ABSTRACT

DNA condensation and phase separation is of utmost importance for DNA packing *in vivo* with important applications in medicine, biotechnology and polymer physics. The presence of hexagonally ordered DNA is observed in virus capsids, sperm heads and in dinoflagellates. Rigorous modelling of this process in all-atom MD simulations is presently difficult to achieve due to size and time scale limitations. We used a hierarchical approach for systematic multiscale coarse-grained (CG) simulations of DNA phase separation induced by the three-valent cobalt(III)-hexamine (CoHex³⁺). Solvent-mediated effective potentials for a CG model of DNA were extracted from all-atom MD simulations. Simulations of several hundred 100-bp-long CG DNA oligonucleotides in the presence of explicit CoHex³⁺ ions demonstrated aggregation to a liquid crystalline hexagonally ordered phase. Following further coarse-graining and extraction of effective potentials, we conducted modelling at mesoscale level. In agreement with electron microscopy observations, simulations of an 10.2-kbp-long DNA molecule showed phase separation to either a toroid or a fibre with distinct hexagonal DNA packing. The mechanism of toroid formation is analysed in detail. The approach used here is based only on the underlying all-atom force field and uses no adjustable parameters and may be generalized to modelling chromatin up to chromosome size.

INTRODUCTION

The compaction of DNA is a problem of outstanding importance in biology with many important applications in polyelectrolyte theory, biotechnology, nanoscience (1-4). While a long (~100 Mbp) chromosomal DNA molecule in low salt solution would adopt a random coil conformation expanding over 100 μm , 46 such DNA molecules are packed inside the confined space of about 10 μm in the human cell nucleus. Similarly, in sperm heads, viruses and bacteria, DNA is extremely densely condensed (4-7). The packaging of the giant genomes of dinoflagellates is another example of compact ordered liquid-crystalline form of DNA (8,9). Notably, in the eukaryotic cell nucleus formation of heterochromatin has recently been proposed to proceed through liquid-liquid phase separation of condensed DNA domains (10,11). DNA condensation has also attracted great attention in gene delivery where the compaction is a key to optimizing DNA transfer (3,12).

For almost 50 years it has been known that *in vitro*, in the presence of highly charged cations like cobalt(III)-hexamine (CoHex^{3+}), spermidine $^{3+}$ and spermine $^{4+}$, DNA in solution condenses into collapsed structures of varying morphologies such as toroids, rod like fibres, globules and liquid crystals (13-17). While liquid crystalline phases are observed for 150 bp or shorter DNA molecules (18-20), long DNA molecules (a few to several hundred kbp) exhibit highly regular toroidal structures with DNA arranged in hexagonal packing inside the toroids (6), which have an outer diameter of around 100 nm, depending on conditions (21,22). This spontaneous formation of DNA toroids in hexagonal arrangement is also observed *in vivo* in viruses and sperm chromatin and has fascinated scientists for a long time (5,6,23,24). This phenomenon has been vastly studied experimentally with a variety of techniques such as X-ray diffraction (25), Cryo-EM (22,24) and more recently with single molecule techniques (26). This has resulted in significant advances in our understanding of the phenomenon both at mechanistic and fundamental level. However, there are still many unanswered problems related to the condensation of DNA induced by multivalent cations resulting in the formation of the ordered DNA liquid crystalline phase, and the collapse of DNA into toroidal structures. There is a lack of rigorous theoretical modelling approaches that are able to predict, reproduce and analyse these phenomena from basic principles.

Although it may seem counterintuitive, the fundamental origin of multivalent ion induced attraction between like-charged DNA molecules leading to condensation is grounded in the electrostatic properties of the highly charged DNA polyelectrolyte. Based on computer simulations as well as on analytical theories, it has been established that the attraction is caused mainly by ion-ion correlations that result in a correlated fluctuation in the instantaneous positions of the condensed counterions on DNA, leading to a net attractive force between DNA molecules (reviewed in (2,27)). In the case of flexible multivalent cations like the polyamines or oligopeptides, the attraction is also generated by the “bridging” effect (28). The origin of multivalent ion induced attraction between aligned DNA-DNA molecules is therefore clear and well described by such polyelectrolyte models, and recently also in all-atom detail (29,30). However, the mesoscale level spontaneous transition of short DNA molecules to a hexagonal liquid crystalline phase and the formation of toroids from kbp-long DNA molecules, have not been rigorously described and analysed theoretically. These phenomena that are

determined by a combination of electrostatic forces and by DNA mechanical properties, are highly important for understanding DNA phase separation in biology.

Computer modelling of DNA condensation to an ordered bundled phase or modelling of single DNA molecule collapse to the toroid structure, have with few exceptions been performed with a description of DNA as a chain of beads using parameterized harmonic bonds. The bending flexibility was commonly tuned to reproduce the DNA mechanical properties from persistence length data (31-34). Furthermore, the DNA-DNA attraction was generally modelled by empirical potentials. Only in a few of these works electrostatic effects were treated directly by including explicit balancing counterions, however, without added salt (31-33). Common to all these approaches is that they treat generic polymer molecules without explicit presence of added salt, using empirical adjustable parameters to describe the relevant potentials in the models. Hence, the connection to the atomistic DNA structure and chemical specificity is lost. The experimentally important phenomenon of the formation of hexagonally ordered liquid crystalline phase of short DNA molecules in the presence of multivalent counterions has to the best of our knowledge never been theoretically demonstrated.

In recent years advances in computer technology have progressed considerably and all-atom biomolecular MD simulations including molecular water can now be performed for very large systems such as a nucleosome core particle and large DNA assemblies (30,35). Yoo and Aksimentiev developed improved ion-phosphate interaction force field parameters and performed all-atom MD simulations of an array of 64 parallel duplex DNA. They demonstrated the correct hexagonal packing of DNA, which was absent in simulation with standard CHARMM or AMBER force field parameters (36). The same authors also investigated the physical mechanism of multivalent ion-mediated DNA condensation at atomistic level. The results supported a model of condensation driven by entropy gain due to release of monovalent ions and by bridging cations (30).

However, all-atom MD simulation of DNA liquid crystalline formation or kbp-size DNA toroid condensation is presently not computationally feasible and hence multiscale approaches linking atomistic and coarse-grained (CG) levels of description are necessary (37). Within a systematic bottom-up multiscale modelling scheme, the macromolecules are reduced to a CG description with effective sites representing groups of atoms and a number of such coarse-graining methods and models for DNA have been developed, each with respective strengths and weaknesses (38).

Although some bottom-up approaches (reviewed in (37)), have recently been used to model DNA and DNA aggregation, they did not treat both electrostatics and solvent effects rigorously or did not reach the mesoscopic scale of DNA condensation. An alternative to systematic bottom-up CG approach for modelling DNA at mesoscale level is represented by recent work by the de Pablo group using a top-down approach to fit the model parameters to experimental data (DNA thermal denaturation) (39,40). The DNA model combined with explicit ions was used in simulations of 4 kbp DNA packaging in the presence of multivalent ions inside a virus capsid (41).

The DNA condensation to a hexagonally ordered phase as well as DNA toroid formation, both induced by the presence of multivalent cations, are phenomena clearly intrinsic to the DNA molecule and inherent in its physico-chemical properties. We hypothesize that this behaviour can be predicted by a bottom-up approach that is based on state-of-the-art all-atom molecular dynamics (MD)

simulations, which is followed by structure-based coarse-graining resulting in effective interaction potentials for the CG model without further adjustable parameters.

Here, we perform systematic multiscale structure-based CG simulations of DNA with explicit electrostatic interactions included, starting from all-atom description going up to mesoscale modelling of DNA. The CG model is simple enough yet captures the structure form of double helix DNA and rigorously treats the electrostatic interactions. The systematic coarse-graining follows the inverse Monte Carlo (IMC) approach to extract solvent mediated effective CG potentials for all interactions in the system (42,43) from structural properties of the underlying system. The model is validated in CG simulations of DNA persistence length as a function of monovalent salt demonstrating outstanding performance. We show DNA condensation induced by the three-valent CoHex³⁺ ion for short DNA duplexes resulting in a bundled phase with hexagonal ordering. Furthermore, adopting a second level “super coarse-grained” (SCG) DNA beads-on-a-string model we show that this approach remarkably predicts the hexagonally ordered liquid crystalline-like phase of short DNA and toroid formation in hexagonal arrangement for kbp-size long DNA, giving mechanistic insight on the DNA condensation process. In order to further advance our knowledge and pave the ground for detailed analysis of the compaction of DNA at mesoscale level in chromosomes, it is necessary to develop chemically informed DNA models that do not rest on adjustable parameters. Such models should have the predictive power to be trusted in modelling biologically important phenomena at mesoscale level for experimentally unexplored scenarios. The present approach represents a first and successful step in this direction.

METHODS

More details on computational methods and parameters used in this work are given in the Supplementary Methods section of the Supplementary Data (SD).

Hierarchy of DNA models

The hierarchical multiscale approach used here implements systematic stepwise coarse-graining of DNA model from the atomistic to a beads-on-string level as illustrated in Figure 1. Coarse-graining is performed at two spatial scales resulting in three DNA models with different resolutions. Figure 1A illustrates the all-atom DNA model which includes explicit water molecules and ions. In the CG DNA model (Figure 1B), the DNA is modelled with five beads, representing a two-base pair unit of DNA (Figure 1D). There are four types of bonds and three types of angles in the bonded interaction terms (Figure 1D). We include explicit mobile ions and charges of DNA phosphate groups while the solvent is considered implicitly. The second level of coarse-graining results in a beads-on-string type of model, called the super CG DNA (SCG) model, which is shown in Figure 1C. Here, a single type of uncharged beads (called “S”) represents three units of the CG DNA model, corresponding to six DNA base pairs. There is one bond and one angle potential. In the SCG model both solvent and electrostatic interactions are implicitly included into the effective potentials.

All-atom Molecular Dynamics simulations

Microsecond-long all-atom MD simulations are performed with four 36 bp-long DNA molecules in presence of water and ions as illustrated in Figure 2. The system contains CoHex³⁺ ions corresponding to 1.5 times the charge of the DNA. Additional salt corresponding to 50 mM K⁺ and 35 mM Na⁺, with neutralizing amount of Cl⁻ ions. CHARMM27 force field is used, supplemented with Car-Parrinello MD (CPMD) optimized CoHex³⁺ parameters obtained in our previous work (44).

Inverse Monte Carlo procedure

In both the CG and SCG DNA models, all effective interaction potentials are obtained in a systematic and rigorous way using the IMC method (42,43). The potentials are constructed to reproduce selected average structural properties of the fine-grained system such as radial distributions functions (RDF) between non-bonded CG sites and bond length and angle distributions for bonded sites. For the CG DNA model, these are obtained by mapping the all-atom MD trajectory from the four-DNA system to a corresponding CG site representation. Thus, no empirical or adjustable parameters are used in the CG DNA model and it rests only on the parameters from all-atom CHARMM27 DNA as well as on the CPMD optimized parameters for CoHex³⁺. The IMC-derived potentials are tabulated and not prescribed by any specific functional form.

The topology of the CG DNA model (Figure 1B and 1D) is similar to our previous CG DNA model (45,46) but with all interaction potentials derived by the IMC method from the underlying atomistic simulations. The total number of bead types is eight: four DNA beads (D, P, as well as terminal DT, PT), one CoHex³⁺, one K⁺, one Na⁺ and one Cl⁻ bead. The complete set of interaction parameters consists of 36 non-bonded terms, 4 bonded terms and 3 angle terms (see details in Supplementary Data). All effective interaction potentials are derived simultaneously, so that all correlations between different interaction terms are taken into account.

The potentials for the SCG model are derived in the same way as for the CG model using the IMC method. Trajectories generated by MD simulation of the CG model are mapped to the SCG representation. Then the RDF between the “S” sites, as well as bond and angle distributions are calculated with the mapped SCG trajectories.

The IMC calculation is carried out with the MagiC software v.3 (47) that is also used for bead-mapping, RDF calculation, analysis and export of the resulting potentials.

Coarse-grained simulations

Following the extraction of effective CG potential with the IMC method, we use these potentials to perform CG MD simulations for a system comprising two hundred DNA molecules and explicit ions to simulate DNA aggregation in the presence of CoHex³⁺. This simulation is used for further coarse-graining to a “super-CG” (SCG) DNA model (Figure 1C) with another step of IMC. The simulations with the CG and SCG DNA models are conducted using the LAMMPS package (48) within the NVT ensemble. CG model simulations were carried out for 200 pieces of 100-bp DNA (50 CG-DNA units) in a 150×150×150 nm³ simulation box containing 13,200 CoHex³⁺ ions (corresponding to a

concentration of 6.5 mM) in the presence of 10 mM K^+ and 10 mM Na^+ ions as well as neutralizing Cl^- ions. The derived effective potentials for the SCG model enable us to simulate DNA condensation and phase separation at mesoscale level. We perform simulations for two systems. The first comprises 400 pieces of 96 bp DNA (represented by a chain of 16 S-beads) and the second system is a single 10.2 kbp-long DNA (1700 S-beads). Within the SCG model, the electrostatic interactions are treated implicitly since they are effectively included into the SCG effective potentials.

Persistence length calculation

To validate the CG DNA model we test its performance in prediction of the salt dependence of the DNA persistence length, L_p . We perform all-atom MD simulations of a single 40 bp DNA in the presence of physiological salt (130 mM NaCl). Following that we perform the mapping of this trajectory to the CG model and extract effective IMC potentials. To estimate the dependence of the persistence length on ionic concentration, a 500 bp long CG DNA is simulated in the range of NaCl salt concentrations from 0.1 mM to 100 mM. Our simulation results are compared with experimental data and with data from other simulation studies.

RESULTS AND DISCUSSION

Validation of the CG DNA model and the approach

First we validate the approach and the CG DNA model (described above) against experimental persistence length data as a function of monovalent salt concentration. We perform a separate all-atom MD simulation of a single 40 bp DNA in the presence of physiological salt (130 mM NaCl). The all-atom trajectory is run for 2 μ s and demonstrates stability of helical parameters and the elasticity of the DNA double helix (data not shown). We then extract effective IMC potentials (see Supplementary Methods for details). Figure S1 of the Supplementary Data (SD) shows all the effective potentials. Following that, we proceed to run several CG simulations of a single 500 bp-long DNA molecule in the presence of varying concentration of monovalent salt in the range 0.1 to 100 mM. Figure 3 compares the dependence of persistence length as a function of salt concentration with experimental data (49-55). We include experimental persistence length data from several sources as there is a large variation in these results depending on the method used and the procedure for analysing the original measurements. Additionally, we also include values predicted by other CG DNA models with explicit ions, obtained using bottom-up approaches based on underlying all-atom MD simulations (40,56,57). Considering the variation in experimental data, the present model demonstrates excellent agreement with experiments for three orders of magnitude variation in salt concentration. In general, the performance of our model is superior to other available explicit ion CG DNA models. This accurate prediction of the effect of electrostatic interactions on DNA flexibility lends confidence to the present approach. The result shows that the model well represents both DNA intrinsic flexibility and electrostatic interactions. A more detailed discussion of DNA flexibility and persistence length prediction from the CG model and how the DNA flexibility depends on choice of underlying force field will be presented elsewhere (Minhas *et al.*, to be published).

DNA-DNA attraction in all-atom MD simulations

We perform all-atom MD simulations for a system with four DNA molecules in all-atom description containing explicit ions (CoHex^{3+} , Na^+ , K^+ and Cl^-) and water is shown in Figure 2. Data from the three independent 1 μs -long simulations are subsequently used in the IMC procedure for extraction of effective solvent mediated potentials for the CG DNA model.

Similarly to the result of our previous work (44), the system shows DNA-DNA attraction and aggregation of DNA into fibre-like bundles induced by CoHex^{3+} as shown in a snapshot in Figure 2. DNA fibres are formed across the periodic boundaries in all three independent simulations (see Supplementary Figure S2, A-C). The snapshots show some variability in the character of DNA-DNA contacts over the periodic images. Since CG models generally present a smoother free energy surface than their fine-grained counterpart, more efficient sampling can be achieved in CG MD simulations. After extracting the effective potentials for the CG model, longer MD simulations of the same system with four DNA molecules, are performed (see more details in the next section). A final snapshot from one CG-MD simulation of this four DNA system is illustrated in the Supplementary Figure S2D. In the CG MD simulations a straight fibre configuration is easily reached. This result is stable and does not vary in different simulations.

Coarse-Grained DNA model with rigorous effective solvent mediated potentials

Following the all-atom MD simulations of the system with four DNA molecules in all-atom representation containing explicit ions (CoHex^{3+} , Na^+ , K^+ and Cl^-) and water as described above, we proceed to extract the effective potentials for the CG model. The trajectories generated by the atomistic MD simulations are mapped from the all-atom to the CG DNA model. We use these for calculation of RDFs and intramolecular (within DNA) distributions of bond lengths and angles between the CG sites, with averaging over all three independent trajectories. Examples of calculated RDFs are shown in Figure 4A-C. Selected distribution functions and effective potentials are plotted in Figure 4A-F. All RDFs and effective potentials for the CG DNA model in presence of CoHex^{3+} can be found in Supplementary Figure S3. Supplementary Figure S4 illustrate convergence in the IMC calculations.

We additionally performed a control all-atom MD simulation without the presence of CoHex^{3+} under conditions that should not lead to DNA condensation. The CoHex^{3+} ions are replaced by the same number of Mg^{2+} ions (with the corresponding decrease in number of Cl^- counterions), resulting in the absence of DNA condensation, which is in agreement with the experimentally known fact that the divalent Mg^{2+} does not induce DNA condensation (1) (data not shown). We follow the same modelling protocol as for the case of CoHex^{3+} to derive effective potentials for this control model.

It may be noted that the D-D RDFs in the Mg^{2+} and CoHex^{3+} systems between the central beads of different DNA molecules (Figure 4A) appear very different. However, the final effective potentials for the D-D pair from both simulations (Figure 4D) have similar features. They are both slightly attractive from about 21 Å to the cut-off 25 Å. In the distance range below 21 Å, both effective potentials are repulsive. In the Mg^{2+} system, the RDF at distances below 25 Å has low amplitude since different DNA fragments repel each other due to electrostatic interactions. The presence of Mg^{2+} counterions cannot overcome this repulsion. In the more strongly coupled CoHex^{3+} system, the presence of the

trivalent counterions creates an overall attraction between DNA segments that results in DNA condensation. Therefore, it is expected that similar D-D potentials result in different D-D RDFs if different ions are present in the system.

Furthermore, the effective potentials for monovalent ion-ion interactions obtained under different conditions are virtually the same as illustrated in Figure 4F for the case of the Na-Cl pair. In Figure 4C the corresponding Na-Cl RDF shows, however, a small but noticeable difference between the aggregating (CoHex³⁺-system) and non-aggregating (Mg²⁺-system) simulations due to different average DNA-DNA distances. However, the final effective potentials from both systems are identical (Figure 4F). We attribute this to the fact that correlations between the different interaction terms are well represented in the present model. In fact, all ionic potentials for the same interaction types, but extracted from different underlying all-atom MD simulations for the present CG DNA model, are indistinguishable or very similar. As a further illustration, Supplementary Figure S5 compares ionic potentials extracted from three DNA all-atom MD simulations having different ionic and different DNA compositions. This behaviour implies good transferability of the derived potentials (see below for further discussion).

DNA condensation in CG simulations

Having rigorously extracted effective potentials for the CG DNA model on the basis of the all-atom simulations, we next proceed to use them in large-scale simulations investigating DNA phase separation induced by the presence of explicit CoHex³⁺ ions. The applied CG approach treats long-range electrostatic interactions explicitly with the presence of all mobile ions in the system. The total solvent-mediated interaction potential between all charged sites in the system is a sum of a Coulombic potential scaled by the dielectric permittivity of water ($\epsilon=78$), and a short-range non-bonded interaction (shown in the figures, e.g. Figure 4) within the cut-off distance, determined by the IMC procedure. This treatment of the long-range electrostatic interactions was validated in our previous work (58). Not only does this lead to a rigorous description of the important electrostatic interactions, but also enables the CG model to be used under varying ionic conditions.

After the significant reduction in the number of degrees of freedom by the coarse-graining, we can easily simulate DNA condensation in a box of size of $150 \times 150 \times 150 \text{ nm}^3$ for extended time. This is 1000 times larger volume compared to what is affordable for the all-atom MD simulations, which have used a box of $15 \times 15 \times 15 \text{ nm}^3$. Here, 200 pieces of 100-bp CG DNA double helices are randomly placed in the box together with CoHex³⁺, potassium and sodium ions as well as the appropriate amount of chloride ions.

Figure 5A displays the short-range energy of the CG model as a function of time with representative snapshots and illustrates that DNA aggregation and phase separation occurs gradually during the simulation. Starting from a randomly dispersed distribution, DNA molecules gradually bundle together. The DNA condensate particle gets larger, forming a single fibre-like particle at the end of the simulation. Interestingly, the DNA molecules demonstrate short-ranged local order of hexagonal arrangement in the fibre bundle. This illustrates that the almost universal hexagonal packing of condensed DNA is intrinsically inherent in the chemical and physical properties of the DNA

molecule as represented by the underlying all-atom force field and preserved in the effective potentials.

The value of the smallest DNA-DNA distance is 22.5 Å, which is also exhibited by the first peak of the RDF in Figure 5B. This is in reasonable agreement with experimental data. Our own observations (unpublished data) from X-ray diffraction measurements of precipitated 177 bp DNA molecules, display a single broad Bragg peak at $q = 0.26 \text{ \AA}^{-1}$. This corresponds to a lateral DNA-DNA separation in the range 24 Å – 27 Å (assuming hexagonal ($r = 4\pi/q\sqrt{3}$) or lamellar ($r = 2\pi/q$) packing). A shorter separation observed for bundled DNA in simulations compared to experiment is likely due to the CHARMM force field presently used in the underlying all-atom MD simulations (59).

To demonstrate the robustness of the CG DNA model, we conduct another simulation where the CoHex³⁺ ions are replaced by K⁺ and Na⁺ ions with equivalent amount of charge, using potentials obtained from the IMC procedure described above. The same CG box size and simulation protocol are adopted. The system exhibits no DNA condensation and the DNA-DNA interaction is repulsive as can be seen from the D-D RDF plotted in Figure 5B (blue line). In contrast to the system with CoHex³⁺, the amplitude of the D-D RDF is low in value, suggesting a large distance between DNA molecules. Additionally, Figure 5B displays the D-D RDF (dashed red line) obtained from a CG simulation where the CoHex³⁺ ions are replaced by Mg²⁺ ions, with all potentials obtained from the all-atom system comprising four DNA molecules and Mg²⁺ ions, as mentioned above in relation to Figure 4D-F. In agreement with the experimental data (1), this system is repulsive and phase separation does not occur. Hence, we can conclude that our CG DNA model is robust and produces realistic DNA aggregation behaviour in large-scale simulations in agreement with experiment.

The result illustrated in Figure 5B furthermore also lends support for the transferability of the effective ionic potentials obtained with the present approach. The CG simulation resulting in the red (repulsive) D-D RDF is performed for a system with 200 DNA molecules of 100 bp length containing only monovalent ions. In such a system the expected macroscopic behaviour is that DNA condensation should not occur. However, the effective ionic potentials used in the CG simulation resulting in this non-aggregating system are obtained from an all-atom MD simulation containing CoHex³⁺ ions that displays aggregation and bundling at all atom level (Figure 2) and in the CG simulations when CoHex³⁺ ions are present (Figure 5). As a further test of the transferability of the ionic potentials, we compare effective potentials for all monovalent ion interactions obtained by the IMC procedure from two different underlying all-atom MD simulations, displayed and discussed in Supplementary Figure S5. An additional test of transferability is illustrated in Supplementary Figure S6.

Mesoscopic-scale simulations of DNA hexagonal phase separation

To investigate DNA phase separation at the mesoscopic level we performed one more step of coarse-graining, constructing the super coarse-grained (SCG) model. The excellent behaviour of the CG DNA model allowed us to confidently build a DNA model with even lower resolution and faster performance in terms of computational time. The ions, as well as all electrostatic interactions are treated implicitly by the effective potentials. RDFs and effective potentials comprising the SCG DNA

model are illustrated in Figure 4G-I. Due to the simplicity of the model there is no significant correlation among the three interaction terms; the bond and angle potential minima are at the same position as the maxima in the corresponding respective distributions. These two terms may in principle be modelled by simple harmonic functions. On the other hand, the non-bonded interaction term cannot be directly fitted by conventional functions, such as a Lennard-Jones or Debye-Hückel potentials. Specifically, although there is a dominant minimum at 23 Å in the non-bonded effective potential, which might be mimicked by a Lennard-Jones potential, the long-range behaviour of the IMC-computed potential is different, with a positive maximum at 35 Å followed by two relatively small minima at about 44 Å and 65 Å. Hence, the final effective potential contains interaction features that preserve the characteristics of the underlying fine-grained CG simulation as well as the all-atom MD simulation. The present systematic hierarchical multiscale modelling approach can thus preserve more detailed information even with a DNA representation as simple as beads-on-a-string.

Finally, the resulting SCG DNA model is used in mesoscale simulations of DNA phase separation for two types of systems. First, 400 relatively short DNA molecules, each one equivalent to 96 bp, are randomly placed in a $150 \times 150 \times 150 \text{ nm}^3$ box. At the end of this simulation DNA condense into large particles consisting of more than 100 DNA molecules as illustrated in Figure 6A. Noticeably, these particles exhibit a hexagonally ordered structure resembling a liquid crystal, illustrated in the cross-section view in Figure 6B. In these particles, DNA molecules are arranged in such a way that the hexagonal structure can be seen from the cross-section of the particle, as reported by experimental studies for short DNA molecules in the presence of the trivalent cations CoHex³⁺ and spermidine³⁺ (18,19).

Secondly, we perform simulations for a single 10.2 kb long DNA molecule with the SCG DNA model. The simulations start from a fully extended DNA conformation. After a short relaxation at the beginning, a loop or a bundle can form at either end of the DNA (see Supplementary Movie S1). The first snapshot in Figure 6C shows the DNA conformation after such a loop formation. Subsequently, the loop and bundle play the role of nucleation sites, attracting more DNA beads to form a toroid that grows in size (see Supplementary Movie S2). Towards the end of the simulation, the whole DNA molecule is condensed into one toroidal particle (see Supplementary Movie S3). The non-bonded interaction energy decreases as the toroid grows in size, illustrated by the energy profile in Figure 6C. Remarkably, as can be seen in Figure 6D, the cross section of the toroid shows that DNA is organized in well-defined hexagonal arrangement. These structural features are consistent with the reported electron microscopy studies (6).

Analysing multiple simulations of single DNA molecules reveals that toroids are mainly formed in two ways. The first scenario suggests that a single loop at one end initiates the toroid formation, while the other end may eventually form a fibre that subsequently joins the toroid at the end of the simulation (example in Supplementary movies S1, S2 and S3). Secondly, a loop may get formed at each end in the beginning of the simulation with the simultaneous growth of two toroids that eventually join together (exemplified in Supplementary movie S4). An interesting feature of DNA toroid formation and size increase, is the sliding motion between contacting DNA segments. DNA toroids can adjust their conformation through this motion simultaneously with the growth due to rolling

and attracting more DNA fragments. It should be noted that not only toroids are formed, but the final condensed structure can be fibre-like, which has also been observed in EM experiments (22). In the simulations, the toroid shape is, however, somewhat more frequently occurring. We also simulate a lambda-DNA size single DNA molecules (48 kbp) that also form toroids, here by the mechanism with one nucleation loop at both ends (data not shown).

Next we perform an analysis of the mechanism of DNA condensation that results in toroid or fibre bundle formation. Here we pay specific attention to the pathways and the initial events during DNA condensation that leads to formation of the major final states of toroid and fibre-like morphologies. To this end we perform 67 independent SCG simulations of the 10.2 kbp DNA (having same initial coordinates but with different starting velocities). Although the mechanism of DNA condensation to either toroid or fibre is complex and stochastic, it is possible to identify several intermediate states as well as transitions between them. The formation of either toroid or fibre can be divided into two stages. The first stage can be characterized as nucleation. Secondly, the growth of the nucleation site occurs by pulling in more and more DNA chains, and by the sliding mechanism mentioned above. Figure 7 summarizes the early event intermediate states and transitions between them. Supplementary Table S1 gives a description of those frequent initial transient structures. In the first few nanoseconds of each simulation, several transient states can be observed, such as state **b** and state **k** in the figure. These are usually simple structures with short lifetimes. As the simulation proceeds, more stable structures can be formed, for example, bundles consisting of three DNA chains (state **c** in the figure) and the double DNA chain loop (state **g**). Based on these more stable structures, the “growth” mechanism can be effective with the remaining part of the DNA chain being pulled in to form larger and more stable structure.

In the early stage of the simulation, fibre-like structures and toroid-like structures can convert between each other. These structures are usually no more than three DNA chains thick. Hence, the energy barrier involved in these transitions should not be prohibitive. For example, a three DNA chain bundle (state **c**) can convert to a single DNA chain loop (state **h**) to form a toroid-like structure (state **i**). On the other hand, this toroid-like structure (state **i**) is soft enough, so that it can go to a bundle (state **d**) just by closing the hole in the middle. These transitions between fibre-like and toroid-like states rarely happen in the subsequent stages of the simulation when more DNA chains become involved in the structures.

We measure the dimensions of toroids formed by the 10kb DNA in multiple simulations shown in Supplementary Figure S7 (details of calculations given in Supplementary Figure S8). The average thickness of the toroid is about 12 nm, which is smaller than in experiments for 3 kbp DNA (~25 nm) (22). Similarly, the observed diameter (~22 nm) and hole diameters (~10 nm) are also smaller than the dimensions observed in the experiments (22). These values are reasonable given the differences between experiments and simulations. The reason for smaller diameter and thickness in simulations as compared to experiments, is the fact that the simulations contain only a single DNA molecule. Experimentally the toroids formed from DNA of sizes below 50 kbp contain several DNA molecules which will lead to larger and thicker toroids (22). The diameter of the hole, on the other hand, is expected to depend on nucleation loop size mechanism of toroid formation (22) and on the DNA

bending properties as well as on effective DNA-DNA attraction. The observed small hole diameter is most certainly in part due to the intrinsic properties of the underlying force field, which compared to real DNA may represent a mechanically more flexible DNA with stronger attraction leading to shorter DNA-DNA distances and tighter packing in the toroid. The fact that toroid dimensions are strongly affected by electrostatic interactions between DNA molecules was earlier shown by Hud and co-workers (21), who demonstrated a pronounced dependence of toroid diameter and thickness as a function of ionic strength.

CONCLUSIONS

In conclusion, we have used a rigorous hierarchical multiscale simulation scheme, which enables simulation of DNA condensation at mesoscale levels. The phenomenon of DNA condensation induced by multivalent ions is clearly inherent in the chemical properties of the DNA molecule. Inspired by this fact, we reasoned that a chemically based starting point, using state-of-the-art molecular force fields for all-atom MD simulations, followed by systematic coarse-graining, and using the IMC approach to extract solvent mediated effective CG potentials, would preserve those features of DNA in the CG models. Indeed, DNA condensation induced by the three-valent cobalt(III)-hexamine ions was demonstrated in large-scale simulations of hundreds of DNA molecules, which exhibited correct experimental structural features. We used a hierarchical approach where the CG model was further coarse-grained to a “super CG” model. Simulations at mesoscale level (10.2 kbp DNA) demonstrated toroid formation into hexagonally packed DNA, with reasonable dimensions in qualitative agreement with experimental observations. These results were obtained without any other underlying assumptions except for the all-atom force field and the DNA topology model adopted in the CG simulations and used no adjustable parameters.

In the present work we used all-atom MD simulations based on the CHARMM27 force field. However, we recently demonstrated similar behaviour in all-atom simulations that showed DNA-DNA attraction and bundling using both CHARMM36 and AMBER parameters (44). It should furthermore be of interest to investigate how the mesoscale simulation results depend on the CG topology comparing different CG DNA models, which include DNA sequence specificity (37,39). It may be noted that the present CG DNA model is not sequence specific, but such an extension can be implemented in our model (46).

The present successful approach lends support for developing CG models for more complicated systems exhibiting DNA compaction at mesoscale level such as chromatin and individual chromosomes. Such models will help understanding the compaction behaviour of chromatin as a function of various variables known to regulate genome compaction such as histone tail modifications that change electrostatic interactions. Although multiscale modelling for nucleosomes and chromatin fibres following the present approach certainly increases the dimensionality of the CG system adding several degrees of freedom necessary to describe histones and their interactions, our present work along those lines shows that such extension is feasible (A. Mirzoev et al, unpublished).

Finally, in order to rigorously evaluate the time dynamics in the mesoscale simulations, generalized Langevin dynamics with friction parameters extracted from underlying detailed simulations can be performed, which enables the study of time-dependent condensation behaviour (60,61).

DATA AVAILABILITY

All data needed to evaluate the conclusions in the paper are present in the paper and/or the Supplementary Data. Additional data related to this paper may be requested from the authors.

SUPPLEMENTARY DATA

Supplementary Data are available at NAR online.

ACKNOWLEDGEMENT

We are indebted to Profs Aatto Laaksonen and Francesca Mocci for discussions and suggestions. We acknowledge the generous support of computer time allocation from the National Supercomputing Centre (NSCC) Singapore.

FUNDING

This work was supported by the Singapore Ministry of Education Academic Research Fund (AcRF) Tier 2 (MOE2014-T2-1-123 (ARC51/14)) and Tier 3 (MOE2012-T3-1-001) grants (to L.N.) and by the Swedish Research Council (grant 2017-03950 to A.P.L.).

CONFLICT OF INTEREST

The authors declare that they have no conflict of interest.

SUPPLEMENTARY METHODS

A. All-atom Molecular Dynamics simulations

In the present work, we use an atomistic CHARMM27 force field (1,2) as a high-resolution reference in the IMC procedure to extract effective potentials. In previous work (3) we have also tested the CHARMM36 and AMBER bsc0 force fields which showed similar results concerning DNA aggregation in presence of CoHex³⁺. However, CHARMM27 provides better preservation of DNA B-form internal structure. Moreover, it has produced an excellent agreement with experimental DNA persistence length data. (see main text and (4)). The all-atom MD simulation is set up with four 36 bp-long double helix DNA molecules placed in a cubic simulation cell with periodic boundaries. The DNA sequence is the same as in our previous work (3) representing a 50-50% mixture of AT and CG pairs. Improved force field parameters for the CoHex³⁺ ions were derived in our recent study (3). The number of CoHex³⁺ ions is determined in such way that the charge carried by CoHex³⁺ is 1.5 times the charge of DNA, which should ensure attraction between DNA molecules. Additional salt is added to reach a salt concentration of 50 mM K⁺ and 35 mM Na⁺, with neutralizing amount of Cl⁻ ions. The improved ion parameters by Yoo and Aksimentiev (5) are used throughout all simulations for all ions except CoHex³⁺ and the TIP3P water model is utilized. The system is illustrated in Figure 1E of the main text.

In total, three trajectories of 1 μ s each are generated from the same starting configuration with DNA oligomers placed randomly in the simulation cell and different starting velocities. The system was equilibrated in three stages. First, DNA and CoHex³⁺ ions are restrained while the system reaches a target temperature of 298 K. Then pressure coupling is turned on to maintain 1.013 bar pressure with only DNA molecules restrained, after which the unrestrained equilibration is conducted under constant temperature and constant pressure for 500 ns.

The production phase is conducted for at least 500 ns. The velocity rescale thermostat (6) and Parrinello-Rahman barostat (7,8) regulate respectively temperature and pressure. Bonds are constrained with the LINCS algorithm (9) implemented in GROMACS 5.1 (10), which enables a 2 fs time step. Electrostatic interaction is treated with particle mesh Ewald method (11) with 10 Å real space cut-off. The van der Waals interaction is treated with a cut-off scheme with the potential shifted to zero at cut-off distance of 10 Å.

Also, a control experiment is set up with the same all-atom simulation box substituting all CoHex³⁺ ions for the same number of Mg²⁺ ions. Additional Na⁺ and K⁺ ions are added to keep charge neutrality. For validation of the CG DNA model by persistence length calculation, a single 40 base-pair DNA with sequence 5'-GGATTAATGGAACGTAGCATATTCTTCAAGTTGTCACGCC-3' (42.5% GC content) was used. To mimic physiological conditions the NaCl concentration is set to 130 mM. All other conditions are similar to the aforementioned simulations with CoHex³⁺.

B. Coarse-grained DNA models

In order to reach the mesoscale level of DNA modelling, we have performed coarse-graining at two spatial scales resulting in two coarse-grained DNA models with different resolutions. The model at the first level is mapped from all-atom DNA (Figure 1A), and is called the CG DNA model (Figure 1B). The second model with lower resolution is called the super CG DNA (SCG) model (Figure 1C). The CG DNA model is designed according to the same concepts as our previous model, which was shown to well reproduce DNA persistence length dependence on salt concentration over a wide concentration range (4). It is simple enough in its design and yet captures the structural form and properties of double helical B-form DNA. The DNA is modelled with consecutive units of five beads, representing a two base pairs of DNA (Figure 1D). Four beads represent the phosphate groups (denoted "P"), while the central one (denoted "D") represents the four nucleosides. There are totally four types of bonds and three types of angles in the bonded interaction terms (Figure 1D), which maintain a helical B-DNA structure where two strands of the phosphate groups form the major and minor grooves (Figure 1B). The pairwise bonds are D-D, D-P, P-P along the strand and P-P cross-strand defined as a shortest P-P bond over the minor groove. The angle bonds are D-D-D, P-D-P, and P-P-P. The units at each end of the DNA double helices are treated specially. Since these units have the opportunity of closely contacting solvent and ions, we used dedicated bead types (denoted "DT" and "PT") to allow different non-bonded interactions. However, the bonded interaction terms remain the same as non-terminal beads.

The model, which includes explicit mobile ions and explicit charges of DNA phosphate groups, pays particular emphasis to electrostatic interactions, where every P-bead has charge $-1e$, and D-beads are kept neutral. The solvent is considered implicitly, via use of the effective short-range

potentials (computed by the IMC method) and screening the electrostatic interactions according to the solvent dielectric permittivity $\epsilon = 78$.

Despite looking similar to its ancestor (4), the present model has several very important and considerably different features. First, the underlying all-atom MD simulations are significantly longer (an order of magnitude compared to the previous model). Second, the effective potentials are derived from the underlying all-atom MD simulation using the Inverse Monte Carlo method. Particularly, all non-bonded interactions are not simply a combination of electrostatic and repulsive truncated Lennard-Jones (as in the case of ref (4)), but are rather complex functions which are capable of describing distribution of ions around DNA in solution according to the underlying atomistic simulations. In the present model, both bonded and non-bonded potentials (shown in Figure S2) are tabulated and are not fitted to any functional form and contain no adjustable parameters.

The next level, beads-on-string SCG model of the DNA prioritizes computation performance over complexity (Figure 1C). In the SCG model, single type of uncharged beads (called "S") represents three units of the CG DNA model that corresponds to six DNA base pairs. Bonded interaction terms include one bond and one angle potentials. Compared to the CG DNA model, in the SCG model not only the solvent is considered implicitly, but electrostatic interactions are implicitly included into the effective potentials. The effective potentials are derived by IMC procedure after mapping the CG-model trajectory to the SCG scheme.

C. Inverse Monte Carlo procedure for extraction of effective CG potentials

In the CG DNA model, all effective interaction potentials are determined solely by the IMC. The only input information is the structural properties extracted from all-atom MD simulations in terms of the relevant RDFs between the sites of the CG model. These are obtained by mapping the all-atom MD trajectory from the four-DNA system to a corresponding CG site trajectory of the MD simulation. Thus, no empirical parameters are used in the CG DNA model and it rests solely on the parameters from all-atom CHARMM27 DNA as well on the CPMD optimized CoHex³⁺ (3)

To derive an effective potential function, the IMC procedure uses a radial distribution function (RDF) corresponding to each interaction in the CG system. During mapping of the atomistic trajectory to a CG trajectory, the "P" sites of the CG DNA model are defined as centre-of-masses of the corresponding phosphate groups (-PO₄-) of the DNA backbone. The "D" sites are determined as centre of masses of the four nucleosides constituting the corresponding two base pair fragment. To avoid end-effect "contamination" of the distribution statistics, the ends of the DNA double helices are treated as separate types (named DT and PT). Thus the total number of bead types in the system is eight: comprising four DNA beads (D, P, as well as terminal DT, PT), one of CoHex³⁺, one of K⁺, one Na⁺ and one Cl⁻; which gives the total number 36 non-bonded interaction terms. All-atom MD trajectories from the three simulations were converted into CG trajectories by mapping procedure described above. Convergence of DNA aggregation is confirmed by comparing DNA-DNA RDFs from trajectory segments at different simulation times. Each final set of RDF is calculated as an average over the equilibrated sections of all three independent trajectories with the total length of 1.5 μ s.

The IMC calculation is carried out with the MagiC software (12,13) (which is also used for bead-mapping, RDF calculation, analysis and export of the resulting potentials). A zero potential is used as the first trial potential for non-bonded interactions, while the potential of mean force (defined as $U_{PMF} = -k_B T \ln(g(r))$) is applied as a trial for bond and angle interactions. The effective potentials are refined in about 20 IMC iterations, with 100 parallel Monte Carlo sampling simulations in each iteration. In each sampling thread, 300 million Monte Carlo steps are performed with acceptance ratio maintained at about 50%. The first half of each thread is considered as equilibration. The cut-off for RDF and non-electrostatic part of the effective CG potentials are set to 25 Å. Long-range electrostatic interactions are treated using Ewald summation with real space cut-off being 40 Å. The dielectric constant is set to 78.0. The Monte Carlo sampling is performed within a constant volume and constant temperature ensemble for the same number of DNA (of the same length) and ions, and in the box of the same size as in the underlying atomistic simulations. The procedure described above is followed in a similar way for deriving the effective CG potentials from the other all-atom systems, namely the one with four DNA and Mg²⁺ ions and the one comprising a single DNA and monovalent salt.

The effective potentials of the SCG model are derived in the same way as for the CG model applying the IMC method. Specifically, the trajectories from the MD simulation of the CG DNA systems are mapped to a SCG trajectory and from these data a bond distribution (S-S) and an angle distribution (S-S-S) as well as one non-bonded DNA-DNA RDF (S-S) were calculated with 200 Å cut off. The IMC calculations are started from zero potential for non-bonded interaction, and with potential of mean force for bond and angle interactions. Temperature and volume are kept constant during

sampling with 100 parallel Monte Carlo simulations. Typically, the effective potentials converge in about 25 iterations.

D. Coarse-grained simulations in the CG model

The tabulated interaction potentials for the CG DNA model, obtained as described above are used in the CG MD simulations with a significantly bigger simulation box compared to the all-atom simulations. The simulations with the CG and SCG DNA models are conducted using LAMMPS package (14) with the NVT ensemble. For the CG simulations, 200 pieces of 100-bp DNA (50 CG-DNA units) are randomly placed in a $150 \times 150 \times 150 \text{ nm}^3$ simulation box. The box also contains CoHex³⁺ ions (carrying charge twice exceeding the one on the DNA) with 10 mM K⁺ and 10 mM Na⁺ ions as well as the neutralizing number of Cl⁻ ions. The CG simulation is started with a 1 fs time step to reach a stable temperature before switching to a 2 fs time step for next 1 million steps of equilibration. Langevin dynamics with damping parameter being 10 ps, is used to initiate the simulation. Finally, the production simulation is performed with 5 fs time step with a velocity rescale algorithm regulating system temperature. The particle-particle particle-mesh (PPPM) method is used to calculate electrostatic energies with a 40 Å real space cut-off. The same cut-off is applied for the short-range interactions. This procedure for CG simulations is conducted analogously for the systems with Mg²⁺ ions and with a single DNA at varying monovalent salt concentrations (persistence length validation).

E. Coarse-grained simulations using the SCG DNA model

Within the SCG model, the electrostatic interactions are treated implicitly since they are effectively included into the SCG effective potentials. The simulation is started with a randomly generated velocity at 298 K. To stabilize the temperature at 298 K, velocity rescaling is used during the 10⁵ equilibration 5 fs-long steps. For the production stages, the time step is set to 200 fs with damping parameter of the Langevin thermostat at 298 K is set to 100 ps to facilitate fast sampling. Two sets of the SCG simulations are carried out: with multiply short DNA (400 pieces of 96 bp DNA, represented by a chain of 16 S-beads); and for single 10.2 kbp-long DNA (1700 S-beads). For multiply short DNAs simulation box was set to $150 \times 150 \times 150 \text{ nm}^3$ and production run consists of 4×10^7 steps; for single long DNA the box is $3450 \times 3450 \times 3450 \text{ nm}^3$ and data collected for 2×10^9 steps.

F. Persistence length calculation

We perform all-atom MD simulations of a single 40 bp DNA in the presence of physiological salt (130 mM NaCl). We perform the mapping of this trajectory to the CG model and extract effective IMC potentials (Figure S1 shows all the effective potentials). A 500 bp long CG DNA is then simulated in a range of NaCl salt concentrations from 0.1 mM to 100 mM. All the simulations are run for at least 3 μs and employ a protocol described above. The values of persistence length, L_p , are calculated by equation: $L_p = -L_c / (\ln \langle \cos \alpha \rangle)$, where L_c is the contour length of the DNA and $\langle \cos \alpha \rangle$ is the average of the cosine between two adjacent segments over the length of the simulation for the corresponding contour length. A 500 bp DNA is divided into 5 equal length segments (100 bp, $L_c \approx 330 \text{ Å}$). That results in 5 data points for each salt concentration. The values of L_p are determined from the slope of the plot L_c versus $\ln \langle \cos \alpha \rangle$ (4). The standard deviation of L_p is evaluated with these 5 data points. The L_p values calculated from different parts of the trajectories show similar values, which confirms convergence of the simulations. Our simulation results are compared with experimental data and with the data of other simulation studies.

SUPPLEMENTARY DATA

Figure S1. RDFs and potentials used for the calculation of persistence length

Interaction potentials calculated by the IMC procedure using RDFs obtained in an all-atom MD simulation of one single 40 bp DNA in the presence of 130 mM NaCl were used for validation of the CG DNA model. These potentials were used to determine salt dependence of the DNA persistence length (see Figure 3 of the main text).

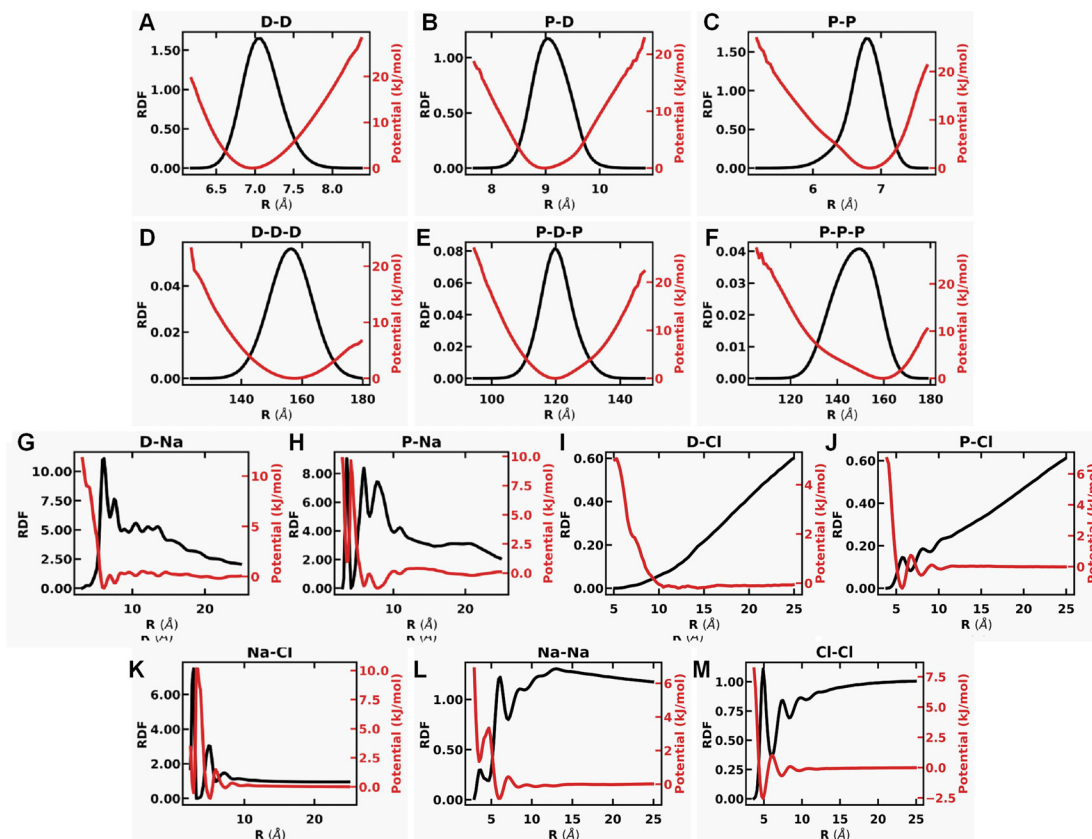

Figure S1. RDFs (black) and effective potentials (red) for interaction terms in the CG DNA model calculated from all-atom MD simulation of DNA in monovalent salt. Panels **A-C** and **D-F** show data for respectively CG DNA bonds and bonded angles; panels **G-J** are for the DNA – ion interactions; panels **K-M** are for the ion – ion RDFs and potentials. Identity of the interaction terms is shown at the top of the graphs.

Figure S2. Snapshots from different all-atom and CG MD simulations modelling DNA-DNA interaction in systems with CoHex³⁺ cations.

Figure S2 (A-C) illustrates variability of DNA bundling from snapshots in the three all-atom MD simulations. The simpler energy profile and significantly longer sampling in the CG MD simulation results in minor variability between different simulations (Figure S2D). Although all three simulations are technically converged (by standard criteria such as constant total energy and their components), when aggregation occurs the DNA bundles may be trapped in metastable states, which is unavoidable in any all-atom MD simulation of a complex system. This is why we perform three independent simulations and used the average RDFs.

Figure S2. (A-C) Final snapshot conformations obtained for all-atom trajectories in the MD simulations with CoHex³⁺. DNA double helices are coloured differently. Periodic images of the DNAs are coloured grey. (D) A snapshot of the final conformation in a coarse grained MD simulation using conditions similar to the all-atom systems and interaction potentials determined from the simulations shown in (A-C).

Figure S3. The complete set of RDF and converged effective potentials of the CG model.

Below, all the RDFs and effective potentials corresponding to all interaction terms in the CG-model simulations with CoHex³⁺ are displayed. DNA is modelled by four bead types (DT, PT, D, P) and 4 types of ions (CO, K, NA, CL) are also present in the system. The complete set of interaction parameters consists of 36 non-bonded terms, 4 bonded terms and 3 angle terms. Analysis of the plots allows observation of correlations among interaction terms. For example, there would be no potential minimum for the D-P non-bonded interaction at 6.5 Å if there is no correlation with other interactions, since there is no peak at 6.5 Å in the D-P RDF.

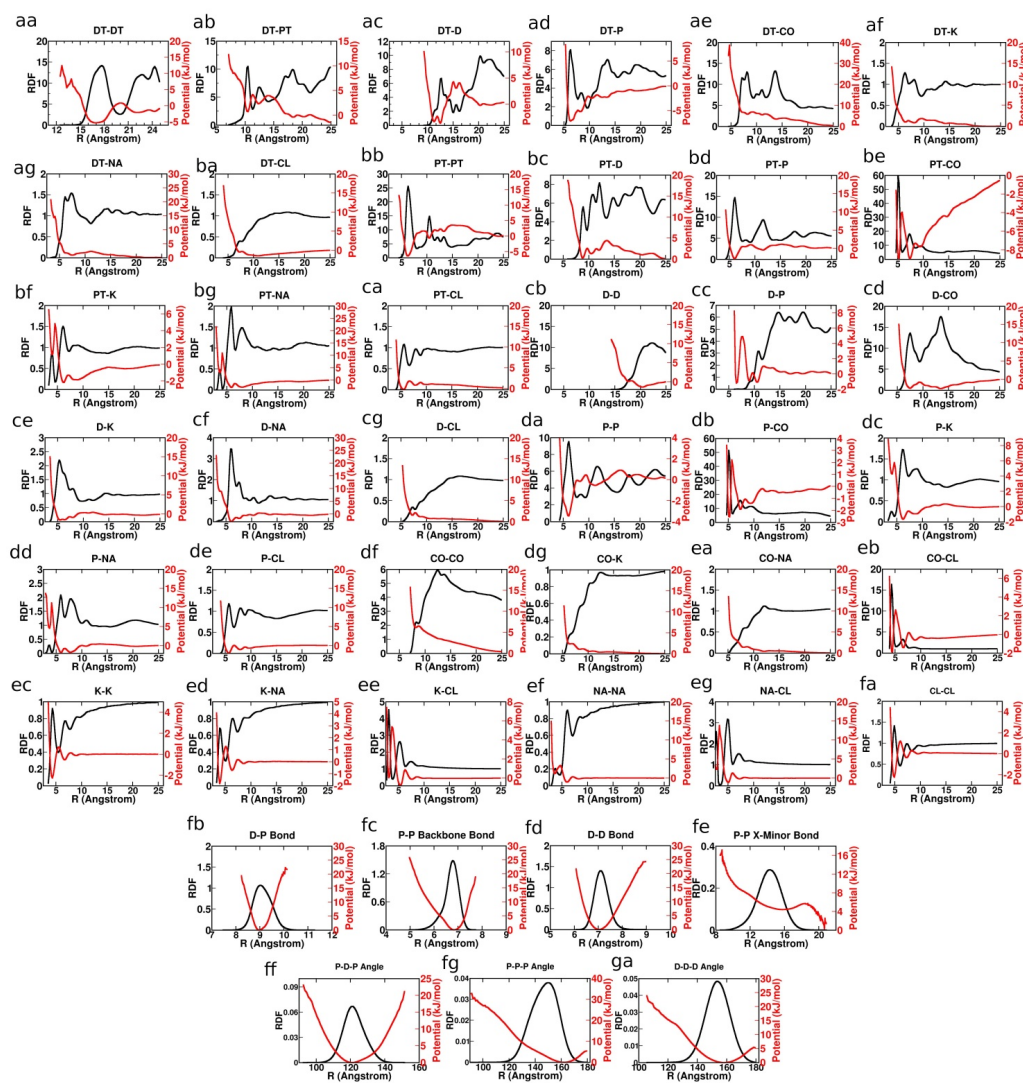

Figure S3. RDFs (black) and the final effective potentials (red) for all interaction terms in the CG DNA simulations with CoHex³⁺. A total of 36 non-bonded interactions (**aa – fa**), 4 bond interactions (**fb – fe**) and 3 angle interactions (**ff – ga**) are shown.

Figure S4. Convergence of the Inverse Monte Carlo procedure.

Examples below compare distribution functions and interaction potentials obtained in several iterations of the IMC procedure.

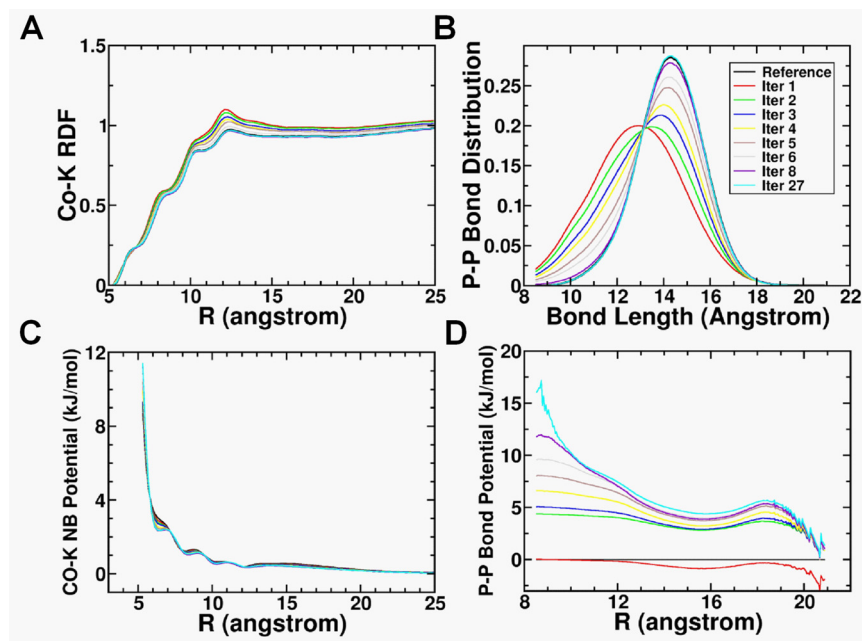

Figure S4. Selected RDF (**A**, **B**) and effective potential (**C**, **D**) plots from several iterations in the IMC calculation. RDFs and potentials of one non-bonded term (Co-K, plots in **A** and **C**) and one bonded term (P-P cross minor groove bond, plots in **B** and **D**) are selected to illustrate the convergence of the RDF and the effective potential. The RDF underwent significant adjustments in the first few iterations of the runs. The adjustment in the potential progressively becomes smaller and smaller. The final potential, reproducing the whole set of reference distribution functions within the computational uncertainty, is achieved after 27 iterations.

Figure S5. Transferability of potentials from different systems I.

Figure S5 demonstrates the transferability of similar interaction types obtained from different underlying systems with different ionic composition and macroscopic properties. It can be noted that the D-Cl potential generated from the DNA system with only NaCl ions in the all-atom setup, displays somewhat different features compared to the same ones generated from the all-atom systems containing either Mg^{2+} or CoHex^{3+} . The reason is that in the NaCl-DNA system there is a limited amount of Cl^- in the close vicinity of DNA, especially in the groove regions (distances less than 10 Å). In case of Mg^{2+} and CoHex^{3+} counterion systems, some Cl^- will be brought to these locations by the presence of these multivalent counterions, which creates a "wave" in the potential at ~ 7.5 Å.

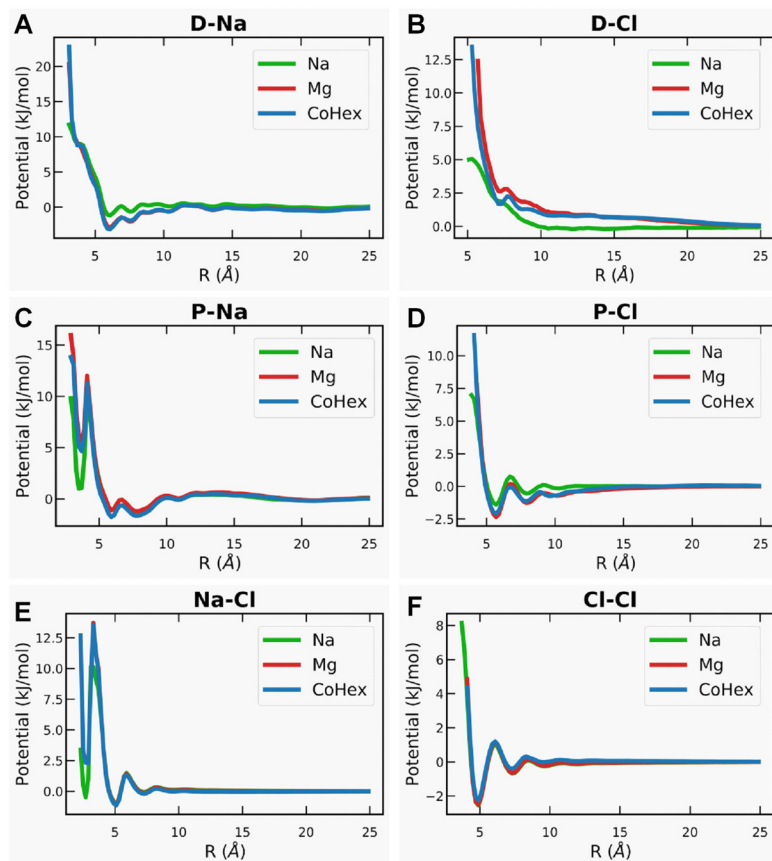

Figure S5. DNA-ions and ion-ion potentials obtained with the CG DNA model using the IMC procedure applied to three different DNA all-atom MD simulations of different ionic composition. (A, B) Potentials between DNA central bead (D) and respectively Na^+ and Cl^- ions; (C, D) potentials between phosphate (P) and respectively Na^+ and Cl^- ions; and (E, F) potentials between Na^+ and Cl^- ions. Although the individual simulations display highly different behaviour, the potentials are very similar. Blue plots are obtained from the 4DNA + CoHex^{3+} simulation, green with 4DNA + Mg^{2+} simulation and the red with 1DNA + Na^+ simulation. See Methods for details.

Figure S6. Transferability of potentials from different systems II.

Figure S6 below additionally demonstrates transferability of the IMC-derived potentials determined from all-atom MD simulations with different ionic conditions and number of DNA molecules in the simulation cell, resulting in very similar behaviour in macroscopic behaviour in the CG simulations. Two different all-atom systems, one with the presence of CoHex^{3+} the other Mg^{2+} were simulated (mentioned in relation to Figure 4). One displays attraction (CoHex^{3+} -system) and the other displays repulsion (Mg^{2+} -system). Then CG simulations for two systems containing 25 CG DNA molecules in the presence of CoHex^{3+} are conducted. One system has monovalent ion effective potentials originating from the repulsive all-atom MD Mg^{2+} -system. The other system has monovalent ion potentials originating from the attractive all-atom MD CoHex^{3+} -system. All other potentials (DNA and CoHex^{3+}) are taken from the CoHex^{3+} -system. The D-D RDF displayed in Figure S6 below illustrates that the macroscopic behaviour in these two simulations, is very similar resulting in attraction and phase separation in spite of the fact that the monovalent ion potentials are extracted from two separate all-atom MD simulations that exhibit different macroscopic behaviour.

Figure S6. DNA-DNA distance distribution calculated for the simulations of 25 CG DNA molecules in the presence of CoHex^{3+} . Black curve is the data obtained in the simulation using IMC-derived potentials from the all-atom MD simulation with CoHex^{3+} that showed DNA-DNA attraction; red curve is calculated for a system with mixed potentials where potentials for monovalent ions were taken from the Mg^{2+} - DNA all-atom MD simulation with net DNA-DNA repulsion.

Figure S7. Statistics of toroid dimensions.

Toroid dimensions, diameter, thickness and hole diameter, are measured in the end of each SCG simulation that have resulted in toroid formation. Example of toroid-dimension calculation is shown in Figure S8 below.

Figure S7. Statistics of DNA toroid dimensions. To determine the size of toroids that are formed in the simulations with the SCG model, multiple single DNA simulations have been conducted and these results are based on 17 simulations with distinct toroid formation.

Figure S8. Measurement of toroid dimensions.

The toroid dimensions are measured by the following method, which tries to mimic the toroid measurement practice in EM experiments. First, the toroid is projected to a plane along the axes parallel to its hole. The projected density map is used to determine two toroid dimension parameters, hole diameter and outer diameter. As shown in Figure S7B, two circles are used to represent the toroid hole and the outer dimension. The diameters of these two circles are recorded. Finally, the toroid diameter is determined to be the arithmetic average of the diameters of the two circles. Toroid thickness is defined as half the difference of the diameters of two circles.

Figure S8. Measurement of toroid dimensions. First, the toroid is projected to a density map, on a plane perpendicular to the axes through the hole, as shown in (A). Then the projected density map was measured using two circles, one to fit the outer perimeter and one to fit the hole (B). The toroid diameter is an arithmetic average of the diameters of the two circles. Toroid thickness is the difference of the radii of the two circles.

Supplementary Table S1

Table S1. Description of intermediate states during formation of DNA toroid and fibre (see Figure 7 of the main text).

Snapshot index (Figure 7)	Description of structure
a	Extended chain.
b	“Hairpin”: there is a turn at the end of DNA, forming a self-contact part consists of two chains of DNA.
c	Three-chain bundle: a bundle of three chains of DNA is formed at the end of DNA.
d	Thick fibre: a bundle of DNA, thicker than c , formed at the end of DNA.
e	“Racket”: usually on one end of the thick fibre, there’s a loop formed by at least two chains of DNA. The shape is similar to a tennis racket without string.
f	Final long and thick fibre: the final fibre we observed, usually longer than d and thicker than c .
g	Double-DNA chain loop: a loop consists of double DNA chains, usually formed from b when the loop in b folding back to the double-chain part.
h	Bundle with a side loop: the loop is formed either by newly recruited DNA or “peeling off” of one DNA chain from the bundle.
i	Primer toroid: toroid that has just been formed. It is usually very flexible.
j	Final toroid that is thick and sturdy. Grown from primer toroid by pulling in DNA chain.
k	Single loop: a loop consists of a single DNA chain part and a double DNA chain part.
l	Double loop: two adjacent single loops on DNA chain.
