Authors' contributions.

RP analysed the data and contributed to the coding of the statistical model, which was developed by MPE and EL. SC provided the tracking data. SB led the project, performed computer simulations, and wrote the first draft of the manuscript, except the part describing the model which was first contributed to by MPE, EL and RP. All authors contributed significantly to the final manuscript.

Key-words: movement ecology, segmentation, clustering, foraging, home range, area-concentrated searching, transit, migration

Abstract

1. Recent advances in bio-logging open promising perspectives in the study animal movements at numerous scales. It is now possible to record time-series of animal locations and ancillary data (e.g. activity level derived from on-board accelerometers) over extended areas and long durations with a high spatial and temporal resolution. Such time-series are often piecewise stationary, as the animal may alternate between different stationary phases (i.e. characterised by a specific mean and variance of some key parameter for limited periods). Identifying when these phases start and end is a critical first step to understand the dynamics of the underlying movement processes.
2. We introduce a new segmentation-clustering method we called segclust2d. It can segment bi- (or more generally multi-) variate time-series and possibly cluster the various segments obtained, corresponding to phases assumed to be stationary. It is easy to use, as it only requires specifying the minimum length of a segment (to prevent over-segmentation) based on biological considerations.
3. Although this method can be applied to time-series of any nature, we focus here on two-dimensional piecewise time-series whose phases correspond at small scale to the expressions of different behavioural modes such as transit, feeding and resting, as characterised by two joint metrics such as speed and turning angles or, at larger scale, to temporary home ranges, characterised by stationary distributions of bivariate coordinates.
4. Using computer simulations, we show that segclust2d can rival and even outperform previous, more complex methods, which were specifically developed to highlight changes in movement modes or home range shifts (based on Hidden Markov or Ornstein-Uhlenbeck modelling, respectively), which, contrary to our method, require truly informative initial guesses to be efficient. Furthermore we demonstrate it on actual examples involving a zebra's small scale movements and an elephant's large scale movements, to illustrate the identification of various movement modes and of home range shifts, respectively.

1 Introduction

2 Landscapes are spatially and temporally variable at various scales (Levin, 1992), and animals are expected
3 to adjust their movements to the characteristics of their local environment, so as to maximize the time spent
4 in profitable (or safe) habitats and minimize time in adverse ones (Pyke, 1978). Recent advances in bio-
5 logging have made it possible to acquire time-series of animal's locations, and possibly ancillary data such
6 as activity level derived from on-board accelerometers, over extended areas and long durations with high
7 spatial and temporal resolutions. Such locational time-series, and the other ones that can be derived from
8 them to describe the movement behaviour (e.g. turning angle, speed), are therefore expected to be piecewise
9 stationary, i.e. to present a specific mean and variance for limited periods corresponding to stationary phases,
10 alternating with rapid transition phases corresponding to changes of area or behaviour. Identifying these
11 phases is a prerequisite to determine the biologically relevant scales of movement (Benhamou, 2014). It is
12 therefore of paramount importance in two types of movement studies:

13 **Identifying behavioural modes.** Foragers are generally expected to alternate intensive (area-concentrated)
14 searching mode, characterized by high tortuosity and low speed, and extensive searching (transit) mode, char-
15 acterized by low tortuosity and high speed (see Dias et al. 2009 for contrasting examples). This alternation
16 of searching modes therefore results in piecewise "behavioural stationarity" when considering time-series
17 of tortuosity and speed. Although different segmentation approaches have been developed to identify be-
18 havioural modes by looking at breakpoints (i.e. rapid transitions between stationary phases Barraquand and
19 Benhamou, 2008; Gurarie et al., 2009; Nams, 2014), a more sophisticated approach based on Hidden Markov
20 Models (HMM) has gained momentum in recent years. In this approach, the joint step lengths and turning
21 angles calculated from successive relocations are categorized among a predefined number of different modes
22 modelled as hidden states (Morales et al., 2004; Beyer et al., 2013; Langrock et al., 2012; McClintock et al.,
23 2012; Michelot et al., 2016). However, the convergence of HMM may require specifying informative initial
24 state-dependent probability distribution parameters (i.e. informative priors when HMM are designed in a
25 Bayesian context), which can be difficult. Here, we aim at developing an alternative approach which does
26 not require such a pre-specification.

27 **Identifying home range shifts.** The recently emerging question of piecewise "locational stationarity"
28 at the home range scale has been addressed in terms of movement scales (Benhamou, 2014), migration
29 characteristics (Naidoo et al., 2012; Cagnacci et al., 2016) and of within-season shifts (Couriot et al., 2018).
30 Indeed, for an animal that exploits various temporary home ranges, the time-series of relocations coordinates
31 can be assumed to be stationary for a relatively long time (when the animal exploited the area where it
32 established its temporary home range), then non-stationary for a relatively short time (when the animal left
33 its home range until it established a new one), and so on. It is worth noting that a shift in home range does
34 not necessarily involve a shift in mean location. It may also correspond to a change in variance if the animal
35 enlarged or shrank its home range, e.g. due to a change in season (Naidoo et al., 2012; Monsarrat et al., 2013)
36 or in reproductive status. Various methods have been proposed to detect home range shifts. The simple
37 univariate approach based on the change of the beeline distance from a starting point (Bunnefeld et al.,
38 2011) appears to be convenient in some cases but fully ignores movements leading the animal at a similar
39 distance from the starting point but in another direction. A more complex approach rests on multi-state
40 Ornstein-Uhlenbeck modelling (OUM Breed et al., 2017; Gurarie et al., 2017). However, as it requires that
41 all home range phases and shifts are explicitly modelled, this approach tends to become cumbersome when
42 there are several shifts to consider. Furthermore, it may require truly informative initial guesses to correctly
43 detect small shifts. We therefore aim at developing an alternative approach that could be more efficient
44 than an OUM-based approach to detect home range shifts and simpler to use. Additionally, as detecting
45 shifts in behavioural modes and in home ranges settlements are conceptually similar, we focused on a generic
46 approach that can be applied to both types of studies.

47 Here we introduce a new method, called `segclust2d`, able to segment a bi- (and more generally multi-)
48 variate time-series, and to cluster similar segments (corresponding to stationary phases) in a common class
49 (corresponding to a given state) if desired. We demonstrate that this method, which is easy to use, can
50 successfully identify stationary phases corresponding to temporary home ranges when based on bivariate
51 locational time-series, as well as movement modes when based on bivariate time-series of metrics such as
52 speed and tortuosity. It thus offers an efficient and user-friendly alternative to previous, more complex,
53 approaches. Furthermore, as this model applies to multivariate piecewise stationary time-series based on

54 any kind of metrics, it can integrate additional time-series of ancillary data (e.g. activity level derived from
55 on-board accelerometers) for a better segmentation-clustering of movement data.

56 2 Methods

57 2.1 Statistical model and parameter estimation

58 **General principle.** Consider a multivariate piecewise stationary time-series assumed to be regular (no
59 gaps), composed of an unknown number of stationary phases. The C components of this signal (each
60 corresponding to a univariate time-series) are assumed to be statistically independent (conditionally to the
61 stationary phases) and should be normalized if they are of different nature, so as to have the same weight
62 in subsequent procedures. One needs a reliable statistical model to find and characterize these phases and
63 possibly to cluster them when they are assumed to be the expressions of a limited number of unobserved
64 states of the underlying process (e.g. behavioural modes). Likelihood-based segmentation methods provide
65 a suitable statistical framework to detect changes of phases but raise two main issues from a statistical and
66 algorithmical point of view: (i) determining the optimal number of segments and (ii) for a given number of
67 segments, finding the optimal segmentation, i.e. determining the locations of the starting/ending points of
68 the segments (called breakpoints). The latter reduces to a well-known discrete optimization problem solved
69 using a dynamic programming algorithm introduced by Bellman (1954; for a recent example, see Rigaiil
70 2015). With n sites where the signal can be cut and K segments, the dynamic programming algorithm
71 reaches the exact maximum likelihood solution with a complexity in $O(n^2K)$, drastically smaller than the
72 complexity in $O(n^K)$ involved by a force brute algorithm when exploring the whole segmentation space. We
73 will first introduce the models and the estimation procedure to optimally segment a multivariate signal for
74 a predefined number of segments K and possibly (if clustering is required) a predefined number of states
75 M . Afterwards, we will show how the optimal number of segments and possibly of clusters can be found
76 based on a penalized likelihood criterion. Our approach is based on Lavielle (2005)'s segmentation method
77 of univariate signals and its extension by Picard et al. (2007) to segment and cluster DNA sequences without
78 assuming any kind of distribution for the segment lengths, such as a geometric distribution as HMM implicitly

79 do (Karlin and Taylor, 1975).

80 **Optimal segmentation in K segments, with optional clustering in M states.** Assume that there
81 are K stationary phases in a bivariate time-series with total length n . A stationary phase corresponds to a
82 segment. It is defined by a sequence of consecutive random variables sharing the exact same distribution,
83 in particular the same mean $\boldsymbol{\mu}$ and variance matrix $\boldsymbol{\sigma}^2$. As soon as one of these parameters changes, a
84 new segment starts. The C components within a given segment $k \in [1, \dots, K]$ starting at time $t = t_{k-1} + 1$
85 and ending at time $t = t_k$ (with $t_0 = 0$ and $t_K = n$) are modelled as sequences of Gaussian independent
86 random variables bY_t , for $t = 1, \dots, n$. In the absence of clustering (segmentation-only model), bY_t (with C
87 components labelled 1 to C) at time t is modelled simply as follows:

$$\mathbf{Y}_t \sim \mathcal{N}(\boldsymbol{\mu}_k, \boldsymbol{\sigma}_k^2) \text{ with } \boldsymbol{\mu}_k = \begin{pmatrix} \mu_{k,1} \\ \mu_{k,\dots} \\ \mu_{k,C} \end{pmatrix} \text{ and } \boldsymbol{\sigma}_k^2 = \begin{pmatrix} \sigma_{k,1}^2 & 0 & 0 \\ 0 & \sigma_{k,\dots}^2 & 0 \\ 0 & 0 & \sigma_{k,C}^2 \end{pmatrix} \quad (1)$$

88 where $\boldsymbol{\mu}_k$ and $\boldsymbol{\sigma}_k^2$ are the mean and variance matrix for segment k . As the model parameters to be esti-
89 mated vary independently between segments, dynamic programming can be used to segment the multivariate
90 signal at best in K segments. Its application is straightforward in this case, as it relies on the log-likelihood
91 of each segment, which is simply equal to the sum of the log-likelihoods of the C components.

92 In the segmentation-clustering model, a state m , among M possible states, is assigned to every segment,
93 and random variables within a segment classified in state m are all assumed to share the same mean $\boldsymbol{\mu}_m$
94 and the same variance $\boldsymbol{\sigma}_m^2$, different from those involved in other states. More formally, let (S_k) , with
95 $k = 1, \dots, K$, denote the state of the segment k : S_k is a latent random variable taking values in $[1, \dots, M]$.
96 It is modelled through a multinomial distribution of parameters $\boldsymbol{\pi} = (\pi_m)$ with $m = 1, \dots, M$, where π_m
97 corresponds to the probability for a segment to belong to state m . Given $S_k = m$, the value of the bivariate

98 signal at time t , \mathbf{Y}_t , is therefore modelled as:

$$\mathbf{Y}_t | S_k = m \sim \mathcal{N}(\boldsymbol{\mu}_m, \boldsymbol{\Sigma}_m) \text{ with } \boldsymbol{\mu}_m = \begin{pmatrix} \mu_{m,1} \\ \mu_{m,\dots} \\ \mu_{m,C} \end{pmatrix} \text{ and } \boldsymbol{\sigma}_m^2 = \begin{pmatrix} \sigma_{m,1}^2 & 0 & 0 \\ 0 & \sigma_{m,\dots}^2 & 0 \\ 0 & 0 & \sigma_{m,C}^2 \end{pmatrix} \quad (2)$$

99 As parameters $(\pi_m, \boldsymbol{\mu}_m, \boldsymbol{\sigma}_m^2)$ that characterise any state m are unknown and are to be estimated, resulting
100 in a mixture distribution where segments are linked in terms of parameters, the optimal segmentation cannot
101 anymore be obtained using dynamic programming alone. Following Picard et al. (2007), we designed the
102 following two-step procedure, which is iterated up to convergence.

- 103 1. Given a set of parameters $(\pi_m, \boldsymbol{\mu}_m, \boldsymbol{\sigma}_m^2)$ with $m = 1, \dots, M$, the best segmentation in K segments is
104 obtained using dynamic programming.
- 105 2. Given this segmentation, the values of parameters are estimated using an expectation-maximization
106 algorithm which is commonly used in latent variable modelling (Dempster et al., 1977).

107 By mixing dynamic programming and expectation-maximization through this iterative procedure, seg-
108 mentation and clustering processes work jointly (rather than the latter after the former) leading to the
109 optimal segmentation given K and M . However, an additional smoothing procedure is required to solve
110 possible convergence issues (see details in Supporting information 1).

111 **Finding the optimal numbers of segments and states.** For both methods (segmentation-only and
112 segmentation-clustering), a minimum segment length L_{min} has to be set not only to speed up the algorithm,
113 but also, more fundamentally, to prevent over-segmenting, based on biological considerations. For example,
114 setting L_{min} to a value of a few weeks when analysing locational time-series will prevent the algorithm from
115 considering an area exploited only for a few days, corresponding to foray outside the usual home range or to
116 stop-over during migration, as a distinct home range. Similarly, setting L_{min} to a value of several minutes
117 when looking for changes in behavioural modes will prevent force the algorithm to assign a given movement
118 bout to a given behavioural mode only if this bout is long enough, even though it may be punctuated by
119 ephemeral events related to another behaviour. To obtain the optimal solution, we calculated the likelihood

120 of all number of segments $K < K_{max} = \lfloor \frac{n}{L_{min}} \rfloor$, and for any number of states $M (< K)$ one wishes to
121 consider if clustering has to be involved. In this case, the optimal values of K and M are determined as
122 those that maximize a Bayesian Information Criterion (BIC; Schwarz et al. 1978)-based penalised likelihood
123 (Supporting information 1). However, as it will be shown in the Results section, it is usually preferable
124 to consider a single value of M based on biologically relevant grounds than to let the model determine an
125 optimal number of states based on a statistical basis (see also Pohle et al. 2017). When only segmentation
126 is involved (no clustering), the optimal number of segments K is based in agreement with Lavielle (2005) on
127 maximizing a K-penalized likelihood curve (Supporting Information 1).

128 2.2 Computer simulations

129 We run simulations to assess the ability of our approach to detect home range shifts and changes in be-
130 havioural modes from bivariate time-series, and to compare it with that of other (OUM-based and HMM-
131 based) methods. For each set of parameters of each type of simulation, we simulated 100 replicates. Distances
132 are expressed in arbitrary unit length u .

133 **Home range shifts.** For simplicity, the animal was assumed to behave as a central place forager. We
134 simulated its fine-scale movement as a central-place biased correlated random walk, which results in a
135 probability of presence decreasing exponentially with the distance D to the central place (Benhamou, 1989):
136 at each time step, the animal turns by an angle α_i drawn from a wrapped Gaussian distribution with a null
137 mean and standard deviation $\sigma_i = \sigma_0 \left[1 + \frac{D_i - D_{i-1}}{2} \right]$, and progresses by 1 unit length ($1u$) in the new
138 direction. In a batch of simulations, σ_0 was set to 0.5 radians, and the central place was first set at a given
139 location for the first 10,000 time steps (phase 1), then shifted to another location by $60u$ in both X and Y for
140 10,000 additional time steps (phase 2), resulting in disjoint home ranges, and then shifted to a third location
141 by $20u$ in both X and Y for 10,000 additional time steps (phase 3), resulting in overlapping home ranges.
142 In another batch of simulations, the central place remained at the same location for the 30,000 time steps,
143 but σ_0 was set to 0.7 radians for time steps 10,001 to 20,000 (phase 2) and to 0.5 radians otherwise (phases
144 1 and 3), involving a transitory enlargement of the home range. We finally sub-sampled the data sets by
145 keeping one location every 60. The home range phases were then defined by 166 locations each, with low

146 serial correlation, and were thus similar to actual datasets that are commonly used in home range studies.
147 Note that in our approach that focuses on the contrast between the stationary phases, the actual lengths of
148 these phases do not matter, provided they are longer than L_{min} .

149 **Changes in behavioural modes.** We simulated a random search movement as a correlated random walk
150 where three types of activity – immobility (resting or standing), intensive (area-concentrated) searching
151 and extensive searching (transit) – alternate, each one lasting 20 time steps, this 60-step sub-series being
152 repeated 5 times. The step lengths L_i were drawn from a log-normal distribution with a mean equal to
153 $0.5u$ in the intensive mode or $1.0u$ in the extensive mode, and with a standard deviation equal to 1/10th of
154 the mean in both modes. Turning angles α_i were drawn from a wrapped Gaussian distribution with a null
155 mean and a standard deviation equal to 0.4 radians in the intensive mode or 0.3 radians in the extensive
156 mode. To mimic possible factors (e.g. GPS recording noise) that can blur the contrast between the modes,
157 the locations obtained in this way, as well those obtained for immobility phases, were submitted to bivariate
158 Gaussian random noise with a null mean and various standard deviations ζ . Note that in order to assess
159 the ability of a method to segment a behavioural time-series, the precise movement rules used in simulations
160 are not important. What really matters is the contrast between the different phases: with a high contrast,
161 all methods should work well, whereas with a low contrast, all methods should fail, whatever the movement
162 rules considered. In the results section, we will present the results obtained with a standard deviation of
163 the noise ζ set to 0.3, involving a moderate contrast between the three modes. The results obtained with
164 a lower noise ($\zeta = 0.2$; high contrast) or higher noise ($\zeta = 0.4$; low contrast) are provided in Supporting
165 Information.

166 **2.3 Metrics**

167 For identifying home range shifts, the two signal components considered are orthonormal Cartesian coordi-
168 nates (x_i, y_i) of locations (GPS locations expressed in decimal degrees as longitude and latitude therefore
169 require to be transformed in terms of easting and northing through a classical projection such as UTM). For
170 identifying behavioural modes, the two components usually considered in HMM-based approaches are the
171 classical metrics corresponding to the step lengths L_i and the turning angles α_i , computed from locations

172 recorded at constant time intervals Δt , and therefore acting as proxies for linear $\left(\frac{L_i}{\Delta t}\right)$ and angular $\left(\frac{\alpha_i}{\Delta t}\right)$
173 speeds, respectively. We used such metrics for comparative purpose, but we also tested some variants, as-
174 sumed to improve the contrast between the different modes. We computed the linear speed as $\frac{L_i + L_{i+1}}{2\Delta t}$.
175 Although this basic smoothing introduces some serial correlation which is not taken into account in our
176 model, it should result in a less noisy signal. Furthermore, angular speed may show faded changes between
177 searching modes because the intensive mode usually involves both a decrease in linear speed and an increase
178 in path tortuosity but angular speed mechanically increases with both of them (Benhamou and Bovet, 1989;
179 Barraquand and Benhamou, 2008).

180 We therefore computed turning angles α_i^* based on a constant step length r rather than at constant time
181 interval. For this purpose, each location $\mathbf{X}_i = (X_i, Y_i)$ is considered the centre of a virtual circle with radius
182 r , and the entrance and exit locations P_{en} and P_{ex} are determined through linear interpolation (Appendix
183 2). The turning angle α_i^* is then computed in $[-\pi, \pi]$ as the angular deviation between vectors $P_{en} \rightarrow X_i$
184 and $X_i \rightarrow P_{ex}$ (both with length r) rather than vectors $X_{i-1} \rightarrow X_i$ (with length L_i) and $X_i \rightarrow X_{i+1}$
185 (with length L_{i+1}) as done to compute α_i . When both L_i and L_{i+1} are larger than r , one gets $\alpha_i^* = \alpha_i$,
186 whereas α_i^* tends, on average, to be larger (random search paths) or smaller (directed paths) than α_i when
187 r is larger. We set r to the median of the step length distribution. In our simulations, we noticed that
188 using a larger radius tends to improve the discrimination between the fast and slow movement modes but
189 to worsen the discrimination between the slow movement mode and the immobility mode. We also tested
190 the two orthogonal signals provided by the 'persistence speed' $\frac{L_{i+1}\cos(\alpha_i)}{\Delta t}$ and 'turning speed' $\frac{L_{i+1}\sin(\alpha_i)}{\Delta t}$
191 (Gurarie et al., 2009; Gloaguen et al., 2015).

192 2.4 Practical implementation of the method

193 Both `segclust2d` procedures (segmentation-only and segmentation-clustering) have been currently imple-
194 mented to work on bivariate times-series (the only ones we considered in this paper) in a R package
195 (<https://cran.r-project.org/package=segclust2d>), which optionally allows K_{max} to be set to a value lower
196 than $\lfloor \frac{n}{L_{min}} \rfloor$ for preventing the algorithm from wasting time in looking for unlikely solutions. An integrated
197 module makes it possible to derive the various movement variables mentioned in this paper from locations

198 data. Because our approach requires large amounts of computer memory, it cannot deal with too long
199 time-series (i , 10000 values) on small desktop computers. To circumvent this limit, some sub-sampling is
200 automatically performed when necessary. It is worth noting however that, even in absence of any mem-
201 ory constraints, it is usually not a good practice to attempt to directly segment very long series, which
202 encompass both very large scale phenomena thanks to their large extent and very small scales phenomena
203 thanks to their high resolution. Indeed, small-scale data are usually not relevant for analysing large-scale
204 patterns and therefore act more as noise than as information in this context. Thus, in home range simula-
205 tions, subsampling by a factor 60 makes it possible to dramatically shorten the time-series by eliminating
206 fine-scale movements (klinokinetic process), which are characterised by a high level of serial correlation in
207 location and in direction. Such details are clearly not relevant for the question of home range shifts, where
208 only the overall phase-dependent mean and/or the variance of locations matter (accordingly, our approach
209 ignores serial correlations occurring in any stationary phase). Conversely, for fine-scale movement studies,
210 the characteristics of the environment are liable to change (e.g. due to seasonal variations) when considering
211 a time-series running over an extended duration, possibly leading to change in the characteristics of the
212 behavioural classes expected. It appears therefore preferable to consider the various phases (e.g. seasons)
213 separately rather than to attempt to deal with the long time-series as a whole.

Figure 1: **Examples of segmentation-only of simulated movements using segclust2d to highlight home range phases and shifts.** Top panels show the simulated paths (after 1/60 subsampling) corresponding to three home range phases (two shifts), either in mean location (a) or in variance (b). The corresponding time series for both location coordinates (x, y) are presented in panel (c) and (d), respectively. The horizontal colour bars running along the time axis show the true occurrences of the three phases, whereas the coloured bands appearing over the x and y signals show their occurrences as estimated using the segclust2d/segmentation-only method (with $L_{min} = 45$ locations, i.e. 2700 unit times) and provide the estimated mean (plain horizontal line running in the middle of the band) \pm standard deviation (band width) for each segment separately.

a Shifts in mean location – path

b Shifts in variance – path

c Shifts in mean location – series

d Shifts in variance – series

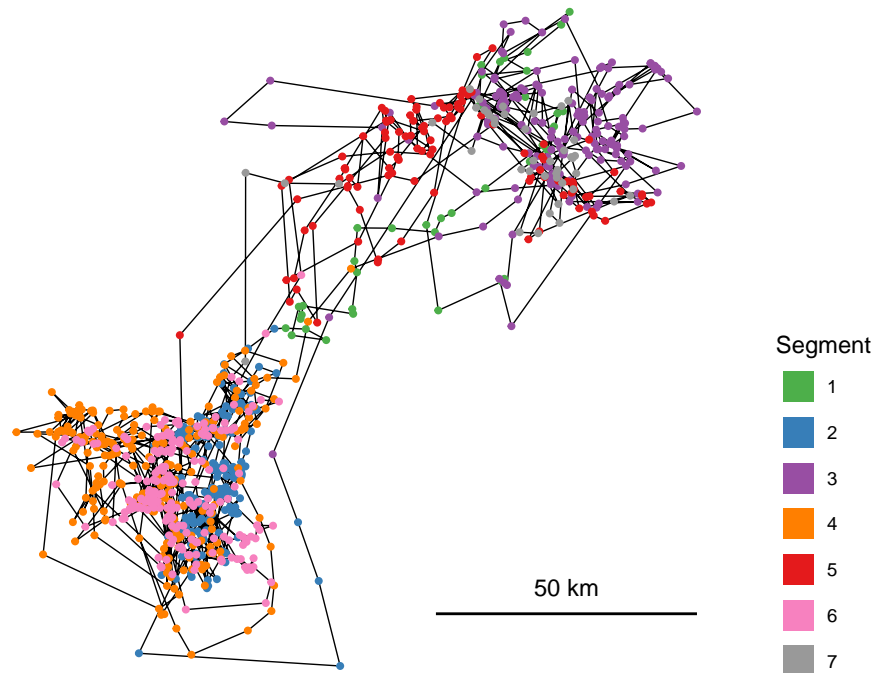

Figure 2: **Example of segmentation-only of an African elephant's movement recorded over 1000 days using segclust2d to highlight home range phases and shifts.** (a) Rough path representation obtained by linking the locations subsampled so as to keep a single GPS location per day; (b) Corresponding time series of locations coordinates (easting and northing). The coloured bands appearing over the time series show the estimated mean (plain horizontal line running in the middle of the band) \pm standard deviation (band width) of each of the seven segments obtained using the segmentation-only method with $L_{min} = 30$ days.

214 3 Results

215 3.1 Identifying home range shifts

216 **Simulated movements.** Figure 1 shows an example where the central place of the home range was shifted
217 by $60u$ between phases 1 and 2, and by $20u$ between phases 2 and 3, in both easting (X) and northing (Y),
218 and an another example where the home range was enlarged during the phase 2 with respect to phases 1
219 and 3. The segclust2d/segmentation-only procedure (with Lmin set to 45 locations, corresponding to 2700
220 time steps because of the 1/60 subsampling) was able to correctly determine the true number of phases (3)
221 in 98 out of the 100 replicates involving shifts in mean location (i.e. central place), and 88 out of the 100
222 replicates involving shifts in variance (i.e. change in home range size). In contrast, the OUM-based algorithm
223 "marcher", which was specifically developed by Gurarie et al. (2017) to identify home range shifts in mean
224 location, requires that the number of shifts has been specified, and is unable to detect shifts in variance.
225 When the true number of phases (3) has been specified, our approach was able to correctly estimate the
226 occurrences of the various shifts (mean \pm SD = 10152 ± 79 and 20092 ± 188 time units for the $60u$ and $20u$
227 shifts in mean location, respectively; mean \pm SD = 10035 ± 1184 and 19942 ± 1314 time units for the first and
228 second shifts in variance of the same amplitude). When the actual home range centres and shift dates were
229 provided as truly informative initial guesses to Gurarie et al. (2017)'s method, it was also able to correctly
230 detect the two shifts in mean location (mean \pm SD = 10152 ± 82 and 19967 ± 239 time units for the $60u$ and
231 $20u$ shifts in mean location, respectively). In contrast, when no information was provided, Gurarie et al.
232 (2017)'s method, which then relies on a k-means procedure to get initial guesses, was still able to detect the
233 large shift in location (mean \pm SD = 10152 ± 937 time units) but was unable to detect the small one (the shift
234 occurred at random between 15000 and 30000 time units, based only on 75 replicates, as the algorithm failed
235 to provide any result for 25 replicates).

236 **Illustrative example.** We used the GPS track of an African Elephant (*Loxodonta africana*), recorded
237 for > 2.5 years to illustrate the way the segclust2d/segmentation-only procedure can identify home ranging
238 phases and shifts (Fig. 2). Considering that a time-series is (roughly) stationary when the partial means
239 and variances obtained for its first and second halves or for its three thirds are not markedly different, the
240 whole time-series of easting and northing coordinates can be said to be both stationary, corresponding to
241 a large multiannual (possibly lifetime) home range, and piecewise stationary, corresponding to temporary
242 (possibly seasonal) smaller home ranges. It can therefore be segmented to highlight these temporary home
243 ranges and shifts between them. However, some of the phases so highlighted are clearly nonstationary. In
244 particular, segments 1 and 5 correspond mainly to a slow south-westwards migration (rather than a temporary
245 home range) between the two core areas of the multiannual home range. Segment 2 also corresponds to a
246 nonstationary, migratory (southwards moving) phase, which went through an area used as a temporary home
247 range during segments 4 and 6. This indicates that a same area can be used in different ways at different
248 periods.

249 3.2 Identifying behavioural modes

250 **Simulated movements.** An example of path with three behavioural modes (extensive searching, intensive
251 searching and resting) is shown in Fig. 3 with the corresponding time-series in terms of turning angle α_i^* and
252 smoothed speed $\left(\frac{L_i + L_{i+1}}{2\Delta t}\right)$. In this example, the segclust2d/segmentation-clustering procedure appears
253 able to detect the true number of modes ($M = 3$) and to attribute almost all locations to the right mode.
254 We compared our method with a HMM-based method specifically designed to deal with movement data
255 (Michelot et al., 2016; McClintock and Michelot, 2018) when the true number of modes has been specified.
256 The results obtained from 100 replicates showed that our procedure rivals with the HMM-based method
257 although the latter was helped by initial state-dependent probability distribution parameters which were
258 tuned to their true values for each behavioural state (Fig. 4 with medium noise level $\zeta = 0.3$). With very
259 low noise level ($\zeta = < 0.2$), an excellent fit was obtained with all methods and metrics considered, whereas
260 with a very high noise level ($\zeta = > 0.4$) the percentage of correct state assignment became closer to the value
261 expected for a random assignment (33%; see Supporting information 3.1 results with $\zeta = 0.2$ and $\zeta = 0.4$).

262 It also appeared that, as expected, the angular $\left(\frac{\alpha_i}{\Delta t}\right)$ and linear $\left(\frac{L_i}{\Delta t}\right)$ speeds are not the most suitable
263 the metrics for detecting behavioural changes. Thus, better results were obtained with both methods when
264 using any other of the couples of metrics considered. The best fits were obtained with turning angle α_i^* or
265 its absolute value $|\alpha_i^*|$ and smoothed speed. When the true number of modes is unknown, our method can
266 also estimate this number as the most likely number of clusters, but the fraction of correct estimate is too
267 low to consider the result as reliable (Supporting information 3.2).

268 **Illustrative example.** We used a 24-h GPS track of a plains zebra (*Equus quagga*) to illustrate the way the
269 segclust2d/segmentation-clustering procedure can identify the occurrences of the various movement modes
270 (Fig. 5). Although that, in this example, the most likely number of modes was estimated to be five, we
271 present the segmentation obtained when setting this number to three, assuming that the biologically relevant
272 modes should be resting (or any other non-moving behaviour such as standing), feeding and transiting (the
273 other two modes detected by our procedure when using five modes were assumed to correspond to mixed
274 behaviours).

Figure 3: **Comparative performances of segclust2d/segmentation-clustering vs. a HMM-based method for highlighting behavioural changes.** The boxplots show the proportion of correct state assignments, obtained for various bivariate signals when the true number of states is known ($M = 3$), as estimated from 100 replicates simulated with the same parameters as to the one illustrated in fig. 4 (noise $\zeta = 0.3$). The star (*) indicates turning angles computed with a constant step length, in terms of arithmetic (α_i^*) or absolute ($-\alpha_i^*$) values. The white boxplots show the results obtained with HMM-based R package `momentuHMM` (McClintock and Michelot, 2018), with Gaussian priors set to the true means and variances of the various metrics in the different states. The grey boxplots shows the results obtained using `segclust2d/segmentation-clustering` with $L_{min} = 10$.

Figure 4: **Example of segmentation-clustering of a 24-h zebra's movement using segclust2d to highlight behavioural changes.** (a) Path representation obtained by linking GPS locations recorded every 8 minutes; (b) Determination using BIC-based penalised likelihood of the most likely numbers of states ($M = 5$) and segments ($K = 20$) (big orange dot), and most likely numbers of segments for the other number of states considered (large squares at the top of the curves), with $L_{min} = 5$ (i.e. 40 min.). (c) Corresponding time-series in terms of absolute turning angle computed with a constant step length, $-\alpha_i^*$, and smoothed speed, $\frac{L_i + L_{i+1}}{2\Delta t}$, segmented with $M = 3$ (leading to $K = 15$); the coloured bands appearing over the two time-series show the estimated occurrences and mean (plain horizontal line running in the middle of the band) \pm standard deviation (band width) for each of the three clusters considered.

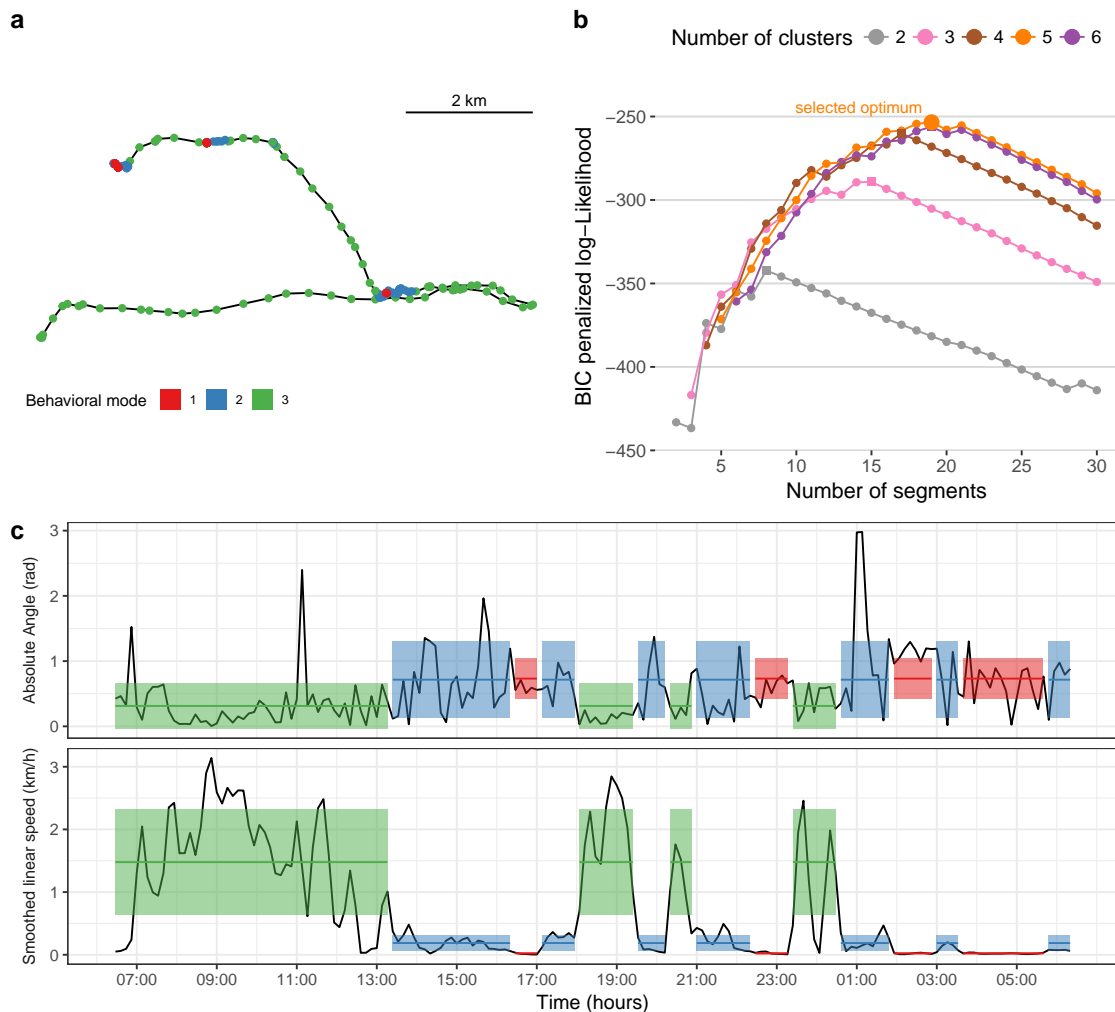

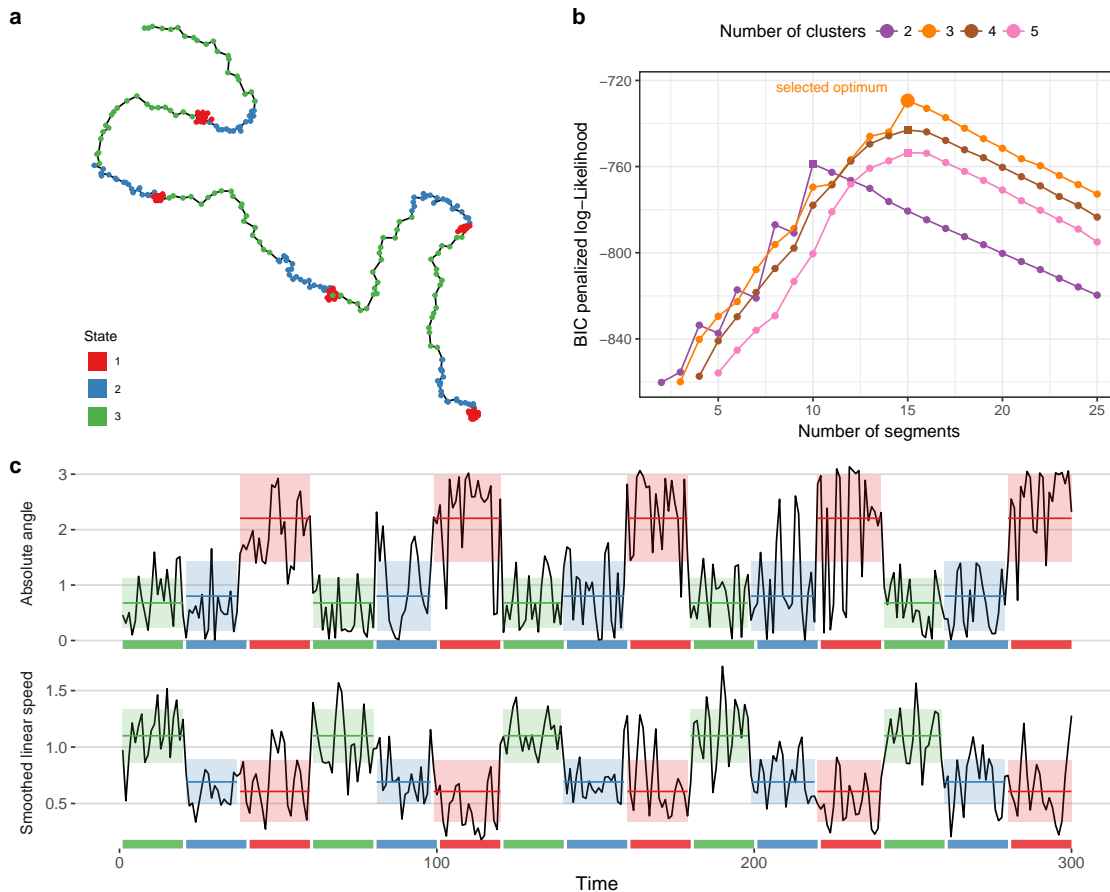

Figure 5: **Example of segmentation-clustering of a simulated movement using segclust2d to highlight behavioural changes.** (a) Simulated path as a composite correlated random walk, with additional noise $\zeta = 0.3 u$; (b) Determination using BIC-based penalised likelihood of the most likely numbers of states ($M = 3$) and segments ($K = 15$) (big orange dot), and of the most likely number of segments for the other three numbers of states considered (large squares at the top of the curves). (c) Corresponding time-series in terms of absolute turning angle computed with a constant step length, $-\alpha_i^*$, and smoothed speed, $\frac{L_i + L_{i+1}}{2\Delta t}$, segmented with $L_{min} = 10$ and $M = 3$; the coloured bands appearing over the two time-series show the est +/- standard deviation (band width) for each of the three movement modes whereas the horizontal colour bars running along the time axis show the true occurrences of these modes.

275 4 Discussion

276 We showed that a generic method, `segclust2d`, that extends Lavielle (2005)'s and Picard et al. (2007)'s
277 methods to multivariate time-series makes it possible to reliably detect two types of changes that are of
278 key importance when studying free-ranging animal movements: home range shifts, based on bivariate time-
279 series of location coordinates (segmentation-only procedure), and changes in behavioural modes, based on
280 bivariate time-series of turning angles and speed (segmentation-clustering procedure). In any case, this new
281 method is straightforward to parameterize: the user has just to set the minimum segment length (L_{min})
282 to a biologically relevant value so as to prevent the time-series from being over-segmented. Nevertheless, it
283 proved to work at least as well as, and often better than, other recent methods specifically designed to deal
284 with either home range shifts (Gurarie et al., 2017) or changes in behavioural modes (Michelot et al., 2016;
285 McClintock and Michelot, 2018)

286 Breed et al. (2017) and Gurarie et al. (2017) independently developed an OUM-based method to identify
287 home range shifts in mean location. Using computer simulations, we compared this approach, as implemented
288 in Gurarie et al.'s "marcher" algorithm, with `segclust2d/segmentation-only`. Both Gurarie et al. (2017)'s
289 and our method are well able to detect large shifts in mean location. However, our method is also able to
290 detect small shifts in mean location, whereas Gurarie et al. (2017)'s one requires a priori information on the
291 actual mean locations and the shifts dates to correctly detect them, although this is precisely in this case
292 that such information is usually lacking (i.e., they can hardly be guesstimated from visual inspection of the
293 data). Furthermore, contrary to Gurarie et al. (2017)'s method, our method can work with any number
294 of shifts, and is furthermore able to correctly estimate the number of shifts by itself in most cases, and it
295 is also able to reveal changes in home range size. Yet, to be efficient, it does not require any more or less
296 informative initial guess. It simply requires specifying a minimum length (L_{min}) for stationary phase to be
297 called a temporary home range, shorter phases being assumed to correspond to transitory exploitations of
298 restricted areas rather than to home ranges. However, contrarily to our method, which considers migrations
299 as simple breakpoints, Gurarie et al. (2017)'s method can estimate the duration of migrations.

300 The elephant we considered in our illustrative example tended to move back and forth between two
301 main areas. This kind of space use is common in migrating birds that commute between reproductive and

302 wintering home ranges. However, there are numerous studies showing more complex patterns, with an animal
303 setting several distinct temporary home ranges successively (Naidoo et al., 2012; Benhamou, 2014; Cagnacci
304 et al., 2016; Couriot et al., 2018). The segmentation of a long piecewise locational time-series in phases
305 corresponding to temporary home ranges opens promising perspectives to understand how the occurrences
306 and durations of home ranges are related to environmental co-variates, which is a prerequisite to infer long-
307 term consequences for population distribution (Mueller and Fagan, 2008). The elephant illustrative example
308 also shows that, although the model underlying `segclust2d` looks for stationary phases, there is no guaranty
309 that all segments obtained are really stationary. This occurs because changes between stationary phases are
310 modelled as breakpoints but may in fact correspond to slow progressive changes.

311 Since the pioneering paper by Morales et al. (2004), HMM-based methods have often been considered the
312 best way to detect changes in behavioural modes of remotely tracked animals. An alternative approach was
313 proposed by Barraquand and Benhamou (2008). It consisted in computing the series of residence time within
314 a virtual circle running along the path and to search for the most likely breakpoints using Lavielle (2005)'s
315 univariate segmentation method. However, although the residence time provides a simple and reliable uni-
316 variate signal easy to segment and interpret, the values obtained depend not only on the type of behaviour
317 that is performed but also on how long it is performed, preventing the segments corresponding to the same
318 behaviour from being easily clustered. In the present study, we show that the `segclust2/segmentation-`
319 `clustering` procedure rivals a HMM-based method when applied to the bivariate signal provided by the two
320 classical metrics that are linear and angular speeds. Importantly, contrarily to what occurs with HMM-based
321 methods, such performance is reached without the need to specify any informative initial state-dependent
322 probability distribution parameters. With both types of method, better results were obtained when using
323 other metrics such as smoothed speed and turning angle measured at constant step length, which were ex-
324 pected to improve the contrast between the intensive and extensive searching modes. Interestingly, using
325 absolute rather than signed values of turning angles measured at constant step length works at best with our
326 method whereas right and left turns were balanced in any mode in our simulated movements. Such metrics
327 should be particularly useful to distinguish between intensive and extensive modes when the former involves
328 turning systematically right or left, i.e. characterized by markedly either negative or positive mean turning

329 angles, whereas the latter involves balanced turning, as occurs in some species (e.g. Smith, 1974). As it
330 results also in a reliable identification when turns are balanced in both intensive and extensive searching, we
331 recommend using it systematically when using our method to distinguish between extensive and intensive
332 searching phases.

333 In the illustrative example on zebra's movements, five behavioural modes were detected by the segclust2d/segmentation-
334 clustering procedure in the time-series of smoothed speed and absolute value of the turning angles measured
335 at constant step length. Nevertheless, based on behavioural observations, we chose to segment the time-
336 series with only three modes assumed to correspond to immobility, feeding and transit. Indeed, although
337 our method can estimate the number of states on a statistical basis as the most likely number of clusters,
338 this estimate was not correct for a number of computer simulations whereas behavioural modes were clearly
339 defined. With actual data, there can be some mixing between modes, for instance transit and opportunis-
340 tic feeding at some times, so that the estimation of the number of relevant modes may become unreliable.
341 Thus, we recommend using the capacity of the segclust2d/ segmentation-clustering procedure to estimate
342 the number of states only when this number cannot be fixed a priori based on biological arguments. A similar
343 conclusion was reached by (Pohle et al., 2017) for HMM-based methods. It is also worth noting that feeding
344 and resting can be distinguished based on movement characteristics only in animals which have to move
345 significantly (with respect to the location recording noise) to feed. For animals which feed mainly without
346 markedly moving, such as some browser herbivores and carcass-eating carnivores, ancillary activity data
347 provided by on-board accelerometers are absolutely required to distinguish these two behavioural modes. As
348 our method can work conjointly on any number of time-series of any nature, future implementation could
349 integrate activity (accelerometer-based) time-series for a better identification of resting vs. active phases.

350 The segmentation of piecewise stationary time-series, possibly complemented by the clustering of the
351 resulting segments into functional classes, is often key to understanding the dynamics of processes. Based
352 on bivariate time-series of metrics such as location coordinates (northing and easting) or speed and turning
353 angles, segclust2d has the potential to facilitate discovery in the field of movement ecology. If necessary,
354 this approach can apply similarly to three and more dimensions, so as to consider ancillary variables such as
355 activity, as well as other metrics such as distance to a nest, proxies of habitat quality, or any other variable

356 that may be relevant when studying animal movements. Finally, as it can deal with two or more variables
357 of any nature, our approach should be useful not only in movement ecology but also in many other fields.

358 **Acknowledgement**

359 We thank Clément Calenge for interesting discussions about segmentation issues. The study was partially
360 funded by the grant ANR-16-CE02-0001-01 of the French 'Agence Nationale de la Recherche', and the
361 Zone Atelier program of the CNRS. Computer simulations were programmed in Pascal and ran thanks to the
362 FreePascal compiler (www.freepascal.org).

363 **Data accessibility**

364 The code of the method is already publicly available as an R package (<https://cran.r-project.org/package=segclust2d>).
365 There are only a few data used as examples, and they will be made publicly available as well.

366 Supporting Information 1: Complements about segclust2d

367 Expectation-Maximization algorithm and smoothing procedure

368 The Expectation-Maximization (EM) algorithm used to estimate the distribution parameters in the segmen-
369 tation-clustering model is known to be sensitive to initialisation, so that it may converge to local maxima of
370 the likelihood. This behaviour has some consequences on the parameters estimates but also makes the choice
371 of the number of segments or states complicated. The classical initialisation solution consists in running the
372 algorithm numerous times and just choose the point with the highest value of the log-likelihood, but this
373 strategy is too computationally demanding. To minimize the risk of reaching local maxima within an unac-
374 ceptable computation time, we propose the following initialisation strategy: (1) perform a pure segmentation
375 of the signal and (2) use a hierarchical cluster algorithm, based on the log-likelihood ratio distance to assign
376 segments to states.

377 Even with smart initialisation points, however, the EM algorithm may still converge to local maxima.
378 This situation appears when looking, for a given number of states M , at the log-likelihood as a function
379 of the number of segments K : whereas it is expected to be somewhat regular, this function can be quite
380 noisy. To solve this issue, we propose to 'smooth' the function based on the parameter estimates of the
381 distribution (π_m, μ_m, Σ_m) obtained for all the 'reliable' solutions, which correspond to the points that lie on
382 the convex hull of log-likelihood curve, as smart initial points for any 'non-reliable' solution, i.e. for which an
383 initialisation problem can be suspected. The improvement in terms of regularity of the log-likelihood curve
384 obtained thanks to this procedure is illustrated in figure 6.

Figure 6: Maximum Likelihood estimates as a function of the number of segments before (in blue) and after (in red) smoothing. For instance the 'reliable' solution obtained with $K = 24$ segments was used to provide starting points for the EM algorithm for $K = 23$ and for $K = 25$, and this smoothing procedure gradually spreads over adjacent points.

385 Model selection

386 Choice of the number of segments K in the pure segmentation model

387 We used the adaptive model selection strategy proposed in Lavielle (2005) consisting in choosing the value
388 of K that maximizes the following penalized log-likelihood : $\mathcal{L}_K - C K$ where \mathcal{L}_K is the log-likelihood of the
389 optimal segmentation in K segments and C is a unknown positive constant to be calibrated. The heuristic
390 proposed by Lavielle (2005) consists in detecting the value of K for which the log-likelihood ceases to increase
391 significantly. More specifically, consider the normalised log-likelihood defined as

$$392 \quad \tilde{\mathcal{L}}_K = (K_{max} - 1) \frac{\mathcal{L}_{K_{max}} - \mathcal{L}_K}{\mathcal{L}_{K_{max}} - \mathcal{L}_1} + 1$$

393 Then, K is chosen as the value such that $\tilde{\mathcal{L}}_K$ displays the largest slope change. Namely, we take :

$$394 \quad \hat{K} = \operatorname{argmin}_K \left\{ (\tilde{\mathcal{L}}_K \tilde{\mathcal{L}}_{K+1}) - (\tilde{\mathcal{L}}_{K+1} \tilde{\mathcal{L}}_{K+2}) > S \right\}$$

395 where the value of threshold S is set to a predefined value (we used $S = 0.7$ as proposed in Lavielle,
396 2005).

397 As the selection relies on a predefined threshold, it is worth checking where the point corresponding to
398 the selected number of segment lies on a plot of the log-likelihood curve (fig. S3.2). The optimal K value
399 obtained in this way should correspond to a noticeable slope change.

Figure 7: log-likelihood of a segmentation as a function of the number of segment. The optimum selected by the criterion from Lavielle (2005) should be located at a break in the increase of the curve.

400 Choice of the number of segments K and states M in the segmentation-clustering model

401 Selection of the best segmentation-clustering model (i.e. of the best couple of K and M values) is a hard
402 task as no method has been yet proposed for this purpose. A log-likelihood is expected to increase with the
403 number of parameters. However, as explained in Picard et al. (2007), if the log-likelihood increases with the
404 number of clusters M , it does not always increases with the number of segments K . Indeed a phenomenon
405 of self-penalization occurs at the ‘true’ number of segments when the detection of breakpoints is easy,
406 stressing to choose K simply as the value that maximizes the log-likelihood. However when the detection

407 of breakpoints is more difficult, choosing the maximum value would tend to overestimate K . Picard et al.
408 (2007) suggested to add a penalty. A Bayesian Information Criterion (BIC)-based penalty appeared to be
409 sufficient in this case, although it does not work in pure segmentation (Picard et al., 2005). As BIC is the
410 most popular criterion to choose the optimal number of clusters in a mixture model (Frühwirth-Schnatter,
411 2006), we propose to use the maximum value of the following BIC-based penalised likelihood $\mathcal{B}_{K,M}$ for the
412 selection of both K and M parameters:

$$\mathcal{B}_{K,M} = \mathcal{L}_{K,M} - \frac{5 \times M - 1}{2} \log(2n) - \frac{K - 1}{2} \log(2n),$$

413 where $\mathcal{L}_{K,M}$ stands for the log-likelihood for the optimal segmentation-clustering with K segments classified
414 into M states. The penalization terms in the BIC criterion is half the number of parameters times the
415 logarithm of the size of the dataset. For our model the number of parameters to be estimated is $2M$ means
416 $+ 2M$ variances $+ M - 1$ proportions for the states, and $K - 1$ breakpoints for the segments, and the size
417 of the dataset for n bivariate values is $2n$.

418 Although this procedure appears to work well for choosing the optimal number of segments, it has been
419 observed to be less reliable for choosing the optimal number of states, which tends to be overestimated. We
420 therefore advise users to set an a priori number of states M , based on biological knowledge. We also advise
421 to look at the plot of the BIC-penalized log-likelihood, as in figure 4b of main text, to check that the solution
422 obtained makes sense.

423 **Supporting Information 2: Interpolating entrance and exit points**
 424 **of a circle**

Figure S2.1: Interpolating entrance and exit points of a circle.

425 Given a series of locations $\mathbf{X}_i = (x_i, y_i)$ recorded at constant time intervals Δt . Whereas turning angle
 426 at constant time intervals α_i (top) corresponds to the change in direction between vectors $\mathbf{X}_{i-1} \rightarrow \mathbf{X}_i$
 427 (with length L_i) and $\mathbf{X}_i \rightarrow \mathbf{X}_{i+1}$ (with length L_{i+1}) and therefore act as a proxy for angular speeds
 428 $\left(\frac{\alpha_i}{\Delta t}\right)$, turning angle at constant length interval α_i^* (bottom) corresponds to the change in direction between
 429 vectors $\mathbf{P}_{en} \rightarrow \mathbf{X}_i$ and $\mathbf{X}_i \rightarrow \mathbf{P}_{ex}$, where \mathbf{P}_{en} and \mathbf{P}_{ex} are the last entrance and first exit locations,
 430 respectively, of a virtual circle with radius r and centred on current location \mathbf{X}_i . Let $\mathbf{I} = (x_{in}, y_{in})$ and
 431 $\mathbf{O} = (x_{out}, y_{out})$ be the last inside and first outside recorded locations, respectively, of the first passage at
 432 the circle perimeter, either backwards ($\mathbf{I} = \mathbf{I}_{en}$, $\mathbf{O} = \mathbf{O}_{en}$, $\mathbf{I}_{en} = \mathbf{X}_i$ if $L_i > r$) to determine \mathbf{P}_{en} , or
 433 forwards ($\mathbf{I} = \mathbf{I}_{ex}$, $\mathbf{O} = \mathbf{O}_{ex}$, $\mathbf{I}_{ex} = \mathbf{X}_i$ if $L_{i+1} > r$) to determine \mathbf{P}_{ex} . The location \mathbf{P} (either \mathbf{P}_{en} or \mathbf{P}_{ex}
 434) corresponds to the point where the vector $\mathbf{I} \rightarrow \mathbf{O}$ intersects the circle perimeter. The length of this vector
 435 is $d_{IO} = (d_x^2 + d_y^2)^{0.5}$, with $d_x = x_{out} - x_{in}$, $d_y = y_{out} - y_{in}$, and its orientation is θ , with $\cos(\theta) = \frac{d_x}{d_{IO}}$ and
 436 $\sin(\theta) = \frac{d_y}{d_{IO}}$. In a new orthonormal frame of reference (U, V) originating at \mathbf{I} and with U axis running
 437 through \mathbf{O} , the coordinates of current location \mathbf{X}_i become $u_i = (x_i - x_{in})\cos(\theta) + (y_i - y_{in})\sin(\theta)$ and
 438 $v_i = (y_i - y_{in})\cos(\theta) + (x_i - x_{in})\sin(\theta)$. By applying Pythagoras' theorem, one gets $r^2 = (d_{IP} - u_i)^2 + v_i^2$
 439 , where d_{IP} corresponds to the distance between \mathbf{I} and \mathbf{P} , with $d_{IP} > u_i$. Entrance or exit location can
 440 therefore be linearly interpolated as $\mathbf{P} = \mathbf{I} + (\mathbf{O} - \mathbf{I}) \frac{d_{IP}}{d_{IO}}$ (i.e. $x_P = x_{in} + \cos(\theta)d_{IP}$ and $y_P = y_{in} + \sin(\theta)d_{IP}$),
 441 with $d_{IP} = u_i + (r^2 - v_i^2)^{0.5}$.

442 **Supporting Information 3: Efficiency of the segmentation-clustering**
 443 **method**

444 **1 Comparison with HMM for low ($\zeta = 0.2$) and high ($\zeta = 0.4$) noise levels**

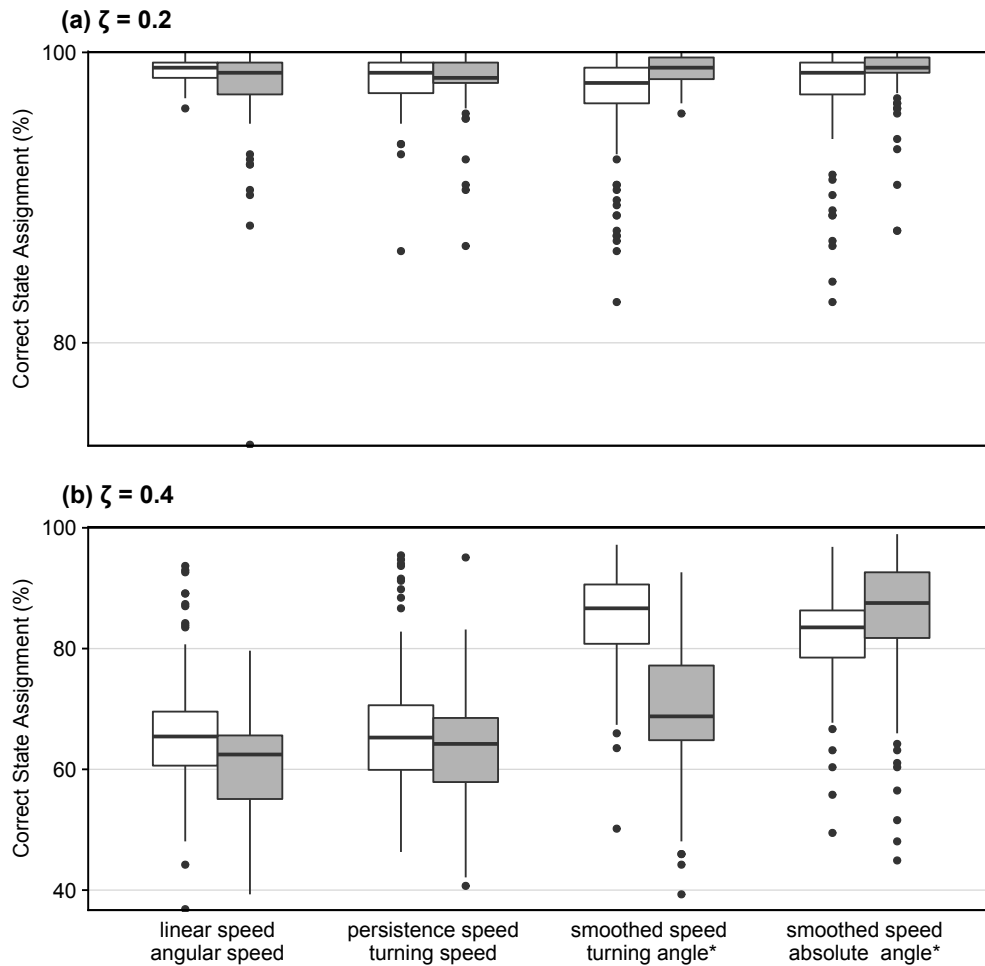

Figure S3.1: The boxplots show the proportion of correct state assignments, obtained for various bivariate signals when the true number of states is known ($M = 3$) with noise level $\zeta = 0.2u$ (a) or $\zeta = 0.4u$ (b), as estimated from 100 replicates. The star (*) indicates turning angles computed with a constant step length, in terms of arithmetic (α_i^*) or absolute ($-\alpha_i^*$) values. The white boxplots show the results obtained with HMM-based R package *momentuHMM* (McClintock and Michelot, 2018), with informative initial state-dependent probability distribution parameters set to the true values of the various metrics in the different states (using the following distributions: Gaussian for persistence and turning speeds, wrapped Cauchy for angular speed and turning angle α_i^* , Weibull for linear speed, smooth speed and $-\text{turning angle}^*$). The grey boxplots shows the results obtained using the *segclust2d/segmentation-clustering* procedure with $L_{min} = 10$.

445 **2 Estimation of the number of states**

Figure S3.2: The various bars show the proportions of simulations resulting in a predicted number of states (i.e. behavioural modes) equal to 2, 3, 4, or 5, for the three noise levels considered ($\zeta = 0.2u$, $\zeta = 0.3u$ and $\zeta = 0.4u$) and the four types of couples of metrics considered. The true number of states is 3. The star (*) indicates turning angles computed with a constant step length, in terms of arithmetic (α_i^*) or absolute ($-\alpha_i^*$) values. The couple of metrics leading to best segmentation when the true number of states is known – absolute turning angle computed with a constant step length and smoothed speed – also leads to the best estimation of the number of states, but this latter estimation is not fully satisfactory, and should be worse with actual data because of possible mixing of movement behaviours.
