134 **Ouantities of total bacteria and actinobacteria.** In tuberosphere, the quantities of bacteria (ANOVA; p<0.001) and actinobacteria (p=0.006) were higher in conducive than in 135 136 suppressive soil. In suppressive soil the quantity of both bacteria (p=0.011) and actinobacteria (p=0.019) was significantly lower in plant tuberosphere compared to bulk soil (Supplementary 137 Tables S2A and S4A). In periderm, the quantity of actinobacteria (ANOVA; p=0.021) was 138 significantly higher in conducive than in resistant cultivar Kariera suppressive soil in both 139 cultivars and was also significantly higher in susceptible cultivar Agria than Kariera in conducive 140 soil (Supplementary Tables S2B and S4B). In summary, quantities of total bacteria and 141 142 actinobacteria depended on soil (suppressive vs conducive)  $\times$  cultivar (resistant vs susceptible)  $\times$ 143 compartment (periderm vs tuberosphere vs bulk soil) combination, with a trend for lower 144 number(s) in supressive soil and resistant cultivar.

Bacterial community composition in bulk soil and tuberosphere by microarray
analysis. The 16S rRNA taxonomic microarray previously validated for bacterial community
analysis of rhizosphere soil samples (15, 17) was expanded for coverage of the genus *Streptomyces*, including pathogen species *S. scabies* and relatives (Supplementary Table S1).

Non-metric multidimensional scaling (NMDS) plot of sample distances calculated from 149 150 microarray data demonstrated that bacterial communities in conducive and suppressive soils were distinct, and in tuberosphere they were also influenced by cultivar (Fig. 2A). According to 151 PERMANOVA, cultivar explained 42% variability and field site 13% variability. In particular, 152 153 bacterial community in tuberosphere of the susceptible cultivar was separated from those of the 154 resistant cultivar and bulk soil. Bacterial communities were significantly closer to each other 155 within conducive or suppressive soil when compared to all samples (PERMANOVA; p=0.003) and samples of bacterial communities were significantly closer within each cultivar 156 157 (PERMANOVA; p<0.001) but not within each bulk soil. In tuberosphere, bacterial communities 158 of resistant cultivar Kariera differed between the soils (PERMANOVA; p<0.001), while bacterial communities of susceptible cultivar Agria did not differ significantly between the two soils but 159 160 differed from those of resistant cultivar Kariera in each soil (PERMANOVA; p=0.029).

In summary, our 16S rRNA probe set was expanded to target also the CS pathogens and other *Streptomyces* taxa. The resulting taxonomic microarray evidenced significant differences in bacterial community features when comparing suppressive vs conducive soil and resistant vs susceptible cultivar.

Discriminant microarray probes according to soil and potato cultivar. Microarray 165 166 probes contributing to separation of suppressive from conducive soil were Brady4 (targeting the family Bradyrhizobiaceae), Pseu33 (Pseudomonadaceae), Aceto3A (Acetobacteraceae), and 167 PalgiG3 (Paenibacillaceae), which were significantly higher in suppressive soil, as well as 168 169 Janaga 2 and 3 (targeting the genus *Janthinobacterium*), which were significantly higher in conducive soil (Supplementary Table S5A). These differences seemed enhanced by tuberosphere 170 of susceptible cultivar Agria, based on lower hybridization of probes targeting the genus 171 172 Streptomyces or families Rhizobiaceae or Bradyrhizobiaceae but higher signals for probes aiming

173 at pathogenic *Streptomyces scabiei* group.

Probes contributing by their higher signal intensity to separation of resistant cultivar and 174 bulk soil from the susceptible cultivar Agria were Rhizo157 and Rzbc1247 (both targeting the 175 family *Rhizobiaceae*), Strepto1, 2, and 3 (targeting the genus *Streptomyces*) and Plancto4.mB 176 (targeting the phylum *Planctomycetes*) (Supplementary Table S5B). Relatively small numbers of 177 probes discriminated between the two soils when assessing bulk soil samples (only 2 probes), 178 179 tuberospheres of the resistant cultivar Kariera (13 probes), and tuberospheres of the susceptible cultivar Agria (26 probes). Differences between samples from a same soil implicated somewhat 180 181 comparable numbers of discriminating probes (Fig. 3A).

In summary, six probes targeting contrasted bacterial taxa discriminated between suppressive and conducive soils. Higher probe signals for CS pathogen were found with the susceptible cultivar.

Bacterial community composition in bulk soil and tuberosphere by Illumina 185 sequencing. A total of 1,213,004 16S rRNA gene sequence reads were obtained, out of which 186 187 944,597 (i.e. 78%) were mapped to 4001 OTUs. On a NMDS plot, bacterial communities of resistant cultivar Kariera, susceptible cultivar Agria and bulk soil were separated from one 188 another within each field (Fig. 2B). When comparing both fields using significantly different 189 190 OTUs (Metastats p < 0.05), bacterial communities of bulk soils were separated, whereas they 191 overlapped when comparisons were made for cultivar Kariera, or for cultivar Agria. The number 192 of discriminating OTUs (Fig. 3B) was only 85 between both fields for resistant cultivar Kariera, 193 382 between bulk soil and resistant cultivar Kariera in conducive soil, and 316 between bulk soil and susceptible cultivar Agria in suppressive soil, whereas the other pairwise differences between 194 treatments implicated 954-1676 discriminating OTUs. 195

196

The relative proportion of bacterial phyla did not differ significantly between bulk soils,

except that Actinobacteria were higher and Acidobacteria lower in suppressive than in conducive 197 198 soil (Supplementary Fig. S1A). Based on comparison with bulk soil, the tuberosphere communities implicated (i) an increase in relative proportion of *Chloroflexi* and decrease in that 199 of Verrucomicrobia, Gemmatimonadetes, Planctomycetes and Proteobacteria in both cultivars 200 (in the two fields; Supplementary Fig. S1A), (ii) an increase in relative proportion of 201 202 Bacteroidetes (particularly the family Sphingobacteraceae) in resistant cultivar Kariera (in the 203 two fields; Supplementary Fig. S1D), and (iii) an increase in relative proportion of *Firmicutes* 204 (especially the family *Paenibacillaceae*) and *Actinobacteria* (especially the orders *Gaiellales*, *Micrococcales, Frankiales* and *Streptomycetales*) in susceptible cultivar Agria (in the two fields: 205 206 Supplementary Fig. S1B,C). This increase in Streptomycetales was contributed by OTU 176, to which also the CS pathogen belongs. However, other members of this OTU contributed more 207 208 significantly because this OTU was defined by centroid sequence, which was at 2.1-2.7% 209 distance from the pathogen (Supplementary Table S6B).

Diversity of bacterial communities based on rarefaction curves showed that in both soils the lowest diversity was in tuberosphere of susceptible cultivar Agria. Above that, the curves were mixed for bulk soil and both cultivars in suppressive soil, while in conducive soil they were mixed only for bulk soil and tuberosphere of resistant cultivar Kariera. Therefore, the diversity in bulk soil was more heterogeneous in suppressive soil and differed more between cultivars in conducive soil (Supplementary Fig. S2).

In summary, Illumina sequencing of 16S rRNA genes evidenced differences between resistant and susceptible cultivars, the latter displaying lower bacterial diversity. Differences were also found and between suppressive and conducive soils, but mainly for bulk soil samples.

219 **Discriminant OTUs according to soil and potato cultivar.** When considering bulk as 220 well as tuberosphere soil samples based on the discriminating OTUs (Metastats, p<0.05),

suppressive soil was enriched in *Plantomycetes* (OTUs 385, 2780) and *Bacteroidetes* (OTUs 1402, 1154, 1408) and conducive soil in *Actinobacteria* (OTUs 355, 1230, 886) and *Chloroflexi*(OTU 1478). Different OTUs separating the two soils were found for *Proteobacteria* (with OTUs 92, 253, 68, 592, 835 enriched in suppressive soil vs OTUs 369, 899, 2391, 1832, 2001 in conducive soil) and *Firmicutes* (OTU 3391 enriched in suppressive soil vs OTUs 2120, 2105, 1772 in conducive soil) (Supplementary Table S6A).

227 The tuberosphere of Agria was enriched in taxa from orders *Frankiales* (*Frankiaceae*, Acidothermaceae, Geodermatophilaceae; OTUs 63, 20, 54, 117) and Micrococcales 228 (Intrasporangiaceae; OTUs 13, 10) (Supplementary Table S6B, Supplementray Fig. S1B) and 229 230 class Gemmatimonadetes (Gemmatimonadaceae; OTU 36), while tuberosphere of Kariera displayed significant enrichment in taxa from phylum Acidobacteria (OTUs 51, 275, 143, 138, 231 232 76; Supplementary Table S6B, Supplementray Fig. S1A). Tuberosphere communities of both 233 cultivars were also separated by different OTUs belonging to the same taxonomic groups. These discriminating taxa included (i) Betaproteobacteria i.e. Burkholderiales (OTU 38 in Agria vs 234 OTU 199 in Kariera), (ii) Alphaproteobacteria i.e. Sphingomonadales (OTU 1 in Agria vs OTUs 235 48, 696, 282 in Kariera), (iii) Actinobacteria i.e. Propionibacteriales (OTU 138 in Agria vs OTU 236 6 in Kariera), Gaiellales (OTUs 21, 140, 41, 114, 104, 19, 8, 309, 213, 110, 23, 946 in Agria vs 237 238 OTUs 16, 12, 30, 46, 107, 105, 24 in Kariera) and Solirubrobacterales (OTU 31 in Agria vs OTU 69 in Kariera), and (iv) Chloroflexi (OTUs 18, 26, 77, 137 in Agria vs OTUs 4, 55, 164, 29, 123, 239 284, 74 in Kariera) (Supplementary Table S6B). 240

In summary, suppressive soil was enriched in *Plantomycetes* and *Bacteroidetes* and conducive soil in *Actinobacteria* and *Chloroflexi*, and soils also differed in their *Proteobacteria* and *Firmicutes* profiles. Resistant and susceptible cultivars differed based on 1 *Gemmatimonadetes*, 5 *Acidobacteria*, 6 *Proteobacteria*, 29 *Actinobacteria* and 11 *Chloroflexi* 

245 discriminant OTUs.

246

#### 247 DISCUSSION

Disease suppressiveness of Vyklantice soil L was shown in previous studies (9, 11) and 248 since the soil has been regularly interrupted by cropping sequence over long time it can be 249 250 considered naturally suppressive to the disease (2). In the current experiment, CS disease severity 251 was assessed again in suppressive soil L and conducive soil H, under field conditions, but this 252 time the significance of cultivar status was also investigated, by comparing two potato cultivars susceptible or resistant to CS. Results indicated that CS severity of the susceptible cultivar grown 253 254 in the suppressive soil was as low as for (i) the resistant cultivar in the same soil, and (ii) the resistant cultivar in the conducive soil. These results showed the effect of soil suppressiveness 255 256 and cultivar resistance on disease severity, and in particular the similar potential of both types of control mechanisms. 257

In contrast to our previous work, the current set-up enabled to compare soil 258 suppressiveness and host resistance, and we further identified that soil suppressiveness was 259 significantly related to (i) low quantities of bacteria and actinobacteria and (ii) low C, N contents 260 and high S content in the tuberosphere, while cultivar resistance was related to high Mg content 261 262 in the periderm. In spite of extensive literature on the positive effect of S on CS severity 263 (reviewed in (18)) it does not seem that S was a key factor for CS control in our soils. A 264 combination of both cultivar resistance and soil suppressivness was related to (i) increased Fe 265 content in both tuberosphere and periderm, and (ii) changes in pathogen populations, which is in agreement with our previous work (11), in which additions of available Fe to soil decreased CS 266 severity. 267

```
268
```

Out of the parameters related to CS severity, the quantity of bacteria including

actinobacteria was previously linked with the amount of available carbon, which differed 269 270 between conducive and suppressive soils (e.g. (19)). Specifically, the quantity and community 271 structure of actinobacteria were connected to pathogen population and its interactions (11, 20). Further to that the quantity of pathogenic streptomycetes (based on numbers of *txtB* genes) did 272 not change with soil suppressiveness or cultivar in tuberosphere and bulk soil, but in suppressive 273 274 soil the number of pathogens decreased in potato periderm possibly due to both microbial 275 interactions and soil chemical conditions depending on location (9, 21). In this study, however, 276 the increased numbers of actinobacteria in periderm of susceptible cultivar did not correspond to 277 pathogenic streptomycetes, so perhaps an antagonistic community of actinobacteria developed 278 there as a response to pathogen infection, similarly as in Rosenzweig et al. (8) or Tomihama et al. (22). 279

The increase of magnesium in resistant cultivar may be explained by several aspects of 280 281 CS disease and plant metabolism. Previously, we did not find any correlation between Mg periderm content and CS, probably because the field site effect was more important (12). 282 However, the importance of site Mg concentration was correlated to CS and quantities of 283 that that the the the term of 284 disease severity was related to contents in exchangeable Ca, Mg, and K cations. Generally, Mg 285 286 has both indirect as well as direct effects on disease (25). Magnesium functions also as a P carrier in plants, and P periderm concentration was negatively correlated with CS in many studies (e.g. 287 (12)). Also, root-microbial activities are key factors that determine plant-available Mg release 288 289 from soils, and Mg was among nutrients affecting microbial community in potato rhizosphere (26). So, we concluded that Mg connection to resistant cultivar is a result of a combination of 290 several factors, which specifically in our experiment resulted in diminishing of CS severity. 291 292 Finally, higher Fe content in resistant cultivar than susceptible cultivar regardless of the nutrient content in soil is probably connected to better acquisition of this element from soil, either by the resistant plant itself or through its selected bacterial community as pointed by Sarikhani et al. (11). This possibility was raised also by Inceoğlu et al. (27), where potato cultivars grown in two soils yielded different contents in C, S and P while selecting microbial communities with different functional capabilities

Bacterial community structure was identified as a major aspect of soil suppressiveness to 298 299 CS (8). In our microarray study, Pseudomonadaceae, Bradyrhizobiaceae, Acetobacteraceae and Paenibacillaceae were associated with disease suppressiveness, and all four include plant-300 301 beneficial species and strains (3, 28). This was not expected, as the last three families were more 302 prevalent in CS conducive than suppressive soil in Michigan (8). Our Illumina sequencing indicated that *Rhizobiales* and *Planctomycetales* were enriched in suppressive soil, as in Cha et 303 304 al. (29), but Actinobacteria, Chloroflexi, Bacillaceae, and Chitinophagaceae that increased with 305 CS suppressiveness induced by rice bran (22) were more prevalent in the conducive soil here. Therefore, different biocontrol consortia may be at work in different types of suppressive soils. 306 Several phyla were more prevalent in the susceptible cultivar Agria, whereas others were more 307 prevalent in the resistant cultivar Kariera, including Nitrospirae and Acidobacteria also enriched 308 in suppressive soil studied by Cha et al. (29). 309

In this work, Illumina sequencing showed that major effects were due to resistant and susceptible cultivars and microarray analysis also evidenced the effect of suppressive versus conducive soils. The most relevant study to compare is that of Rosenzweig et al. (8) because they also studied CS suppressive soils using next generation sequencing, but they used a single, relatively CS resistant potato variety (Snowden), so they could not demonstrate the effect of cultivar in combination with soil suppressivity. In comparison, Weinert et al. (30) showed the effect of potato cultivar on rhizosphere bacteria selection, while Inceoğlu et al. (27) described

317 more profound influence of soil type over potato cultivar on bacterial rhizosphere communities 318 but studied two soil types not disease suppressive and conducive soil. Therefore, our results 319 brought new insight to bacterial community differences with respect to suppression of CS 320 disease, possibly with a more general implication to other pathogen-plant systems.

Finally, the data obtained by Illumina sequencing and taxonomic microarrays are 321 322 differently biased and to some extend showed different results. Microarray showed more 323 differences between the two soils, while Illumina sequencing stressed differences between 324 cultivars. In particular, microarray demonstrated increase of *Streptomyces* (Actinobacteria), 325 Bradyrhizobium, Burkholderia (Proteobacteria) or Nitrospira (Nitrospirae) in suppressive soil, 326 while increase of Acidibacteria, Pseudomonas, Agrobacterium and Janithobacterium (Proteobacteria) in conducive soil. Streptomyces and Rhizobiaceae were associated with resistant 327 328 cultivar Kariera, while Burkholderia and Stingomonas (Proteobacteria) were associated with 329 susceptible cultivar Agria. Illumina sequencing discriminated the two soils similarly to microarray by increase of Bradyrhizobiaceae and other Proteobacteria, but also Bacteroidetes 330 and *Firmicutes* in suppressive soil, while different families of *Proteobacteria*, *Actinobacteria* and 331 Firmicutes increased in conducive soil. For resistant cultivar Kariera, Chloroflexi, Gaiellales 332 (Actinobacteria) were found enriched, while in susceptible cultivar Agria, similarly to microarray 333 334 results Burkholderia and Sphinomonas (Proteobacteria) and Actinobacteria were enriched. We 335 explain the differences by specific characteristics of the two methodological approaches (14–16, 336 31, 32).

In conclusion, we demonstrated the cultivar-specific community selection with respect to their susceptibility or resistance to CS and above that we included comparison of this trait in suppressive and conducive soils. We showed that CS can be controlled either with resistant cultivar or with suppressive soil, with no additive effect between them. Out of the two factors,

potato cultivar had a higher effect on tuberosphere bacterial community composition than soil in
 our experiment. Results highlighted the usefulness of both cultivar resistance and soil
 suppressiveness traits in understanding and managing disease control of crops.

344

#### 345 MATERIALS AND METHODS

**Sites.** Vyklantice is a site where fields suppressive (L for low disease severity), and conducive (H for high disease severity) to potato CS occur at about 100 m distance. The two fields differ in common scab severity by observations over 30 years, while their geological context, soil type, climate and management are similar. The fields were regularly planted under a four-year crop rotation system including rapeseed, clover, potatoes, and grains (wheat or oats) in the past two decades (9).

**Field experiment.** Potatoes were planted in the beginning of May and samples of bulk 352 353 soil, tuberosphere soil and potatoes were collected after 80 days. One susceptible cultivar (Agria) and another resistant (Kariera) to CS were used. Potatoes were all certified seed tubers (common 354 scab below 5% of surface). Four plots of each cultivar were planted at each field and the plots 355 were arranged in a Latin square design. Each plot was planted with 3 rows of 12 potato plants (36 356 plants) separated by 50 cm of bare soil. Fields were fertilized with 100 kg N/ha (ammonium 357 358 sulphate, 21% N), 35 kg P/ha (monocalcium phosphate, 35%  $P_2O_5$ ), and 60 kg K/ha (potassium 359 salt, 50% K<sub>2</sub>O). Potatoes were treated with pesticides, once with Nurelle D (EC) (chlorpyrifos, 360 cypermethrin) at 0.6 l/ha to prevent Colorado potato beetle (Leptinotarsa decemlineata), and 361 twice with Acrobat MZ (dimethomorph, mancozeb) at 2 kg/ha and Ridomil Gold MZ Pepite (mancozeb, metalaxyl-M) at 2.5 kg/ha against the potato blight. Fungicides were not used. 362

363 Sampling. One potato plant growing in the center of each plot was sampled. Potatoes364 from this plant were collected and washed in distilled water. All potatoes were carefully pealed

using a sterile potato peeler (taking approximately 1 mm thick periderm samples), peels were 365 366 homogenized and mixed, and subsamples (1 subsample per plant) were taken for further analyses ('periderm' samples). Tuberosphere soil samples were collected no further than 3 mm from a 367 potato tuber (for details see (9)). Bulk soil was collected at a distance of approximately 30 cm 368 from the closest plant within each plot using a small sterile spade (1 sample per plot). Common 369 370 scab severity was evaluated on 20 potato tubers per plot using a 9-degree scale (33). Potatoes 371 used for evaluation were those of the collected plant and several more plants from each plot to 372 achieve at least 20 measurements per plot.

Soil and potato periderm analyses. To determine total soil C, N, and S contents, 2-g 373 374 samples of homogenized soil from both bulk soil and tuberosphere were dried, milled, and analyzed using Vario MAX CNS analyzer (Elementar Analysensysteme, Hanau, Germany). To 375 376 determine all other elements, soil subsamples were leached with boiling nitro-hydrochloric acid (aqua regia) and assessed by optical emission spectroscopy with inductively coupled plasma 377 (ICP-OES) by Aquatest Inc. (Prague, Czech Republic). Analyses of potato periderm were 378 performed by service laboratory of the Institute of Botany (Trebon, Czech Republic). For total 379 nitrogen analysis, 1-3 mg dried periderm was mineralized by modified Kjeldahl method in  $H_2SO_4$ 380 with catalyzer at 360°C. For total phosphorus, 20 mg of dried periderm was sequentially 381 382 decomposed by  $HNO_3$  and  $HCIO_4$ . In mineralized samples, both N and P were determined by 383 flow injection analysis with spectrophotometric detection using FIA Lachat QC 8500 analyzer 384 (Lachat Instruments, Hach Company, Loveland, CO). Cation contents in periderm were 385 determined by atomic absorption spectrometry using AAS spectrometer ContrAA 700 (Analytik Jena, Jena, Germany) after mineralization with nitro-hydrochloric acid. 386

387 Soil DNA extraction. Soil samples from tuberosphere and bulk soil were homogenized
388 and subsamples of 0.5 g were used for DNA extraction by method SK described by Sagova-

Mareckova et al. (34). Briefly, the method is based on bead-beating and phenol/chloroform extraction followed by purification with CaCl<sub>2</sub> and GeneClean Turbo kit (MP Biomedicals, Santa Ana, CA). For DNA extraction from potato periderm, 3 g of periderm samples were fine cut in sterile Petri dish, homogenized, and a 0.3 g subsample was processed in the same way as soil samples to obtain total periderm DNA.

**Real-time PCR (qPCR).** Quantifications were performed with primers eub338f (5'-394 395 ACTCCTACGGGAGGCAGCAG-3) (35) and eub518r (5'-ATTACCGCGGCTGCTGG-3') (36) amplifying a 197 bp fragment of the 16S rRNA gene from bacteria, act235f (5'-396 397 CGCGGCCTATCAGCTTGTTG-3') (37) and eub518r yielding a 280 bp product for 398 Actinobacteria, and StrepF (5'-GCAGGACGCTCACCAGGTAGT-3') and StrepR (5'-ACTTCGACACCGTTGTCCTCAA-3') yielding a 72 bp amplicon of the thaxtomin biosynthetic 399 gene txtB (38), respectively. The analyses were done on a StepOne Plus Real-Time PCR System 400 (Applied Biosystems, Foster City, CA) using 96-well plates with GoTaq qPCR Master Mix 401 (Promega) containing SYBR Green as a double-stranded DNA binding dye. The reaction mixture 402 403 contained in a total volume of 15  $\mu$ l: 1× GoTaq qPCR Master Mix, 0.2  $\mu$ M primers, and 0.2-2 ng diluted DNA sample. For all of the mentioned targets the PCR cycling protocol consisted of 404 initial denaturation at 95°C for 10 min, followed by 45 cycles of 95°C for 15 s, 60°C for 30 s and 405 406 72°C for 30 s. Melting curves were recorded to ensure qPCR specificity. Baseline and threshold calculations were performed with the StepOne v. 2.2.2 software. The inhibition was tested by 407 408 serial DNA dilution from each site, and the dilutions without inhibition of qPCR reactions were 409 used for quantification. All qPCR measurements were done in duplicate. Standards for qPCR 410 were prepared by cloning fragments of target genes from *Streptomyces europaeiscabiei* DSM 41802 in pGEM-T Easy vector system (Promega). After PCR verification and isolation of cloned 411 412 constructs by Pure Yield Plasmid Miniprep System (Promega), a linear standard was prepared by

413 cleaving with SalI enzyme (New England Biolabs, UK) in a 200  $\mu$ l reaction mixture containing 414 1× reaction buffer, 2  $\mu$ g circular plasmid, and 20 U restriction endonuclease for 2 h in 37°C. The 415 linearized plasmid DNA was purified by phenol-chloroform extraction. Aliquots of linearized 416 and purified standard diluted to 20 ng / $\mu$ l were stored in -70°C. Results were expressed per g dry 417 soil. All results (including for *txtB*) were above detection limit.

16S rRNA gene-based taxonomic microarray. A taxonomic microarray based on DNA 418 419 probes targeting 16S rRNA genes representing 19 bacterial phyla at different taxonomic levels (15) was used to assess soil samples from potato fields. This microarray was validated previously 420 421 (15, 17). Twelve probes targeting the genus *Streptomyces*, as well as *S. scabies* and relatives 422 (Supplementary Table S1) were added to the previous probe set (1033 probes) in this study. The probe KO 08 (39) for genus Streptomyces was obtained via the probeBase server (40) 423 424 (http://probebase.csb.univie.ac.at). The other 11 probes (20-mers) were designed in this study using ARB sofware (41) (http://www.arb-home.de) and the parameters of the Probe Design 425 function chosen by Sanguin et al. (31, 42). Probe specificity was tested with the Probe Match 426 427 function in ARB against the reference Silva-104 and with the TestProbe online tool against Silva 126 database (43) (http://www.arb-silva.de), at the weighted mismatch value of 1.5 (15). 428 Hybridization properties of probes (e.g. melting temperature, potential formation of secondary 429 430 structures and 3'dimers) were further tested *in silico*, according to Sanguin et al. (31, 42).

Universal bacterial TAATACGACTCACTATAG-431 primers T7-pA (forward; AGAGTTTGATCCTGGCTCAG) and pH (reverse; AAGGAGGTGATCCAGCCGCA) were 432 433 used to amplify 16S rRNA genes from total DNA extracts (44). Primer T7-pA includes at the 5' end the sequence of T7 promoter, which enabled T7 RNA polymerase-mediated in vitro 434 transcription using purified PCR products as templates. PCR reactions were carried out using Taq 435 Expand High Fidelity (Roche Applied Science, Meylan, France) and cycling conditions described 436

in Kyselková et al. (15). Purified PCR products (50 ng/ $\mu$ l) were fluorescently labelled (Cy3) by *in vitro* transcription, according to Stralis-Pavese et al. (45). Purified RNA was fragmented by incubation with ZnSO<sub>4</sub>, as described (45), and 400 ng subjected to hybridization on the microarray. Each probe was present in four copies per slide, and two slides were hybridized per sample.

Hybridization was carried out according to Sanguin et al. (31). Slides were scanned at 532 442 443 nm, images were analyzed with GenePix Pro 7 (Molecular Devices, Sunnyvale, CA), and spot quality was checked visually, as described previously (31). Data filtration was conducted using R 444 445 3.3.0 (46) (http://www.r-project.org). Hybridization of a given spot was considered positive when 446 80% of the spot pixels had intensity higher than the median local background pixel intensity plus twice the standard deviation of the local background. Intensity signals (median of signal minus 447 background) were replaced by their square root value and intensity of each spot was then 448 expressed as a fraction of the total intensity signal of the basic pattern it belongs to (42). Finally, 449 a given feature probe was considered as truly hybridized when (i) hybridization signals were 450 superior to the mean signal of the negative controls and (ii) at least 3 of 4 replicate spots 451 displayed positive hybridization (15). 452

Illumina MiSeq sequencing and analysis. From the DNA samples, a fragment of the 453 454 bacterial 16S rRNA gene including the variable region V4 was amplified by PCR using universal 455 primers with CS1-515F (5'overhang adapters ACACTGACGACATGGTTCTACAGTGCCAGCMGCCGCGGTAA-3') and CS2-806R 5'-456 457 TACGGTAGCAGAGACTTGGTCTGGACTACHVGGGTWTCTAAT-3') (47). Construction of amplicon libraries and sequencing using MiSeq sequencer (Illumina, San Diego, CA) were done 458 at the DNA Services Facility, Research Resources Center, University of Illinois (Chicago, MI). 459 Resulting paired sequence reads were merged, filtered, aligned using reference alignment from 460

the Silva database (43), and chimera checked using integrated Vsearch tool (48) according to the 461 462 MiSeq standard operation procedure (Miseq SOP, February 2018) (49) in Mothur v. 1.39.5 software (50). A taxonomical assignment of sequence libraries was performed in Mothur using 463 the Silva Small Subunit rRNA Database, release 128 (51) adapted for use in Mothur 464 (https://mothur.org/w/images/b/b4/Silva.nr\_v128.tgz) as the reference database. Sequences of 465 plastids, mitochondria, and those not classified in the domain Bacteria were discarded. The 466 467 sequence library was clustered into OTUs using the Uparse pipeline in Usearch v10.0.240 software (13), and the OTU table was further processed using tools implemented in the Mothur 468 software. Distance matrices describing the differences in community composition between 469 470 individual samples were calculated using the Yue-Clayton theta calculator (52). Analysis of molecular variance (AMOVA) (53) was based on a matrix of Yue-Clayton theta distances. 471 472 Metastats analysis (54) was used to detect differentially represented OTUs.

Statistical analyses. Analysis of variance (ANOVA) and Fisher LSD tests were used to 473 test differences between soils and cultivars for soil chemical parameters and copy numbers of 474 bacterial and actinobacterial 16S rRNA genes, and *txtB* genes in soil and periderm samples. 475 Permutational multivariate analysis of variance (PERMANOVA) was used to compare distance 476 matrices between microarray samples (55). AMOVA was used to test differences between 477 478 distance matrices (Yue-Clayton Theta) between Illumina samples. The distance matrices were 479 plotted by Sammon's Multidimensional Scaling (56).

480

Accession number. MiSeq 16S rRNA gene amplicon sequences have been deposited in 481 the NCBI Sequence Read Archive (www.ncbi.nlm.nih.gov/sra) as BioProject PRJNA474544.

482

#### **ACKNOWLEDGEMENTS** 483

484

This work was supported by the Ministry of Agriculture of the Czech Republic, grants

485	QK1810370 and RO0417. We would like to thank Stefan Green and the DNA Service Facility of
486	the UIC for MiSeq sequencing.

**FIG 3** Differences between bacterial communities in tuberosphere of CS-susceptible cultivar Agria (circles) and CS-resistant cultivar Kariera (squares), and in bulk soil (pentagons) assayed by 16S rRNA taxonomic microarray (A) and 16S rRNA gene Illumina amplicon sequencing (B) in CS-suppressive (L, open symbols) and CS-conducive (H, grey symbols) soils. Numbers indicate the numbers of probes (A) and OTUs (B) significantly contributing to the difference between samples in pairwise comparisons (Metastats, p < 0.05).
