15 Short title: RoguePlots of ichneumonid fossils

16 **Abstract**

17   The fossil record constitutes the primary source of information about the evolutionary

18 history of extant and extinct groups, and many analyses of macroevolution rely on fossils that

19 are accurately placed within phylogenies. To avoid misinterpretation of the fossil record,

20 especially by non-palaeontologists, the proper assessment and communication of uncertainty

21 in fossil placement is crucial. We here use Bayesian morphological phylogenetics to evaluate

22 the classifications of fossil parasitoid wasps (Hymenoptera, Ichneumonidae) and introduce

23 'RoguePlots' to illustrate placement uncertainty on the phylogeny of extant taxa. Based on an

24 extensive, newly constructed morphological matrix of 222 characters in 24 fossil and 103

25 extant taxa, we test three different aspects of models of morphological evolution. We find

26 that a model that includes ordered characters, among-character rate variation, and a state-

27 space restricted to observed states achieves the highest marginal likelihoods. The individual

28 RoguePlots reveal large differences in confidence in the placement of the different fossils

29 and allow some refinements to their classification: *Polyhelictes bipolarus* and *Ichninsum*

30 *appendicrassum* are moved from an uncertain subfamily placement to Pimplinae,

31 *Plectiscidea lanhami* is transferred to *Allomacrus* in Cylloceriinae (*Allomacrus lanhami*,

32 comb. nov.), *Lithotorus cressoni* is moved from Diplazontinae to Orthocentrinae, and we note

33 uncertainty in the generic placement of *Xanthopimpla*? *messelensis.* We discuss potential

34 artefacts that might result in biased posterior probabilities in Bayesian morphological

35 phylogenetic analyses, pertaining to character and taxon sampling, fossilization biases, and

36 model misspecification. Finally, we suggest future directions both in ichneumonid

37 palaeontology, in the modelling of morphological evolution, and in the way Bayesian

38 phylogenetics can improve both assessment and representation of fossil placement

39 uncertainty.

40   **Introduction**

41   The fossil record provides crucial information about the evolutionary history of a group and

42   allows us, by facilitating the inference of absolute ages, to put said history into a

43   palaeogeographic and palaeoecological context. Many analyses that use the fossil record rely

44   on a firm placement of fossils in the phylogenetic or at least taxonomic context of extant

45   species. This is especially true for the dating of molecular trees through fossil calibrations [1],

46   but also for the inference of ancient interactions between different groups of organism [2,3]

47   and for the study of evolutionary trends in morphological characters over large timescales

48   [e.g., 4,5]. Unfortunately, the correct taxonomic interpretation of fossils can be a formidable

49   challenge due to incomplete preservation, difficulties in the taphonomic interpretation, and

50   long gaps in the fossil record [6,7,8]. The proper communication of this uncertainty is crucial

51   in order to avoid future misinterpretations and overconfidence in analyses that are relying on

52   reliably placed fossils.

53   Even though the "open nomenclature" framework [9] provides some means to express

54   uncertainty in the placement of a fossil by way of adding a question mark after the genus

55   name or explicitly not placing it in higher ranks (as 'incertae familiae', 'incerti ordinis', etc.),

56   these tools are not very flexible and have been used inconsistently by different authors.

57   Furthermore, the need for a binomial when describing new species often leads to new fossils

58   being placed in extant genera without sufficient evidence for such placement. The

59   justification for fossil classifications is often limited to brief mentions of character evidence,

60   which might or might not be sufficient, depending on the group in question and preservation

61   of the fossil. An alternative way to arrive at a well-grounded classification of fossils is to

62   make use of a morphological phylogenetic analysis, which allows obtaining both a 'best

63   estimate' for the position of the fossil and, even more importantly, some measure of support

64   for said placement.

65   Until recently, the phylogenetic analysis of fossil taxa has been relying largely on

66   parsimony as an analysis approach, while model-based approaches became the gold standard

67   for molecular characters already quite a while ago [10,11]. Recent developments in the field

68   of modelling the evolution of discrete morphological characters [e.g., 12,13,14,15] have

69   readied morphological phylogenetics for stochastic frameworks such as maximum likelihood

70   and Bayesian inference, a realization that has also impacted several palaeontological studies

71   [16,17,18,19,20,21]. The stochastic framework allows for the explicit testing of alternative

72   fossil placements, thus providing a vital tool for the assessment of its uncertainty. Bayesian

73   approaches are especially interesting in this respect, as they directly provide posterior

74   probabilities of a fossil attaching to different branches in a tree and thus allow assessing

75   alternative placements in an intuitive way [11].

76   Due to the often severely incomplete preservation of fossils, uncertainty in their

77   placement is typically very high. In a phylogenetic analysis, fossils thus often behave as

78   'rogue' taxa [22], i.e., taxa that drift around in the tree and thus substantially deteriorate the

79   resolution and clade support values in a consensus tree [e.g., 23]. This is the case irrespective

80   of whether a strict or majority-rule consensus is constructed, or whether it is based on a set of

81   most parsimonious trees, bootstrap trees, or trees sampled during a Bayesian Markov Chain

82   Monte Carlo (MCMC) analysis. To illustrate the phylogenetic placement of such 'rogues',

83   they are best excluded before a consensus tree is created, which then might be much better

84   resolved, and information of fossil attachment is then summarized on this tree. We here

85   introduce a graphic representation of fossil placement uncertainty that summarizes Bayesian

86   posterior probabilities, so-called 'RoguePlots', and apply it to assess the placement of 24

87   fossils in a group with a severely understudied fossil record: ichneumonid parasitoid wasps.

88   The Ichneumonidae are the largest family of parasitoid wasps and contain more than

89   25,000 described [24] and many more undescribed species [25]. Studying only the literature,

90   one would come to the conclusion that the fossil record of the group is rather poor, as less

91   than 300 species have been described to date [26]; however, this low number rather reflects

92   the lack of palaeontologist working on that group, as ichneumonids are often among the more

93   abundant insect groups found, at least at various Cenozoic localities [27,28,29]. Several

94   recent studies have greatly furthered our understanding of the ichneumonid fossil record

95   [7,28,30,31,32,33,34,35,36,37], but our knowledge of the evolutionary history of the group

96   remains very patchy. Placement of fossil ichneumonids, even just into subfamilies, is often

97   particularly difficult because of pronounced homoplasy in this group, which is probably the

98   result of unrelated lineages attacking similar hosts in similar ecological niches [38].

99   Phylogenetic approaches have the potential to aid in identifying such homoplasies and thus

100   improve fossil placement – or at least provide a realistic measure of their uncertainty.

101   However, to date, no study has used a phylogenetic framework to place ichneumonid fossils

102   in relation to their extant counterparts.

103   We here review 24 fossil ichneumonid species that we have described or revised

104   recently [7,28,37], and formally test their phylogenetic placement. To this end, we assembled

105   a large morphological matrix that includes both extant and fossil ichneumonid taxa, and

106   perform Bayesian phylogenetic analyses under a range of evolutionary models. We use

107   'RoguePlots' to summarize the posterior distribution of a fossil's position on the consensus

108   tree of extant taxa, detail the implications of these results for their classification, and discuss

109   the advantages of the Bayesian approach to fossil placement, especially with respect to the

110   representation of phylogenetic uncertainty.

111

Materials and Methods

Taxon sampling and morphological matrix

We included 24 fossils that we have recently described or revised (Table 1) [7,28,37], with the taxonomic placements at the time supported by character evidence only. For most species, we studied the holotype and sometimes paratype directly, but in a few cases [listed in 7], we only obtained high-resolution photographs of the holotypes. No permits were required for the described study, which complied with all relevant regulations.

Morphology of all fossils was studied in detail and characters were coded into a morphological matrix. Morphological nomenclature follows Townes [25], except for wing venation characters, which are based on Kopylov [36] with few modifications (Fig. 1).

Figure 1. Wing vein and forewing cell nomenclature used in the current study.

The morphological matrix consists of 222 morphological characters of the adult insects scored for 103 extant and 24 fossil taxa. To this day, it represents the largest matrix of this kind composed for ichneumonids (Supplementary File S1). We aimed to get a good representation of the ichneumonid subfamilies (24 out of 42) while focusing on

128   Pimpliformes, where we included 80 extant genera. In cases of heterogeneous and potentially

129   non-monophyletic genera, we included representatives of several species groups. The full list

130   of included taxa with specimen numbers and collection details is given in Supplementary File

131   S2. Our matrix is partly based on the morphological matrix from Gauld et al. [39] (~50% of

132   the characters), which had been designed to capture the morphological diversity within a

133   single ichneumonid subfamily, the Pimplinae. It was complemented with characters from

134   Bennett et al. (unpublished) (~15% of the characters), which had a broad but sparse taxon

135   sampling across ichneumonids. In order to cover most of the morphological diversity of the

136   taxa scored in this study, we have re-defined and expanded many of the character definitions,

137   and added specific characters for previously underrepresented subfamilies. To maximise the

138   morphological information coming from fossils, we added some characters that are not

139   traditionally used in ichneumonid taxonomy but are often well (and sometimes exclusively)

140   preserved in fossils, such as wing venation characters. The full list of characters and states

141   including detailed descriptions is given in Supplementary File S3.

142   Out of the 222 morphological characters, a majority are multistate characters, while

143   34% are binary. The 13 continuous characters represent ratios of length measurements

144   designed to capture the shape of structures (except of the fore wing length which was

145   included as a measure of size). In order to be able to analyse them along with the remaining

146   characters we eventually transformed them to ordered six-state discrete characters following

147   the gap weighting approach as defined in Thiele [40]. Six states is currently the upper limit

148   for ordered characters in the used phylogenetic software (see below). We took special

149   considerations when scoring fossils (but also extant taxa) and coded uncertain interpretations

150   as polymorphisms; initially, many questionable coding were noted with "?" (e.g., "1?"), and

151   preliminary analyses with either keeping the states ("liberal approach") or keeping the

152   question marks ("conservative") resulted in better support values when the liberal approach

153 was applied, while not creating any supported conflict in tree topology compared to the

154 conservative approach. We thus decided to continue with the more liberal interpretation.

155 *Bayesian phylogenetic analyses*

156 Phylogenetic analyses of the morphological matrix were conducted in MrBayes 3.2

157 [41]. To model the evolution of the morphological data, we used the approach described in

158 the seminal work by Lewis [15]. In its most basic version, his so-called 'Mk model' assumes

159 that all states of a multi-state character are equally likely, as are the respective transition rates

160 between them (we refer to this as the 'unordered Mk' model). An extension of this model,

161 which was adopted from parsimony approaches, allows considering some of the characters as

162 'ordered', i.e., allows transitions only between adjacent states [42]. In a character with three

163 states represented by labels '0', '1' and '2', only the transitions between '0' and '1' and

164 between '1' and '2' are allowed in an ordered character, but never directly between '0' and

165 '2'. As an additional extension, one can assume that there are unobserved states, i.e., states

166 that are possible but that are not found in any of the included taxa. This might be a reasonable

167 approach when a morphological matrix is reduced to include only part of the taxa; in such a

168 situation, we know of possible states that a character can adopt, even though they are not

169 realized among the taxa in our matrix. We call this the 'full-state Mk' model. To account for

170 different characters evolving at different rates, we also included gamma-distributed among-

171 character rate variation (ACRV) in the same way it is done for molecular data [among-site

172 rate variation or ASRV, 43].

173 We tested the four models described above on our morphological matrix by estimating

174 their marginal likelihoods under stepping-stone sampling [44] in MrBayes. For the

175 'unordered Mk' analysis, we made sure that the highest number used as a state label for each

176 character corresponded to the number of states minus one (as '0' is also used as a label). For

177   the 'ordered Mk' analysis, we chose *a priori* those characters that can be considered to evolve

178   in an ordered fashion; this included both characters that were originally continuous and

179   transformed by us into discrete states (see above) and other characters that have been

180   conceptualized in a way that suggests that they would likely adhere to a step-wise pattern of

181   evolution (58 characters in total, see Supplementary File S3). For the 'full-state Mk' model,

182   we obtained the maximum number of realized states in each character from a larger matrix at

183   hand, which includes about twice as many ichneumonid taxa. Our data was then re-coded so

184   that the largest state label reflects the thus estimated true size of the state space. This

185   procedure changed the state space in 52 out of the 222 characters, in most cases only by a

186   single state difference, but sometimes by up to three states. The R scripts to perform these

187   matrix manipulations and the resulting morphological matrices are available as

188   Supplementary File S4 (and as R package 'rogue.plot' from CRAN). For the best-scoring

189   model, we also ran stepping-stone sampling with equal rates among sites instead of gamma-

190   distributed ACRV ('no ACRV'). Stepping-stone sampling was conducted by running 50

191   million generations each in four independent runs under all four models, with one million

192   generations set as an initial burn-in and then 49 steps from posterior to prior [44]. Each step

193   consisted of one million generations, half of which were discarded as a within-step burn-in.

194   The alpha value determining the skewness of the sampling distribution was set to 0.4 (the

195   default value).

196   The preferred model as identified by the marginal likelihoods was then used for a

197   Bayesian analysis with four independent runs, each of which with one cold and three heated

198   chains, for 50 million generations. The 'variable' coding bias was invoked, as no constant

199   characters have been scored for our dataset, but some characters showed autapomorphic

200   states. We assessed convergence by examining plots of log likelihoods over time,

201   ascertaining that the potential scale reduction factor (PSRF) for all scalar parameters of the

202   model had dropped below 1.02, and recording the average standard deviation of split

203   frequencies (ASDSF) between the four independent runs. ASDSF was below 0.015 after 50

204   million generations, despite the large phylogenetic uncertainty (and thus large parameter

205   space to cover by the MCMC) introduced by the incompletely scored fossils. Half of the

206   generations were then excluded as a conservative burn-in. All calculations were performed on

207   UBELIX (http://www.id.unibe.ch/hpc), the HPC cluster at the University of Bern,

208   Switzerland.

209   *RoguePlots to illustrate taxon placement uncertainty*

210   To illustrate the uncertainty in the placement of fossil taxa, we developed R scripts to

211   generate what we call 'RoguePlots'. These plots show the posterior probabilities of the

212   placement of a fossil on a partially resolved phylogeny, such as a consensus tree. Especially

213   when there is a lot of phylogenetic uncertainty in a dataset, which is rather the rule than the

214   exception in morphological data, fossils might with a non-negligible probability attach to

215   branches that are not represented in a consensus tree (which can happen even if it is fully

216   resolved, unless it is a strict consensus). Figure 2 illustrates how RoguePlots solve this issue:

217   in order to represent such cases and thus ascertain that the posterior probabilities of

218   attachments shown on a tree sum to one, the branches that are parallel to the direction of a

219   rectangular phylogram of a RoguePlot represent fossil placements on this very branch, while

220   the perpendicular branches stand for attachments to any unrepresented branch of which the

221   corresponding node is the most recent common ancestor (MRCA).

222   Based on the majority-rule consensus tree from the Bayesian analysis of the

223   morphological matrix and on 1,000 trees sampled evenly from the post-burn-in phase of the

224   four independent runs, we generated RoguePlots to illustrate phylogenetic placements for

225   each of the 24 fossils covered here in order to re-evaluate their genus- and higher-level
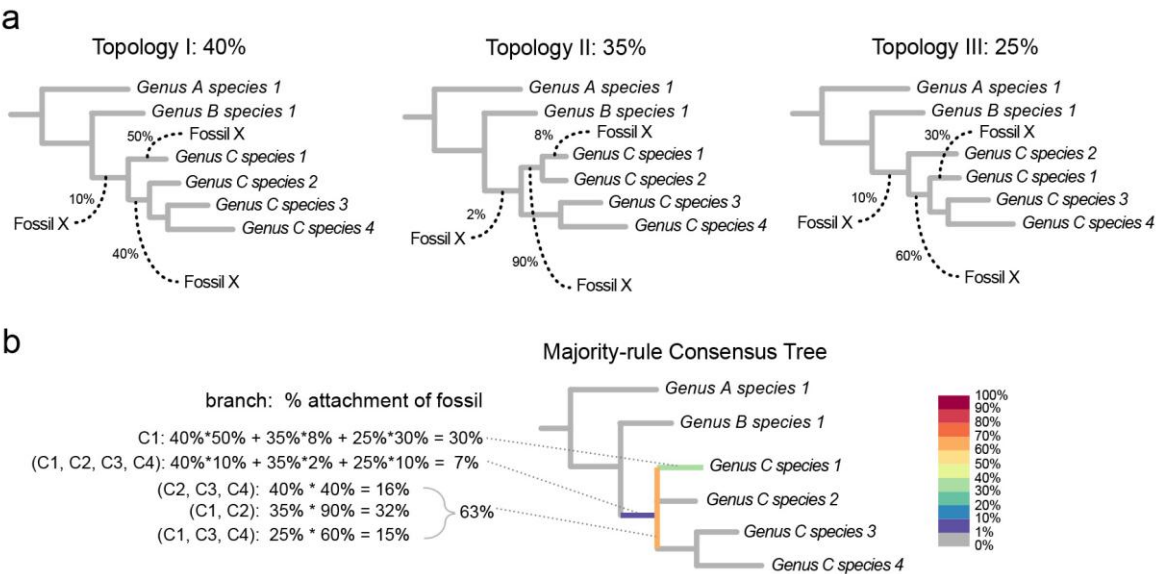

226   classifications.

227

228   Figure 2. Illustration of the generation of a 'RoguePlot'. Panel (a) shows three different topologies (I –

229   III) as they might be found during a Bayesian MCMC analysis or based on a set of bootstrapped matrices. The

230   frequency with which each topology is encountered is shown above. Fossil X attaches to one of three different

231   branches in each tree. Two of these branches are also present in the majority-rule consensus tree shown in panel

232   (b), while the third branch, respectively, is in conflict between the trees and thus appears as a polytomy in the

233   consensus. Fossil attachment frequencies to branches present in the consensus are reflected by the colour of the

234   branches parallel to the direction of the tree, while those to branches not present are shown on the perpendicular

235   branch that corresponds to its most recent common ancestor. In the current example, the percentages of Fossil X

236   to attach to a branch in the crown group of genus C sums to 93 %, while it is 7 % for it being a stem-group

237   representative and 0 % to be with either of the other genera A and B. Classifying it as belonging to genus C is

238   thus well-supported in this fictitious example. In addition to showing fossil placements, RoguePlots can be used

239   to illustrate the attachment points of any taxon in a phylogeny, such as a species that was identified as a rogue.

240

241   **Results**

242   *Phylogenetic analyses*

243   The morphological matrix has an overall coverage of 76.0 % when counting

244   polymorphisms as informative, or 71.6 % otherwise, which corresponds to an average of 53

245   of the 222 characters missing per taxon. Among the extant taxa, coverage values are much

246   higher (88.9 % and 84.5 %, respectively, depending on how polymorphisms are counted),

247   while the fossil taxa as expected show much more missing data and thus lower coverage

248   (20.6 % and 15.9 %, respectively). The fossil with the lowest number of characters, *Eclytus*

249   *lutatus* Theobald, had 92.3 % of characters missing (only 17 of 222 characters scored), while

250   the most completely scored fossil was *Scambus fossilobus* Spasojevic et al. [37], with 'only'

251   67.1 % missing data (73 characters scored).

252   The comparison of the model likelihoods obtained from stepping-stone sampling

253   revealed very large differences between the models, judging from Bayes factor comparisons

254   (Table 2). While the variance in the marginal likelihoods between the four independent runs

255   was always below six log units, the differences between the models were in the order of

256   several hundreds. The 'ordered Mk' model, which treated 58 characters as ordered

257   (Supplementary File S3), very clearly outperformed the other models and was used for all

258   further analyses. The 'full-state Mk' model, which increased the state space of each character

259   to that observed in other, not sampled ichneumonid taxa, reached the second-best marginal

260   likelihood, followed by the 'unordered Mk' model. The model that used ordered characters

261   but did not include among-character rate variation ('no ACRV'), was clearly behind all other

262   models, with a drop in likelihood of almost 850 log units (Table 2).
13

Figure 3. Majority-rule consensus tree of the topologies of the extant taxa sampled during the Bayesian

analysis of a morphological dataset of 222 discrete characters. Values near nodes represent posterior

probabilities of clades. Informal subfamily groups (Xoridiformes, Ophioniformes, etc.), the subfamily Pimplinae

and the *Polysphicta* genus group (which includes parasitoids of spiders) are indicated by bars on the right. Tips

are coloured according to their subfamily placement, and either subfamily or tribal (in the case of Pimplinae)

classification is also indicated by the first three letters in the label as follows: Aca – Acaenitinae, Ano –

270   Anomaloninae, Ban – Banchinae, Bra – Brachycyrtinae, Cam – Campopleginae, Col – Collyriinae, Cre –

271   Cremastinae, Cry – Cryptinae, Cte – Ctenopelmatinae, Cyl – Cylloceriinae, Del – Delomeristini, Dia –

272   Diacritinae, Dip – Diplazontinae, Eph – Ephialtini, Ich – Ichneumoninae, Lab – Labeninae, Lyc – Lycorininae,

273   Met – Metopiinae, Oph – Ophioninae, Ort – Orthocentrinae, Phy – Phygadeuontinae, Pim – Pimplini, Poe –

274   Poemeniinae, Rhy – Rhyssinae, The – Theroniini, Try – Tryphoninae, Xor - Xoridinae.

275

276   The majority-rule consensus tree of the analysis under the preferred model has a poorly

277   resolved backbone, as can be expected from a morphology-only dataset, but recovers most of

278   the subfamilies (Fig. 3). When rooting with *Xorides*, as supported by a previous molecular

279   analysis that included *Xorides* as the only represenative of Xoridinae [45], the remaining

280   subfamilies of Ichneumonidae were recovered as a monophyletic group (or in other words,

281   the two xoridine taxa included here grouped together). We thus rooted the tree between

282   Xoridinae and the remaining subfamilies. Higher-level relationships among subfamily groups

283   were not resolved, despite some of these groupings having been proposed on morphological

284   grounds (Ophioniformes, Ichneumoniformes, Pimpliformes). However, they were based

285   mostly on larval characters, which were not included in our matrix because of extensive

286   missing data even among extant taxa. Some of the subfamilies were not recovered either

287   (Tryphoninae, Cylloceriinae, and Diacritinae), but most of the other subfamilies and the four

288   tribes within Pimplinae received reasonable support. Some groups were only recovered as

289   paraphyletic, such as Campopleginae, Delomeristini and Theronini, and the acaenitine genus

290   *Coleocentrus* clustered with Rhyssinae. The genera *Xanthopimpla* and *Lissopimpla*, for

291   which a separate tribe or even subfamily has been discussed previously [45], render the

292   Theronini paraphyletic in our tree, but on a rather long branch. Overall, the tree is largely

293   congruent with a more sparsely sampled molecular tree published recently [45], even though

294   the latter showed better resolution along the backbone. As the goal of the current study is to

295   re-evaluate the classification of fossil species, which relies heavily on morphology, we at this

296   point use the morphological tree only. It allows re-assessment of most subfamily and genus

297   placements of fossils; however, because of the low resolution of relationships between

298   subfamilies, its value is limited when it comes to placing taxa that are backbone

299   representatives within Ichneumonidae.

300   *Phylogenetic placement of 24 fossil ichneumonids*

301   The confidence in the phylogenetic placement of the fossils (Figs 4–9) ranged from very

302   high, with up to 99.9 % probability for attachment to a single branch (in *Xanthopimpla*

303   *praeclara*, Fig. 9d), to two or three competing placements that could be either in closely

304   related (e.g., in *Rhyssella vera*, Fig. 7d) or in unrelated groups (e.g., in *Carinibus molestus*,

305   Fig. 4a), to very low probabilities on any individual branch (e.g., *Dolichomitus*? *saxeus*, Fig.

306   4d). Images of the studied fossils, along with partial RoguePlots that include all consensus

307   tree branches that have a higher than 1 % attachment probability, are shown in Figures 4–9

308   (complete RoguePlots are available as Supplementary File S5). We here briefly discuss the

309   placement of the individual fossils and, in some cases, revise the genus- and/or subfamily

310   assignments. The fossils are sorted alphabetically according to the genus name in the original

311   description. Taxon names are followed by the percentage of characters scored for the

312   individual fossil species.

313   *Carinibus molestus* Spasojevic et al. [7] – 22 %, Figure 4a. This taxon was described in

314   its own genus with uncertain subfamily placement. We can confirm this notion but can

315   narrow down potential subfamilies: The most likely placement in our analysis is with the

316   acaenitine *Mesoclistus* (42%), and the total probability for it to be an acaenitine sums to 55%.

317   But there is an alternative placement in the subfamily Metopiinae (total 32%), with a

318   probability so high that it cannot be ignored. Given the unique combination of characters

319   described by the authors [7], the genus might well represent an ancestor or extinct subfamily;

320   we thus leave the genus in *incertae subfamiliae*.

321

Figure 4. Partial RoguePlots of four fossil species including all consensus tree branches reaching more

than 1 % attachment probability. Xoridinae as outgroup and in some cases subfamilies in which the fossil has

been placed previously are included regardless of attachment probabilities. Branches parallel to the direction of

325   the phylogram are coloured according to the probability of direct attachment of the fossil to the branch, while

326   perpendicular branches represent the sum on any branch not in the consensus tree, of which the corresponding

327   node is the most recent common ancestor. The scale bar in the photographs represents 1 mm. a) *Carinibus*

328   *molestus*, holotype USNM 580881. b) *Crusopimpla rediviva*, holotype #2156, ©President and Fellows of

329   Harvard College. c) *Crusopimpla tadushiensis*, holotype #PIN 3364/277, ©Russian Academy of Sciences,

330   Moscow. c) *Dolichomitus*? *saxeus*, holotype #PIN 3364/31, ©Russian Academy of Sciences, Moscow.

331

332   *Crusopimpla*? *rediviva* [27,28] − 18 %, Figure 4b. This species attaches to various

333   places in the tree, as does the type species of the genus, *C. tadushiensis* (see next fossil), with

334   the exception that a placement as one of the more ancestral lineages within Pimplinae

335   received some support (22 %). The placement on the stem branch of Orthocentrinae was

336   deemed more probable, however (25 %), but due to the possibility of an artefact due to model

337   misspecification (see discussion section), we leave it in its current position.

338   *Crusopimpla tadushiensis* Kopylov et al. [28] − 17 %, Figure 4c. This species appears

339   all over the tree in our analysis, with placements in seven different subfamilies and on the

340   ancestral branch of Ichneumonidae minus Xoridinae, but never in the subfamily Pimplinae in

341   which it was originally described. This genus was erected as a stem-lineage representative of

342   the subfamily. Given the possibility that model misspecification caused this difference in

343   interpretation, and that the preferred placement in Orthocentrinae (22 %) seems highly

344   unlikely given the invariably smaller size of its representatives, we refrain from suggesting

345   any changes to its classification.

346   *Dolichomitus*? *saxeus* Kopylov et al. [28] − 14 %, Figure 4d. The placement of this

347   taxon was highly uncertain, which might be expected given its poor preservation, but there

348   seems a clear tendency for it to take up a basal position. This might reflect a true ancestral

349   placement of the fossil or could be due to 'stem-ward slippage' [46], the phenomenon that

350 incompletely preserved fossils tend to attach closer to the root than would be accurate (see

351 also discussion section). The sparse character evidence precludes any clear assessment of this

352 question, and as a placement within Pimplinae could not be ruled out either (17 %), and

353 genus assignment was already marked with a question mark by the authors of the original

354 description, we leave it in its current taxonomic position.

355 *Eclytus*? *lutatus* Scudder [47] – 8 %, Figure 5a. Even though it was described in a

356 tryphonine genus, this fossil received very high support in our analysis to belong to

357 Orthocentrinae (95.2 %), and there-in to the *Orthocentrus*-group of genera (85.3 %). All

358 placements on other branches in the tree, including anywhere near the three Tryphoninae taxa

359 we included, had less than 1 % frequency. The fossil is not very well preserved and its

360 placement difficult, as pointed out previously [7,48]. Furthermore, we did not manage to

361 include an extant member of the genus *Eclytus* in our analysis, and this high placement

362 probability might be due to insufficient taxon sampling and/or size-related homoplasy of the

363 scored morphological characters (see discussion). We thus agree with the decision taken by

364 Spasojevic et al. [7] and leave it as questionable within its original genus. Future analyses

365 might include more taxa from the morphologically quite diverse Tryphoninae and thus allow

366 for a more meaningful conclusion. However, a placement in Orthocentrinae should definitely

367 be considered, given the similarities to some genera of that subfamily in terms of the small

368 size and shape of the first tergite.

369 *Eopimpla grandis* Cockerell [49] – 16 %, Figure 5b. As stated previously [7], there is

370 little evidence for placing this fossil in Pimplinae, and the phylogenetic analysis was highly

371 ambiguous about subfamily placement. The fossil clustered with 22.5 % with *Ortholaba*

372 (Diacritinae), 19 % with *Netelia* (Tryphoninae), and 16.5 % on the ancestral branch leading

373 to Ichneumonidae without Xoridinae. Removing it from Pimplinae into an uncertain

374 subfamily association [7] thus seems justified.

375

Figure 5. Partial RoguePlots of four fossil species including all consensus tree branches reaching more than 1 % attachment probability. Xoridinae as outgroup and in some cases subfamilies in which the fossil has been placed previously are included regardless of attachment probabilities. Branches parallel to the direction of the phylogram are coloured according to the probability of direct attachment of the fossil to the branch, while perpendicular branches represent the sum on any branch not in the consensus tree, of which the corresponding node is the most recent common ancestor. The scale bar in the photographs represents 1 mm. a) *Eclytus*? *lutatus*,

382   holotype PALE-1418, © President and Fellows of Harvard College. b) *Eopimpla grandis*, holotype USNM

383   66581, © Smithsonian Institute. c) *Glypta transversalis*, modified from original drawing [Plate X, Fig. 25 in

384   47]. d) *Ichninsum appendicrassum*, holotype UCM 39378.

385

386   *Glypta*? *transversalis* Scudder [47] – 12 %, Figure 5c. Spasojevic et al. [7] suggested

387   that this fossil does not fit very well in Banchinae, but instead could be associated with

388   Lycorininae or with the genus *Physotarsus* in Tryphoninae. While the fossil was never

389   recovered with the banchine in our dataset (*Apophua*, a genus closely related to *Glypta*), it

390   indeed clustered most often with *Physotarsus* (13%), but there were also numerous

391   alternative placements that could not be ruled out. In lack of a well-supported alternative, we

392   leave the fossil in its original placement, but follow Spasojevic et al. [7] in adding a question

393   mark behind the genus name.

394   *Ichninsum appendicrassum* Spasojevic et al. [7] – 26 %, Figure 5d. The authors of this

395   genus avoided subfamily placement because of presumably plesiomorphic character

396   combinations. Our results here confirm what they suggested as the most likely subfamily

397   placement (Pimplinae) with quite high cumulative posterior probability (65.3 %). Even

398   though the fossil cannot be associated with a single tribe within the subfamily, we move it

399   from *incertae subfamiliae* to Pimplinae.

400   *Lithotorus cressoni* Scudder [47] – 20 %, Figure 6a. This fossil was described in the

401   subfamily Diplazontinae, but both Townes [50] and Spasojevic et al. [7] mentioned the

402   possibility that it is instead closely related to the *Helictes*-group of genera in Orthocentrinae.

403   Our results confirm this notion and place it either as a sister taxon to *Entypoma* or as a stem-

404   lineage representative of the subfamily (without *Hyperacmus*). The sum of placement

405   probabilities in Orthocentrinae approaches 98.5 %, while the original placement in

406   Diplazontinae is not supported at all. We thus move the genus *Lithotorus* to Orthocentrinae.
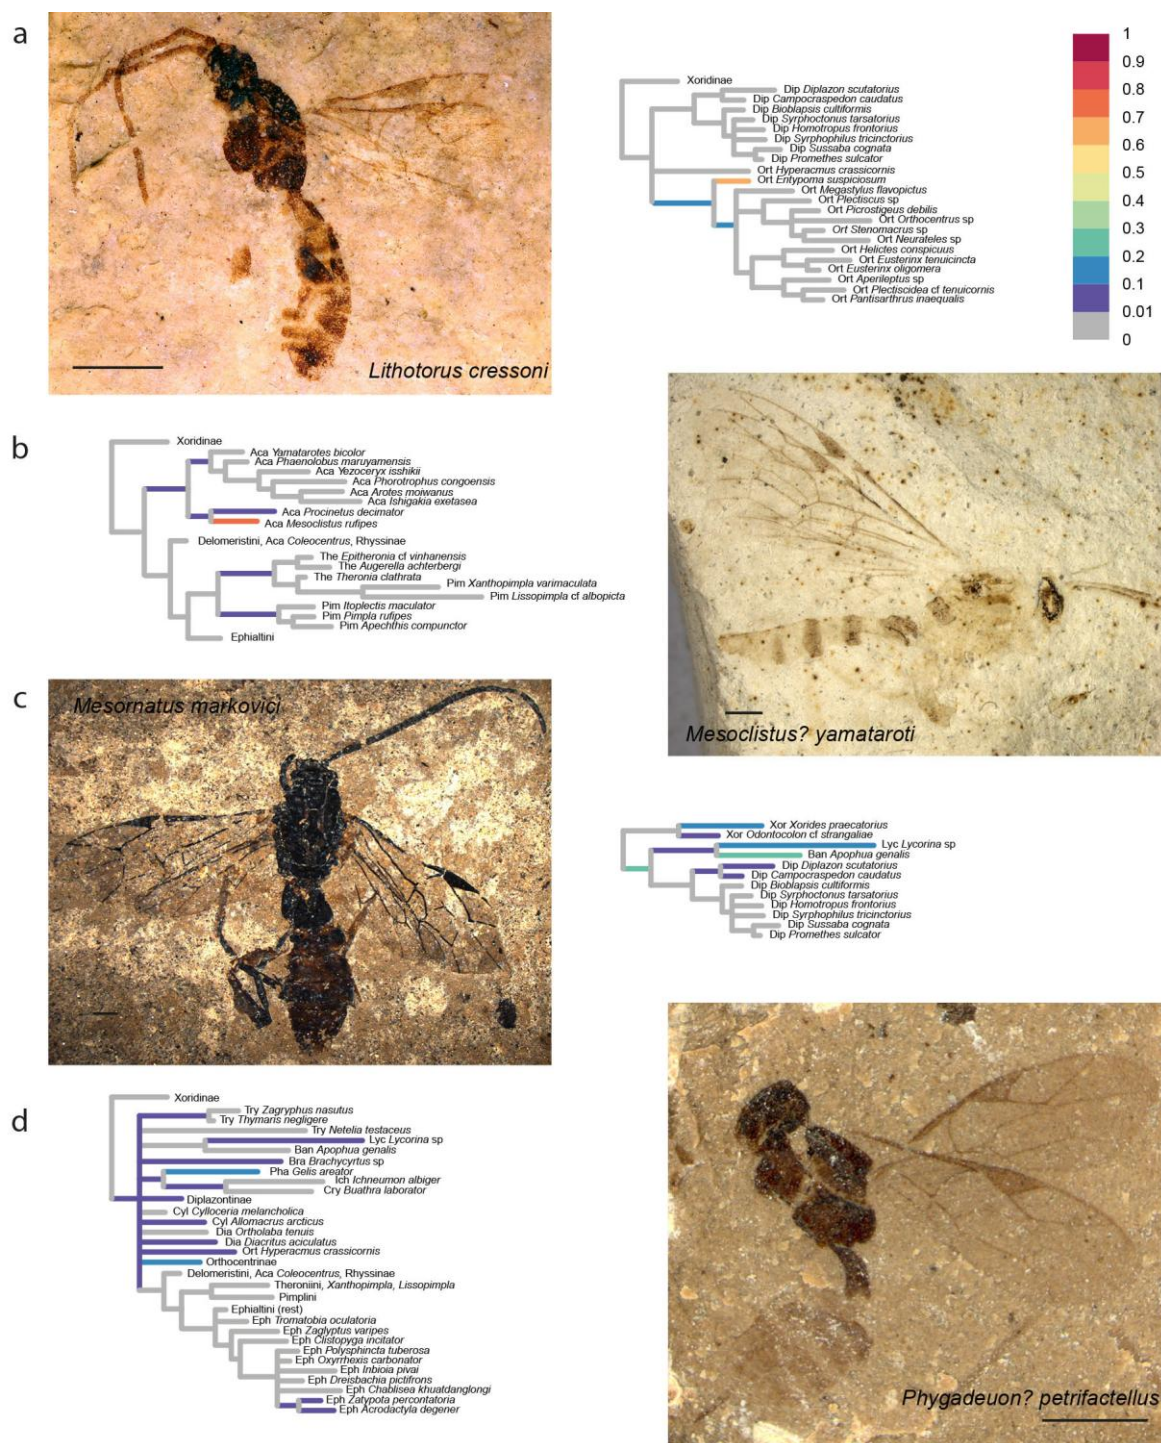

407

Figure 6. Partial RoguePlots of four fossil species including all consensus tree branches reaching more than 1 % attachment probability. Xoridinae as outgroup is included regardless of attachment probabilities. Branches parallel to the direction of the phylogram are coloured according to the probability of direct attachment to the branch, while perpendicular branches represent the sum on any branch not in the consensus tree, of which the corresponding node is the most recent common ancestor. The scale bar in the photographs represents 1 mm. a) *Lithotorus cressoni,* holotype PALE-4652, © President and Fellows of Harvard College. b)

414   *Mesoclistus*? *yamataroti,* holotype UCM 62725. c) *Mesornatus markovici*, holotype SF MeI 15245. d)

415   *Phygadeuon*? *petrifactellus*, holotypeUSNM 66580 © Smithsonian Institute.

416

417   *Mesoclistus*? *yamataroti* Spasojevic et al. [7] – 23 %, Figure 6b. We can confirm the

418   subfamily placement here (Acaenitinae: 96%), and indeed observed the highest probability of

419   it clustering with *Mesoclistus* (77%). As we have only included two other genera of the

420   *Coleocentrus* genus group in this analysis (*Coleocentrus* and *Procinetus*), we leave the genus

421   placement as uncertain, as it was already suggested in the original description.

422   *Mesornatus markovici* Spasojevic et al. [37] – 27 %, Figure 6c. This taxon is placed

423   with 23 % probability on the stem lineage leading to all ichneumonids except Xoridinae, and

424   with 20 %, 15 %, and 14.5 %, respectively, with *Apophua* (Banchinae), *Lycorina*

425   (Lycorinae), and *Xorides* (Xoridinae). We can thus confirm the uncertain subfamily

426   placement of this genus; it might even belong to a stem lineage or now extinct subfamily.

427   *Phygadeuon*? *petrifactellus* Cockerell [49] – 14 %, Figure 6d. Spasojevic et al. [7]

428   added a question mark to the genus assignment, but left the taxon within the then subfamily

429   Cryptinae. As this subfamily has in the meantime been split by Santos [51], the correct

430   placement would now be in the subfamily Phygadeuontinae. Our results largely agree with

431   this placement, but emphasize even more the large uncertainty: it grouped with *Gelis areator*

432   18 % of the time, but was also found as a stem-lineage representative of Orthocentrinae in 14

433   % of the trees. We leave the current classification unchanged but emphasize the uncertainty
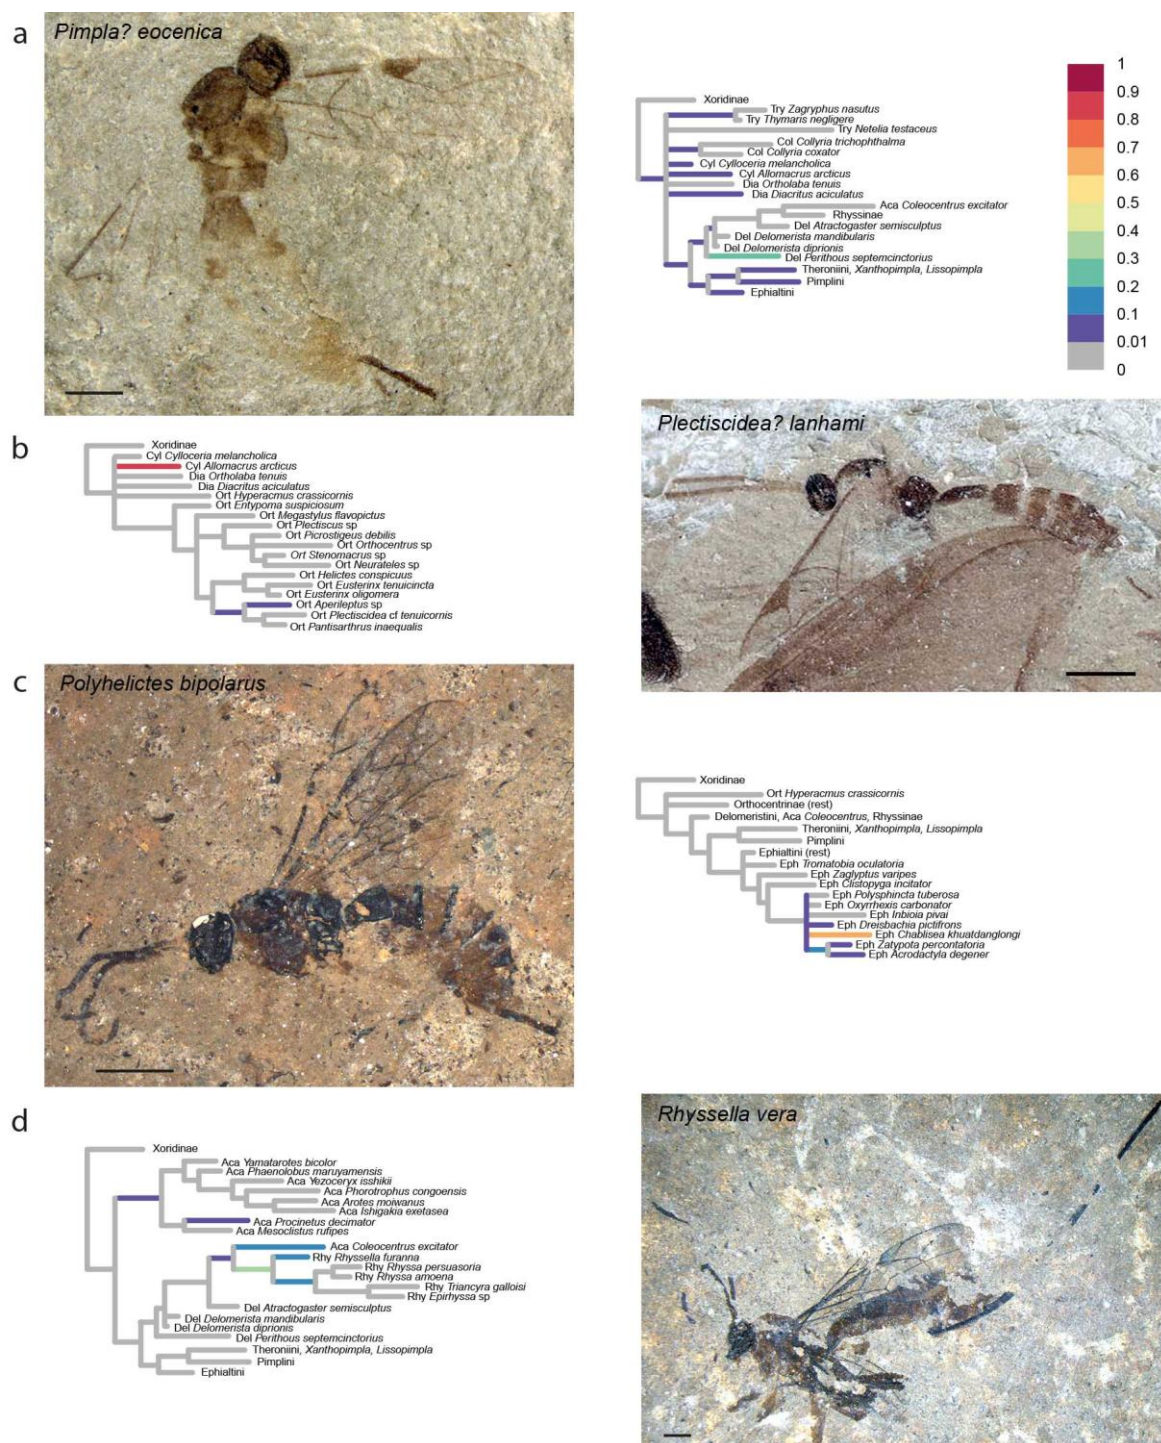

434   of the placement.

Figure 7. Partial RoguePlots of four fossil species including all consensus tree branches reaching more than 1 % attachment probability. Xoridinae as outgroup is included regardless of attachment probabilities. Branches parallel to the direction of the phylogram are coloured according to the probability of direct attachment to the branch, while perpendicular branches represent the sum on any branch not in the consensus tree, of which the corresponding node is the most recent common ancestor. The scale bar in the photographs represents 1 mm. a) *Pimpla*? *eocenica*, holotype USNM 66582, © Smithsonian Institute. b) *Plectiscidea*?

442   *lanhami*, holotype UCM 19167, © University of Colorado Museum of Natural History. c) *Polyhelictes*

443   *bipolarus*, holotype MeI 16069. d) *Rhyssella vera*, holotype MeI 8814.

444

445   *Pimpla*? *eocenica* Cockerell [52] – 16 %, Figure 7a. Spasojevic et al. [7] revised this

446   fossil and added a question mark to the genus assignment, citing high uncertainty in this

447   genus placement due to poor preservation of the fossil. Our morphological analysis

448   confirmed the high uncertainty in the placement, which attached on several mostly rather

449   basal branches within Pimplinae, but also with other subfamilies, most of all Diacritinae,

450   Collyriinae, and Cylloceriinae. Summing the probabilities of it associating with pimpline taxa

451   revealed a slight preference of this over any other subfamily (56 %); within the subfamily, *P.*

452   *eocenica* was most often ending up in the tribes Delomeristini, Pimplini and Theroniini or on

453   the branches close to the ancestor of the subfamily. The highest probability (23 %) was for *P.*

454   *eocenica* to be sister to *Perithous septemcinctorius*, a placement not supported by any

455   particular character. We thus leave *P. eocenica* in Pimplinae and, with a question mark, in the

456   genus *Pimpla*.

457   *Plectiscidea lanhami* Cockerell [53] – 13 %, Figure 7b. Spasojevic et al. [7] noted

458   uncertainty in the generic placement of this fossil, mostly due to the pentagonal areolet which

459   does not occur in any of the recent representatives of the genus. But they agreed with the

460   placement in Orthocentrinae. Our analysis now recovers the fossil with 89 % with the very

461   small genus *Allomacrus*, and only with about 7.5 % in Orthocenrinae. However, *Allomacrus*

462   was variously classified within either Cylloceriinae or Orthocentrinae and these subfamilies

463   are certainly closely related. Even though *Allomacrus* has an open areolet, its shape indicates

464   that it might be pentagonal when closed. As far as visible in the fossil, the wing venation (i.e.,

465   proportions of pterostigma and fore wing cells), humped first tergite and proportions of the

466   remaining tergites, and possibly long ovipositor are indeed very similar to *Allomacrus*, thus

467   we transfer the fossil to this genus: *Allomacrus lanhami*, comb. nov.

468   *Polyhelictes bipolarus* Spasojevic et al. [37] – 26 %, Figure 7c. The authors of this

469   genus and species mentioned that the character combination would allow placement in two

470   not very closely related groups: the *Helictes* genus group in Orthocentrinae, or the spider

471   parasitoids of the *Polysphincta* genus group in the pimpline tribe Ephialtini. This ambiguity is

472   expressed both in the genus and species names of the taxon. However, our analysis places it

473   very firmly in the *Polysphincta* group (100 %). This somewhat surprising result is probably

474   due to some measurement characters in the fore wing that were not taken into account when

475   the taxon was described, such as the rather elongate radial cell and relatively long vein r-rs in

476   the forewing, which are consistently short in Orthocentrinae.

477   *Rhyssella vera* Spasojevic et al. [37] – 27 %, Figure 7d. This fossil received highest

478   probability for attaching to the stem lineage of the Rhyssinae taxa we sampled (36 %),

479   followed by being sister to the extant *Rhyssella furanna* (18 %) or on the branch leading to

480   the remaining Rhyssinae (17 %). There was some probability also that it clustered with

481   Acaenitinae (total 24 %), mostly with *Coleocentrus* (12 %), which was recovered here as the

482   sister group to Rhyssinae. Nevertheless, we consider the original placement as being

483   supported by this analysis (total in Rhyssinae: 72 %), with the genus *Rhyssella* as the best

484   option.

485   *Scambus fossilobus* Spasojevic et al. [37] – 33 %, Figure 8a. Our analysis recovers this

486   taxon with high certainty within Pimplinae (91 %), where the highest probability attaches it

487   to the stem- of the tribe Ephialtini (67%). This confirms the author's claim of the first

488   unequivocal representative of the subfamily, and the genus placement, even though not

489   directly confirmed here, cannot be refuted, as we did not adequately sample the diversity of

490   the large genus *Scambus*.
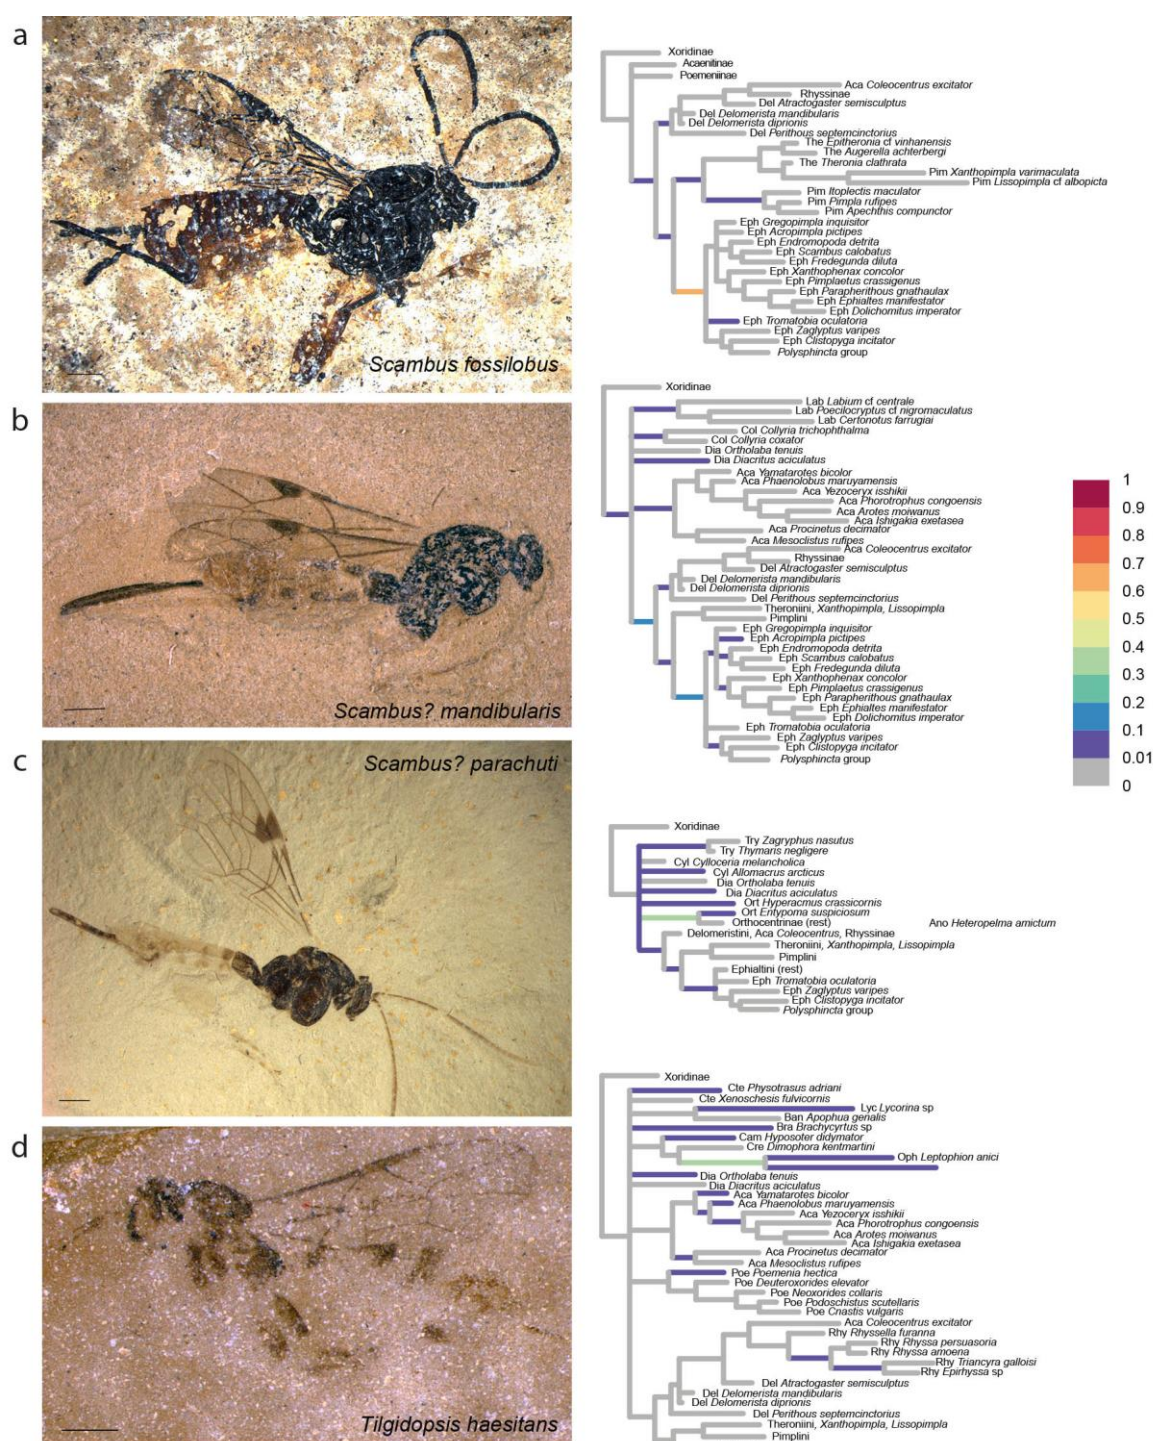

491

492   Figure 8. Partial RoguePlots of four fossil species including all consensus tree branches reaching more

493   than 1 % attachment probability. Xoridinae as outgroup is included regardless of attachment probabilities.

494   Branches parallel to the direction of the phylogram are coloured according to the probability of direct

495   attachment to the branch, while perpendicular branches represent the sum on any branch not in the consensus

496   tree, of which the corresponding node is the most recent common ancestor. The scale bar in the photographs

497   represents 1 mm. a) *Scambus fossilobus*, holotype SF MeI 13431. b) *Scambus*? *mandibularis*, holotype USNM

498   501474. c) *Scambus*? *parachuti*, holotype 565885. d) *Tilgidopsis haesitans*, holotype USNM 66931, ©

499   Smithsonian Institute.

500

501   *Scambus*? *mandibularis* Spasojevic et al. [7] – 20 %, Figure 8b. This fossil also was

502   placed mostly on stem lineages in various subfamilies, but with most of the weight in

503   Pimplinae (sums to 53%), most likely either as a stem lineage representative or ancestral to

504   the tribe Ephialtini. Genus placement is not resolved though, and we thus leave it as uncertain

505   within *Scambus*.

506   *Scambus*? *parachuti* Spasojevic et al. [7] – 29 %, Figure 8c. This taxon received a

507   placement in various subfamilies, but mostly in a very basal position or even as a stem

508   lineage. This is also the case for the subfamily Pimplinae in which it was described. The

509   highest probability is observed for a stem-lineage placement in Orthocentrinae, but this is not

510   decisive (36 %). Even though the placement in Pimplinae is not supported here, it cannot be

511   rejected either (sums to 8 %). We thus leave it as uncertain in the genus *Scambus*.

512   *Tilgidopsis haesitans* Cockerell [54] – 11 %, Figure 8d. Described in Ophioninae but

513   with reported similarities to the unrelated Poemeniinae, Cockerell already made it clear that

514   subfamily placement is not simple in this taxon. Spasojevic et al. [7] formalized this by

515   moving it to *incertae subfamiliae*. Interestingly, our analyses put it closer to Ophioninae

516   again, but most likely as a stem lineage with 37.5 % probability to attach to the branch

517   leading to *Leptophion* (Ophioninae) and *Heteropelma* (Anomaloninae). Other placements in

518   various subfamilies (Acaenitinae, Brachycyrtinae, Diacritinae, Ctenopelmatinae, etc.) cannot

519   be fully excluded either.

Figure 9. Partial RoguePlots of four fossil species including all consensus tree branches reaching more than 1 % attachment probability. Xoridinae as outgroup is included regardless of attachment probabilities. Branches parallel to the direction of the phylogram are coloured according to the probability of direct attachment to the branch, while perpendicular branches represent the sum on any branch not in the consensus tree, of which the corresponding node is the most recent common ancestor. The scale bar in the photographs represents 1 mm. a) *Trigonator macrocheirus*, holotype SF MeI 17304. b) *Tryphon amasidis*, holotype UCM

527   15690, © University of Colorado Museum of Natural History. c) *Xanthopimpla messelensis*, holotype SF MeI

528   16988. d) *Xanthopimpla praeclara*, holotype SF MeI 17300.

529

530   *Trigonator macrocheirus* Spasojevic et al. [37] – 23 %, Figure 9a. Despite rather sparse

531   sampling of the subfamily Labeninae, this fossil is firmly placed within that subfamily (87

532   %), with closest ties to *Poecilocryptus* (80 %) and *Certonotus* (6 %), the sole representatives

533   of the two tribes that the authors associated it with. However, without a denser sampling of

534   the labenine genera, tribal placement of the genus cannot be made with any certainty.

535   *Trymectus amasidis* [55] – 22 %, Figure 9b. This fossil was originally described in

536   *Tryphon* and is rather well preserved; the more surprising was its unresolved placement. It

537   ended up on the branch leading to the Tryphoninae taxa *Zagrphus* and *Thymaris* in 24% of

538   the trees, with the rest of the probabilities distributed rather evenly among numerous taxa in

539   subfamilies as different as Metopiinae, Ctenopelmatinae, Banchinae, Pimplinae etc., or on

540   some of the most basal branches in the tree. The placement as a new genus *Trymectus* with

541   uncertain subfamily placement by Spasojevic et al. [7; named after the first letters of the first

542   three afore-mentioned subfamilies] can thus here be confirmed.

543   *Xanthopimpla messelensis* Spasojevic et al. [37] – 30 %, Figure 9c. While the

544   similarities of this fossil with recent representatives of the genus seem striking at first glance

545   [see Fig. 3 in 37], our analysis placed it with higher probability in Acaenitinae (50 % with

546   *Mesoclistus*), even though *Xanthopimpla* and its sister genus *Lissopimpla* remain a clear

547   possibility (19 % in total). We acknowledge that we judged some of the characters typical of

548   *Xanthopimpla* as not clear enough for scoring in the fossil, even though they are indicated,

549   e.g., the groves on the metasomal tergites and enlarged claws. Adding these characters and

550   achieving a better coverage of the morphological diversity among extant *Xanthopimpla*

551   species would probably tip the scale in favour of the original placement. The shape and

552   length of the ovipositor and absence of a large, triangular hypopygium strongly contradict a

553   placement in Acaenitinae. We thus refrain from making any formal subfamily changes here,

554   but put a question mark behind the genus name to express the uncertainty in the phylogenetic

555   placement. Especially, the fossil could also belong to a stem lineage of *Xanthopimpla* +

556   *Lissopimpla* or of Theronini.

557   *Xanthopimpla praeclara* Spasojevic et al. [37] – 29 %, Figure 9d. In contrast to the

558   previous fossil, this species was placed very firmly (99.9 %) with the recent *Xanthopimpla*

559   *varimaculata*, confirming that this genus dates back to the Early to Mid Eocene.

560   **Discussion**

561   *Evolutionary models for morphological data*

562   The application of model-based approaches to a specific type of character requires the

563   availability of sufficiently realistic models of its evolution, and the discussion whether the

564   simplifying Mk model [15] is suitable to infer phylogenetic relationships from discrete,

565   morphological data is still on-going. It was further sparked by a simulation study suggesting

566   the superiority of the Bayesian approach over parsimony for morphological data [56], but the

567   specifics of the simulation procedure, especially the single set of relative branch lengths used,

568   are still under discussion [57,58].

569   Even though a lot remains to be done in the field of morphology models, the stochastic

570   framework allows for a direct comparison of the fit of different models, as we have

571   conducted here when comparing the unordered versus ordered Mk models and the expansion

572   of the state space as implied by a larger morphological matrix (Table 2). The very large

573   differences in model likelihoods revealed by stepping-stone sampling suggest that provided

574   with a large-enough data matrix (222 characters times 127 taxa), such comparisons are very

575   instructive. In our case, the largest effect was observed when comparing the 'ordered Mk'

576   model with or without gamma-distributed among character rate variation (ACRV), an

577   observation made earlier for molecular data [59]. ACRV will likely constitute a vital part of

578   any morphology model, as was already suggested by Lewis [15], but systematic reviews of

579   empirical matrices are currently missing. The second-ranked Bayes factor resulted from the

580   comparison of 'unordered' versus 'ordered' data, with characters for ordering chosen *a priori*

581   according to character conceptualization (Supplementary File S3). Some of the 'ordered'

582   characters (13 out of 58) in fact represent discretised continuous characters, and it remains to

583   be shown whether character ordering is vital also in datasets where continuous characters are

584   analysed as such [60]. Finally, we tested whether increasing the state space of each character

585   by adding unobserved states as they appeared in a larger matrix of ichneumonid taxa

586   (unpublished data). Even though one might argue that such an approach leads to a more

587   realistic morphology model, it received lower marginal likelihoods in our analyses (Table 2).

588   A possible explanation of this is that we used a fully symmetrical model, where transitions

589   between different states and thus also state frequencies are assumed to be equal at

590   stationarity. Adding states that are not actually observed among the data creates additional

591   asymmetry in state frequencies, which might be the reason for the lower marginal likelihood

592   of that model.

593   We also attempted to run an asymmetric model which allows state frequencies to be

594   unequal following a beta distribution for two-state or Dirichlet distribution for multi-state

595   characters. This extension to the model has already been suggested by Lewis [15] and is

596   implemented in MrBayes [41]. It has been demonstrated recently to outperform the

597   symmetric model in about half of 206 empirical datasets, most of which were rather small

598   [14]. On our data matrix of 222 characters times 127 taxa, even using a fixed level of

599 asymmetry instead of a hyper-prior, we found computation times to be prohibitive (more than

600 1,100 CPU hours for 10 million generations).

601 *Bayesian phylogenetic fossil placement*

602 Our morphological phylogenetic analysis exemplifies the use of Bayesian inference in

603 the classification of fossil taxa and shows how placement uncertainty can be illustrated using

604 RoguePlots. The advantages of reproducible, stochastic analyses of fossil placement have

605 been discussed previously [16,61], and we here further emphasize the benefits of the direct

606 assessment of alternative placements that comes with Bayesian approaches. Placing fossils in

607 a classification system that is strongly biased towards extant taxa, as it is the case in most

608 groups with a poor (or at least poorly studied) fossil record, triggers difficulties that go

609 beyond incomplete fossil preservation. Representatives of a stem lineage might not yet

610 possess all the synapomorphies of the crown group, requiring an extension of the

611 circumscription of a taxon. And even more important, because the divergence times for most

612 taxa remain poorly known or contentious, it is often unclear to what degree a fossil species

613 can be placed at all in a certain taxonomic rank: the genus, tribe, or even family in question

614 might not have existed yet at the time the species fossilized. A phylogenetic perspective on

615 fossil classification is thus vital for a proper evaluation and communication of both the

616 position of a fossil in the taxonomic system and the amount of uncertainty associated with it.

617 RoguePlots provide a natural way of representing placement uncertainty on a tree

618 summary like a consensus tree, but also on individual trees, such as a maximum likelihood

619 tree or shortest tree under the parsimony criterion. The approach can take sets of trees from a

620 Bayesian analysis, but also those resulting from bootstrapped data matrices; it illustrates the

621 frequencies with which different fossil placements occur among the different trees. One

622 difficulty arising from the need to represent relationships among fossil and extant taxa in a

623   potentially very heterogeneous set of topologies lies in the restrictions imposed by using a

624   single tree plot: even if the tree in question is fully resolved, some of the trees in the set will

625   most likely contain clades not represented in it. RoguePlots circumvent this issue by making

626   use of the distinction in branches that are parallel versus perpendicular to the direction of a

627   rectangular phylogram: parallel branches are used to illustrate the probability of direct

628   attachment to the branch, while perpendicular branches represent the sum on any branch not

629   in the tree, of which the corresponding node is the most recent common ancestor. This

630   approach ascertains that the shown placement probabilities sum to one, which might not be

631   the case otherwise [e.g., see Fig. 8 in 23]. While it is possible to produce RoguePlots based

632   on trees obtained from a maximum likelihood or parsimony analysis of a morphological

633   dataset, their interpretation is much more intuitive in the Bayesian context, where the

634   frequency of a clade in the set of trees represents its posterior probability. In contrast,

635   bootstrapping a morphological matrix will necessarily remove some characters, while

636   multiplying others, precluding a straight-forward interpretation of the resulting placement

637   frequency.

638   *Morphological phylogenetics versus character evidence for fossil placement*

639   Using a stochastic framework for the phylogenetic analysis of fossil taxa does neither

640   replace nor preclude careful character evaluation, but instead is based on it being made

641   explicit. The step of coding morphological observations into discrete characters and states is

642   crucial for this endeavour and certainly comes with a string of pitfalls, from character

643   conceptualization to the delimitation of character states. In the ideal case, characters that

644   would have been used as arguments to place a fossil can be adequately represented in a

645   morphological matrix, in which case the phylogenetic reconstruction method identifies them

646   as characters that evolve at a low rate (which is nearly equivalent to identifying them as

647   synapomorphies). They will lead to a high probability of the predicted placement of the

648   fossil, or at least to an accurate representation of the uncertainty of this placement (but see

649   below). In our analyses, this was the case for the vast majority of fossils, where the

650   RoguePlots provided matching illustrations for alternative placements that had already been

651   discussed using character evidence in the original descriptions or revisions of the fossils

652   [7,28,37]. In several cases, the morphological phylogenetic analysis helped identify

653   informative characters that have not been used much previously to define higher taxa, and

654   were thus omitted from consideration in the original descriptions. The best example here is

655   *Polyhelictes bipolarus*, a taxon originally described with uncertain subfamily association

656   [37], as the traditionally used characters would imply a placement either in the *Helictes*-group

657   of genera in the subfamily Orthocentrinae, or among the spider parasitoids of the

658   *Polysphincta*-group in Pimplinae. Examination of the morphological matrix showed that the

659   unequivocal placement in the latter group in the morphological phylogeny was driven mostly

660   by measurements of forewing veins and cells, characters not typically used in ichneumonid

661   subfamily diagnoses. A phylogenetic analysis can also expose overconfidence in fossil

662   placements that are based on individual characters by identifying alternative placements. This

663   was probably the case with *Rhyssella vera*, which was initially described in the recent genus

664   based on the strongly petiolate areolet (Spasojevic et al. 2018), while our analysis suggests a

665   more basal placement as a stem lineage rhyssine.

666   On the other hand, a phylogenetic analysis is only as good as the underlying

667   morphological matrix, and generating the latter does not come without its pitfalls. We below

668   discuss five issues that can result in erroneous phylogenetic placement of fossils: limitations

669   in character sampling, limitations in taxon sampling, artefacts caused by the fossilization

670   process, limited phylogenetic signal in the morphological data, and misspecification of the

671   evolutionary model. The identification of resulting artefacts is crucial when interpreting the

672   results of a morphological phylogenetic analysis and can point to way to improving the

673   representation of the morphological diversity of extant and fossil taxa in the matrix in the

674   future.

675   *Insufficient character sampling* – Probably the most common cause of differences

676   between the *a priori* assessment of the placement of a fossil and that resulting from a

677   phylogenetic analysis are differences in the representation of character evidence. While the

678   coding of some discrete characters is rather straight-forward, such as the presence or absence

679   of a unique structure, other character concepts might require more careful consideration. In

680   fossils, shape characters often contribute to an initial intuition about their placement, while

681   they can be difficult to translate properly into discrete character states. Other characters might

682   be omitted out of convenience or due to some uncertainty associated with the interpretation of

683   the fossil. This was probably the cause of the unexpected placement of *Xanthopimpla*

684   *messelensis.* This fossil showed a higher probability of belonging to Acaentinae than

685   Pimplinae, and within the latter was rather associated with the sister genus *Lissopimpla* than

686   with *Xanthopimpla* (Fig. 9c). Several characters that were used for the placement in the

687   original description were not or not adequately represented in the morphological matrix: the

688   enlarged claws (delimitation of this character was deemed too difficult and it was thus not

689   included in the matrix), the potentially twisted mandible and short hypopygium (due to some

690   uncertainty in the interpretation), the very narrow triangular areolet (as it is somewhat

691   difficult to delimitate from other triangular areolets), and the slightly medially down-curved

692   ovipositor (because it was not present in any other scored taxon). Similar shapes of the

693   areolet and ovipositor occur in some extant *Xanthopimpla* species [62], and our failure to

694   include them in the morphological matrix might have hindered the placement of the fossil. To

695   achieve a more accurate estimate of the placement uncertainty in this fossil, a review of the

696   character matrix would be warranted. When it comes to characters pertaining to shape and

697   general 'habitus' of a taxon, morphometric approaches might improve current estimates.

698   Continuous characters can in principle as easily be combined with discrete, morphological

699   characters as the latter with molecular data [63], provided the respective models are

700   implemented in the analysis software [60,64,65].

701   *Insufficient taxon sampling* – The estimate of the posterior probability of a taxon

702   placement in a phylogeny can of course only take into account taxa that have in fact been

703   sampled. If the closest relatives of a fossil are not included in a data matrix, then posterior

704   probabilities are not actually conclusive, as has been the case for the fossil *Eclytus*? *lutatus*

705   included here. As no extant representative of the genus *Eclytus* was sampled, the high

706   probability of the fossil being associated with Orthocentrinae cannot be taken at face value,

707   even though this alternative placement should be considered further in the future. Even if all

708   potentially close relatives are included in an analysis, omission of other taxa might bias

709   posterior probability, for instance if a certain character state is unique among the sampled

710   taxa, but occurs in some not sampled groups as well. Not including these groups will imply a

711   lower evolutionary rate of the character than is actually the case and thus overconfidence in

712   the fossil placement. Adequate taxon representation is thus crucial for a meaningful

713   morphological phylogenetic analysis.

714   *Fossilization artefacts* – If the fossilization process favours the preservation of ancestral

715   character states in comparison with those that have evolved rather late in the history of a

716   group, or if taphonomic loss of a character is erroneously interpreted as its absence, fossils

717   might show more ancestral placements in a phylogeny than warranted, a phenomenon

718   referred to as 'stem-ward slippage' [46]. While detailed studies of insect decay are missing,

719   the fact that they lack biomineralized tissues means that they need exceptional conditions in

720   order to fossilize, such as fine-grained lacustrine or shallow marine environments [6]. There

721   is usually a pronounced difference in the preservation of different body parts, with the flat

722   wings often exceptionally well preserved, including details of their venation, while the head

723   with its compound eyes shows strong signs of decay; furthermore, legs and other appendages

724   are often the first to dislocate from the body and are thus lost often for interpretation.

725   However, it remains unclear whether these biases are aligned with the taxonomic significance

726   of the character states, especially in ichneumonids. Characters used to diagnose ichneumonid

727   subfamilies include characters from all over the body, including wing venation as well as

728   carination on the body or structure of the ovipositor; it thus remains to be shown whether

729   stem-ward slippage is an issue in this group, for instance causing the ancestral position of the

730   poorly preserved *Dolichomitus*? *saxeus* (Fig. 4d).

731   *Limited phylogenetic signal* – Molecular phylogenies have all but replaced

732   morphological phylogenies in the recent literature, of course unless fossils are included, and

733   this transition has happened mostly because the phylogenetic signal in morphological data is

734   believed to be relatively limited and prone to biases due to convergence and homoplasy

735   [66,67,68]. The Ichneumonidae tree is no exception here: while most subfamilies have been

736   recovered in our analysis, the backbone of the tree is very poorly resolved, which causes

737   severe limitations for the interpretation of fossil placement. For instance, the higher-level

738   groupings Ophioniformes, Ichneumoniformes, and Pimpliformes were not recovered here,

739   which precludes us from even obtaining an estimate of the probabilities that a fossil belongs

740   to a stem lineage of either of the three subfamily groups. This is for instance the case for

741   *Eopimpla grandis* or *Mesornatus markovici*, both of which might be stem-lineage

742   representatives of certain subfamilies or even of more ancestral lineages. As the phylogenetic

743   uncertainty in this area of the tree is very high, no single branch that would potentially

744   resolve the polytomy at the base of Ichneumonidae without Xoridinae obtained high

745   attachment probabilities of the fossils.

746   In the case of ichneumonids, the limited phylogenetic signal in the morphological data

747   is partly due to the high levels of homoplasy reported for the group (Gauld & Mound 1982).

748   Many character states, especially those related to parasitoid life style and host choice,

749   converged in distantly related groups (e.g., long ovipositor in parasitoids of wood boring

750   insects; short and thick legs in parasitoids of concealed hosts, etc.). Another example is

751   homoplasy due to similar size, which influences several character systems, leads to

752   correlation among multiple characters in morphological matrices. For example,

753   miniaturisation is often followed by a reduction of certain wing veins, changes in the shape of

754   wing cells and pterostigma, and an overall stouter body. Such correlated morphological

755   characters should in general be avoided, as much as possible, in phylogenetic analyses; but

756   they can also be recognised as fast evolving and 'down-weighted' in Bayesian inference

757   when enough information is present. *Eclytus lutatus* might be a case where a lack of

758   information to infer homoplasy due to size (no data for the genus *Eclytus* or other small

759   Tryphoninae genera) biased its placement in favour of Orthocentrinae, a subfamily of small

760   to very small ichneumonids.

761   A potential solution when confronted with limited phylogenetic signal in a

762   morphological matrix would be to perform a combined analysis with molecular data in order

763   to get a better-resolved consensus tree on which fossil placement could then be plotted; this is

764   certainly a valid alternative approach. However, we decided to use morphology only, and

765   even only adult, external morphological characters which are potentially visible in fossils,

766   because we this way obtained a consensus tree which in itself shows the limits of achievable

767   fossil placement certainty: it demonstrates the limitations of the phylogenetic signal in the

768   morphological dataset even for extant taxa, for which many more characters can be scored

769   than for fossils. Interestingly, however, our morphological tree is not in fact that much less

770   resolved than a molecular tree resulting from a recent 93-gene study, with the exception of

771   the three afore-mentioned subfamily groups [45]. The signal in the morphological data is thus

772   not even that much weaker, and the addition of larval characters would likely even improve

773   resolution along the backbone of the tree [69].

774   *Model misspecification* – While testing the 'unordered', 'ordered' and 'full-state' Mk

775   models, we were not able to include the full range of models that have been developed for

776   morphology, as this would have been beyond the scope of this study [12,14,15]. However, we

777   would like to point out a potential artefact caused in our data by model misspecification that

778   pertains to the stationarity assumption [13] and concerns the two species of *Crusopimpla*

779   (Figs 4b, c). This genus was erected as a stem-lineage representative of the subfamily

780   Pimplinae, with the presence of several carinae on the propodeum as a defining characteristic.

781   None of the extant pimplines has complete carination (even though it is rather extensive in

782   some Theronini), which might explain why such a placement was never chosen. However,

783   propodeal carination might evolve in a very non-stationary manner in Ichneumonidae: the

784   earliest branching subfamily, Xoridinae, has complete carination of the propodeum, and the

785   character distribution on the phylogeny [28] suggests that this carination has progressively

786   been reduced in parallel in several of the more derived ichneumonid subfamilies, including

787   Pimplinae. The fact that different sets of propodeal carinae are reduced in different tribes of

788   Pimplinae provides further support for the hypothesis that its ancestor might have had a more

789   complete carination. If this is indeed the case, it would require the use of a directional model

790   of character evolution, such as the one used to study the reduction in hymenopteran wing

791   venation and muscles [13]. However, this model is not currently available for multistate data.

792   *Future directions*

793   Model-based phylogenetics already represents a powerful tool for assessing the

794   relationships among fossil and extant taxa, and the future developments of models of

795   morphological evolution are likely to further improve these estimates. Besides relaxing the

796   assumptions of equal rates among characters [43], symmetry of transition rates [15], and

797   process stationarity [13], morphological data might also evolve with higher differences in

798   effective branch lengths among characters than molecular data [57], even though this remains

799   to be demonstrated. A no-common-mechanism model for morphology [70] would quickly be

800   beyond the scope of any stochastic analysis approach and lead to a strong discrepancy

801   between the number of parameters in the model and available data points from which to

802   estimate them. However, if morphological data can be partitioned according to biological

803   characteristics such as functional units, using separate sets of branch lengths for each

804   partition might still be tractable. An equivalent approach has been taken in the context of a

805   calibrated phylogeny of mammals, where different morphological partitions were allowed to

806   evolve according to a separate relaxed-clock model [71].

807   Another natural extension of our approach would include the ages of fossils to improve

808   their placement, either in the context of morphology-only tip dating [19,20] or combined with

809   molecular data in total-evidence dating [23,72]. This might have a considerable impact; for

810   instance, knowing that a fossil is older than the inferred splits in the crown group would

811   enforce its placement as a stem-lineage representative. However, including age information

812   might interact with the morphology model to produce artefacts, especially if a character

813   evolves far from stationarity on the time scale covered by the phylogeny [13]. Carful model

814   testing would expose such artefacts and improve our understanding of character evolution. In

815   any case, using the context of a calibrated phylogeny to further test the placement of

816   ichneumonid fossils would represent a natural next step and lead to a better understanding of

817   the evolutionary history of this highly species-rich taxon.

1008 **Tables.**

1009   Table 1. Fossil taxa examined. The taxonomy reflects the status before our study; taxa

1010   marked with an asterisk before the genus name are transferred in this study.

Subfamily	Genus	Species	Epoch	Locality
Acaenitinae	*Mesoclistus?*	*yamataroti*	Early Eocene	Green River
Banchinae	*Glypta?*	*transversalis*	Early Eocene	Green River
Labeninae	*Trigonator*	*macrocheirus*	Early/Mid Eocene	Messel
Orthocentrinae	**Plectiscidea*	*lanhami*	Early Eocene	Green River
Phygadeuontinae	*Phygadeuon?*	*petrifactellus*	Early Eocene	Green River
Pimplinae	*Dolichomitus?*	*saxeus*	Early Eocene	Tadushi
Pimplinae	*Scambus*	*fossilobus*	Early/Mid Eocene	Messel
Pimplinae	*Scambus?*	*mandibularis*	Early Eocene	Green River
Pimplinae	*Scambus?*	*parachuti*	Early Eocene	Green River
Pimplinae	*Pimpla?*	*eocenica*	Early Eocene	Green River
Pimplinae	*Xanthopimpla*	*messelensis*	Early/Mid Eocene	Messel
Pimplinae	*Xanthopimpla*	*praeclara*	Early/Mid Eocene	Messel
Pimplinae	*Crusopimpla*	*tadushiensis*	Early Eocene	Tadushi
Pimplinae	*Crusopimpla*	*rediviva*	Late Eocene	Tadushi
Rhyssinae	*Rhyssella*	*vera*	Early/Mid Eocene	Messel
Tryphoninae	*Eclytus?*	*lunatus*	Early Eocene	Green River
incertae subfamiliae	*Carinibus*	*molestus*	Early Eocene	Green River
incertae subfamiliae	*Eopimpla*	*grandis*	Early Eocene	Green River
incertae subfamiliae	**Ichninsum*	*appendicrassum*	Early Eocene	Green River
incertae subfamiliae	**Lithotorus*	*cressoni*	Early Eocene	Green River

incertae subfamiliae	*Mesornatus*	*markovici*	Early/Mid Eocene	Messel
incertae subfamiliae	**Polyhelictes*	*bipolarus*	Early/Mid Eocene	Messel
incertae subfamiliae	*Tilgidopsis*	*haesitans*	Early Eocene	Green River
incertae subfamiliae	*Trymectus*	*amasidis*	Early Eocene	Green River

1011

1012 Table 2. Marginal likelihoods of the different models of morphological evolution as obtained

1013 under stepping-stone sampling.

Model	Unordered Mk	Ordered Mk	Full-state Mk	No ACRV[1]
Run 1	-12,829.9	-12,510.6	-12,711.5	-13,353.5
Run 2	-12,829.8	-12,509.9	-12,713.9	-13,354.3
Run 3	-12,831.6	-12,508.1	-12,712.9	-13,358.9
Run 4	-12,829.8	-12,509.7	-12,710.1	-13,356.3
Mean	-12,830.1	-12,509.1	-12,711.2	-13,354.5
Bayes factor[2]	642.0	-	404.1	1,690.7

1014 [1] ACRV = among-character rate variation

1015 [2] Bayes factor comparison with the best model (ordered Mk). Bayes factors were calculated

1016 as 2*(lnL(Model A) – lnL(Model B)). A Bayes factor larger than 10 is considered very strong

1017 support for Model A.

1018 **Supplementary material.**

1019 Supplementary File S1. Morphological matrix in NEXUS format.

1020 Supplementary File S2. Full list of all coded extant and fossil taxa. Extant specimens

1021 were labeled with a project number (Ichn_#XXXX) and are deposited at the specified

1022 collections. Collection abbreviations: KYU (Department of Entomology, University of

1023 Kentucky, USA), MCZ (Muzeum of Comparative Zoology Harvard), MNHN (Museum

1024 National d'Histoire Naturelle), NHM (Natural History Museum London), NHRM

1025 (Naturhistoriska Rijkmuseet Stockholm), NMB (Naturhistorisches Museum Basel,

1026 Switzerland), NMBE (Naturhistorisches Museum Bern, Switzerland), NMNH (National

1027 Museum of Natural History Smithsonian), PIN (Paleontological Institute of Russian

1028 Academy of Science), SMF (Senckenberg Forschungsinstitut und Naturmuseum), UCM

1029 (University of Colorado Museum of Natural History), WC (Waite Insect collection,

1030 University of Adelaide, Australia), ZMUT (Zoological Museum of the University of Turku,

1031 Finland). For the fossils collections, we provide the collection's individual numbers. The

1032 gender of the coded specimens was indicated by (f) for female and (m) for male.

1033 Supplementary File S3. Description of morphological characters. Illustrated list of the

1034 morphological characters and their states used in this study.

1035 Supplementary File S4. R functions to create RoguePlots and to prepare morphological

1036 matrices that include polymorphisms for analysis.

1037 Supplementary File S5. Complete RoguePlots of the individual fossils.
