36 Abstract

37 Recently, both the WHO/IARC (World Health Organisation/International Agency for 38 Research on Cancer) and the American Joint Committee on Cancer (AJCC) have classified 39 the oropharyngeal squamous cell carcinoma (OPSCC) on the basis of HPV status. For this 40 purpose, the WHO/IARC recommended direct molecular HPV testing. In practice, formalin-41 fixed, paraffin-embedded (FFPE) biopsy specimens are frequently the only available samples. 42 We herein compared in parallel two commercially available molecular assays that were firstly designed for cervical HPV detection and genotyping: Inno-Lipa[®] HPV genotyping extra II 43 assay (Fujirebio, Gent, Belgium) (IL) and Anyplex[™] II HPV 28 (Seegene, Seoul, South 44 45 Korea) (AP28). 46 Both assays were carried out on the same DNA extracts obtained from prospectively collected 47 FFPE biopsies from OPSCC origin and results were compared. 48 A total of 55 samples were tested. By IL assay, chosen as reference assay, 27 (49.1%) 49 biopsies were positive for HPV16, 10 (18.2%) were positive for HPV but negative for 50 HPV16, and 18 (32.7%) were negative for HPV. A valid result with AP28 was obtained for 51 51 biopsy samples (92.7%). Among 37 HPV-positive samples by IL, 33 (89.2%) were 52 positive by AP28. The agreement between both assays was good (Cohen's $\kappa = 0.78$). Among 53 the six discrepancies between assays, always associated with low HPV16 viral load, four 54 biopsies positive for HPV16 by IL could not be detected by AP28. 55 Taken together, these observations demonstrate that both assays could be used in routine for

56 HPV detection and genotyping on FFPE-biopsy samples of head and neck tumour.

57

59 Introduction

60 With 600,000 cases per year, head and neck cancer was estimated to be the sixth most 61 common cancer worldwide (1). Head and neck squamous cell carcinoma (HNSCC) represents 62 90% of them. Since 2007, human papillomavirus (HPV) was considered as an independent 63 risk factor for HNSCC by the World Health Organization's International Agency for Research 64 on Cancer (WHO/IARC) (2). Broad genetic distribution of HPV has been reported in 65 oropharyngeal squamous cell carcinoma (OPSCC), including HPV16 in 85% of cases, 66 followed by HPV18, 31, 33, 35, 45, 51, 52, 56, 58, 59, 68 and 82 (3, 4). Finally, OPSCC is 67 currently considered as an epidemic viral-induced carcinoma, since the incidence of HPV-68 positive carcinoma of the tonsil nearly doubled every 10 years (5–8).

69 Recently, the major modification in the eight edition of the American Joint Committee 70 on Cancer (AJCC) Staging Manuel, Head and Neck Section was the introduction of a specific 71 staging algorithm for high-risk (HR) HPV-associated OPSCC (9). Furthermore, the 2017 72 edition of the WHO/IARC on Head and Neck tumor classified the OPSCC on the basis of 73 HPV status (10–12). HPV-positive OPSCC constitutes a tumor entity with better prognosis, a 74 distinct epidemiological profile, with specific genetic features and clinical presentations and 75 outcomes. Immuno-histochemical detection of HPV using p16 staining as surrogate marker of 76 HPV has been until now widely carried out (13). The 2017-revised WHO/IARC 77 recommendations introduced direct HPV testing based on *in-situ* hybridization and/or PCR in order to classify the OPSCC according to HPV status (12). Until now, several commercially 78 79 available assays have been clinically validated for the detection and genotyping of HPV-80 associated cervical cancer (14, 15), whereas to our knowledge none have been validated for 81 OPSCC. Furthermore, formalin-fixed, paraffin-embedded (FFPE) biopsy samples are 82 frequently the only available ones for molecular testing after pathological examination. Such

83 FFPE samples however necessitate specific processing before PCR analysis because formalin

84 fixation induces fragmentation of nucleic acids (16–18).

Taken together, the aim of the present study was to evaluate a new multiplex real-time
PCR-based assay (Anyplex[™] II HPV 28, Seegene, Seoul, South Korea) (AP28), allowing to
detect and genotype a wide range of high-risk HPV genotypes and previously tested for
cervical samples (19, 20), in a prospective series of OPSCC FFPE samples, by reference to
Inno-Lipa[®] HPV genotyping extra II assay (Fujirebio, Gent, Belgium) (IL) chosen as
reference assay (21–23).

91

92 Materials and methods

93 Collection of biopsy samples and processing. Head and neck biopsy samples received 94 before treatment at the European Georges Pompidou hospital were prospectively included 95 between 2014 and 2017 for routine pathologic examination. Patient had not received any 96 treatment for their cancer at the time of the biopsy. The biopsies were fixed in formalin 10% 97 overnight and included in paraffin. FFPE-biopsies diagnosed as HNSCC were selected by a 98 pathologist for further cutting in 5- to 20- µm sections. Five sections were sent to the ISO 99 15189-accredited virology laboratory of the hospital for DNA extraction prior to HPV 100 detection and genotyping by IL and, in parallel, by in-house quantitative real-time PCR 101 targeting E6 gene from HPV16 (HPV16 qPCR). Afterwards, same DNA extracts were 102 subjected to multiplex HPV PCR by AP28.

103 **DNA extraction procedures.** Sections of FFPE-biopsies were deparaffinised overnight at 104 $+56^{\circ}$ C with 40 µl of proteinase K (Qiagen, Hilden, Germany) and 360 µl of ATL buffer 105 (Qiagen). Afterwards, 200 µl of ATL buffer were added and incubated 10 min at $+70^{\circ}$ C. 106 DNA was further extracted using QiaAmp DNA Mini Kit (Qiagen), and eluted in 50 µl of 107 PCR-grade water. For discordant results between IL and AP28, 5 new sections of biopsy samples were also subjected to DNA extraction procedure optimized for FFPE-biopsies, as
previously described by Steinau *et al* (17).

110 HPV detection and genotyping in routine. Two molecular HPV assays are used in parallel 111 for routine HPV detection and genotyping on FFPE-biopsies. The IL assay consists of PCR 112 amplification of a small 65 bp-fragment of the L1 gene using SPF10 primers sets and the 113 ubiquitary gene human leukocyte antigen-DPB1 as internal control, followed by hybridization 114 of specific HPV probes in a dedicated automat according to manufacturer's instructions. The 115 IL assay detects 13 HR HPV (HPV -16, -18, -31, -33, -35, -39, -45, -51, -52, -56, -58, -59, -116 68), 9 low-risk (LR) HPV (HPV -06, -11, -40, -42, -43, -44, -54, -61, -81), 7 genotypes 117 reported as possibly carcinogenic (HPV -26, -53, -66, -67, -70, -73, -82) and 3 genotypes not 118 described as carcinogenic (HPV -62, -83, -89) (24).

HPV16 qPCR was also systematically carried out, as previously described (25), in
order to double check every sample for HPV16 which constitutes the most prevalent HPV
genotype in HNSCC (26), as well as to assess lack of contamination by IL. For quantification,
serial dilutions of titrated Caski cells (Amplirun, Orgentec, France) were used to plot external
standard curve.

Positive controls for HPV16 and HPV18 consisted in DNA extracted from SiHa and
HeLa cell lines, respectively; water was used as negative control.

HPV detection and genotyping by multiplex PCR. The AP28 assay that distinguishes 28 HPV genotypes, by amplifying 100 to 200 bp-fragments of the L1 gene [including 13 HR types (HPV -16, -18, -31, -33, -35, -39, -45, -51, -52, -56, -58, -59, and -68), 8 LR types (HPV -6, -11, -40, -42, -43, -44, -54, -61) and 7 genotypes reported as possibly carcinogenic (HPV -26, 53, -66, -69, 70 -73 and -82)], and human gene β-globin in two different reactions was used for multiplex HPV molecular testing (27). Melting curves were obtained at 30, 40, and 50 cycles. Results were first automatically analysed using the Seegene Viewer software,

version 2.0 (Seegene) and raw data of results were checked by the virologist. The results were
considered as invalid when the negative controls were negative and no HPV was found. An
estimation of the viral load was approached by indicating the cycle number at which the
positivity was detected: + (50 cycles), ++ (40 cycles) and +++ (30 cycles).

137 Ethical clearance. All included patients belonged to a cohort declared and approved by the

138 Ethics Committee (Comité de Protection des Personnes Ile de France II, no. 2015-09-04)

139 Statistical analysis. IL assay was chosen in our laboratory as the reference technique for 140 HPV detection and genotyping, because the assay was reported to show high analytical 141 sensitivity and specificity on FFPE samples (28, 29). Results strictly similar by AP28 and IL 142 assays were defined as identical; results giving at least one identical HPV genotype by AP28 143 and IL assays were defined as compatible; other results were defined as discordant. 144 Agreement between IL and AP28 assays was assessed by the Cohen's κ test: 1 indicating 145 perfect agreement; 1 to 0.81, very good agreement; 0.80 to 0.61, good agreement; 0.60 to 146 0.21; moderate to poor agreement. The Mann-Whitney test was used to compare HPV16 viral 147 loads between samples showing concordant or discordant results. A linear regression model 148 was used to assess the relation between the viral load and the semi-quantitative result of 149 AP28.

150

151 Results

Fifty-five biopsy samples from patients followed for HNSCC were prospectively selected. By the IL assay, 27 (49.1%) biopsies were HPV16-positive and 10 (18.2%) were HPV-positive but not HPV16-positive, as depicted in the Table 1. Among the 37 positive samples, 3 (biopsies #8, #19 and #33) were positive for more than one HPV. Finally, 18 (32.7%) biopsy samples were HPV-negative.

158 Comparison of HPV detection and genotyping results between IL and AP28 assays.

159 The same DNA extracts from the 55 selected biopsy samples tested by IL were further 160 subjected to AP28 assay. Among 7 discordant samples, one that was initially negative when 161 analyzed with the Seegene Viewer software was finally classified as positive after raw data 162 analysis; the raw data analysis of the remaining discordant samples (corresponding to 10.9% 163 of samples) gave similar results to the ones obtained by automatic analysis. Final results are 164 shown in the Tables 1 and 2. A valid result with AP28 was obtained for 51 biopsy samples 165 (92.7%) (Table 2). Among the 37 HPV-positive biopsy samples by IL, 33 (89.2%) were 166 found positive by AP28, including 90.9% of identical results and 9.1% of compatible results, 167 the remaining results being either invalid (n=2) or negative (n=2). Finally, the vast majority 168 (n=16; 88.9%) of 18 biopsy samples negative by IL were also negative by AP28; only 2 IL-169 negative biopsies were found invalid by AP28. The overall agreement between both assays 170 was good (Cohen's κ coefficient = 0.78). Among the 27 samples that were HPV16-positive 171 with IL, AP28 detected HPV16 in 23 (85.2%), 2 (7.4%) were negative and 2 (7.4%) invalid 172 (Table 1). AP28 did not detect any HPV16 in samples that were negative for HPV16 with IL. 173 Regarding HPV16 detection, the agreement between both assays was good (Cohen's 174 κ coefficient=0.75).

175 HPV16 viral load. HPV16 qPCR was carried out on the 55 biopsy samples. All HPV16-176 positive samples with IL were positive by HPV16 qPCR and all HPV16-negative samples 177 with IL were also negative with HPV16 qPCR (Table 1). The median of HPV16 viral loads 178 was higher in concordant than in discordant samples [20,800 copies/ μ l (4.32 log/ μ l), range, 179 $734-595000 \ versus 503 \ copies/\mu l (2.70 \ log/\mu l), range, 133-512; P=0.00077]$. Interestingly, the 180 HPV16 viral loads of IL-positive/AP28-negative results were low (Table 1). As expected, 181 using a linear regression model, a significant relation (P=0.000388) was observed between the 182 viral load (expressed in log_{10}) and the AP28 semi-quantitative results with a linear coefficient

of 0.79 log between each level of AP28 (negative, +, ++ and +++). The Figure 1 depicts the
results of HPV16 viral loads and AP28 semi-quantitative results.

185

186 **Discussion**

187 We herein compared on a large series of FFPE-biopsy samples of HNSCC two 188 commercially available molecular assays targeting L1 gene for routine HPV detection and 189 genotyping. Nearly half of FFPE-biopsy samples from patients followed for HNSCC in our 190 hospital was found positive for HPV DNA using IL as reference assay, emphasizing the need 191 to strictly follow the recent 2017-revised WHO/IARC recommendation of direct HPV testing 192 in case of OPSCC. Both assays showed good agreement for HPV detection as well as for 193 genotyping. However, rare discrepancies between assays could be observed with positive 194 samples for HPV16 by IL which were not detected by AP28. Interestingly, these 195 discrepancies were always associated with low HPV16 viral load. These observations 196 demonstrate that both assays could be used in routine for HPV detection and genotyping on FFPE-biopsy samples of HNSCC, keeping in mind that a few biopsy samples with low 197 198 HPV16 viral load could be missed. Taken together, our findings clearly emphasize the 199 necessity to validate commercially available molecular assays on patients' biopsy samples, 200 and to confront the results with other molecular technics in case of low HPV viral load.

In the present series, the calculated agreement between IL and AP28 results was good, both for HPV16 and other genotypes. However, around ten percent of biopsy samples gave discrepancies between both assays, including biopsies positive for HPV16 by IL which were not detected by AP28. Using HPV16 qPCR, low HPV16 viral load was clearly associated with the misdetection of HPV16 by AP28 assay. Although HPV16 viral load was not normalized on extracted DNA quantity, the experimentations were carried out on the same tissue extract allowing accurate comparison of the results obtained by AP28 and HPV16

208 qPCR. The capability of IL assay to detect HPV16 in samples harboring low HPV16 viral 209 load is likely due to sufficient amplification efficiency in samples containing fragmented 210 DNA. Indeed, it is well reported that DNA recovering in FFPE specimens may be influenced 211 by several factors, such as formalin quality and concentration, length of fixation, paraffin 212 quality and temperature (30). As a consequence, DNA in FFPE biopsy is either completely or 213 partially degraded into DNA fragments of 200 bp or less (16). The IL assay relies on the 214 amplification of shorter fragments than AP28 assay, a feature which could partly explain the 215 discrepancies observed between both assays in our series. Furthermore, discordant results 216 could also be associated with extract quantity used for experiment. Thus, the IL assay requires 217 more quantity of tissue extract (10 μ l) than AP28 (5 μ l), according to manufacturers' 218 instructions. The possibility may be also envisioned that mutations affecting the priming sites 219 of AP28 primers could have led to misdetection. This hypothesis should be however ruled out 220 because the correlation between the efficiency of detection by AP28 and HPV16 viral load 221 was marked. Finally, we checked that observed discrepancies were not due to extraction 222 procedures.

223 In our series, one negative sample by AP28 which was positive by IL was finally 224 diagnosed as positive for HPV16 after analysis of the raw data. This finding indicates that raw 225 data of every AP28 negative samples need to be analyzed in order to detect some of the false-226 negative results. Indeed, the automatic analysis and cut-off used by AP28 test may miss out 227 some HPV-positive samples since the assay was primarily designed to detect HPV on either 228 cervical swab or liquid based cytology specimen and not on FFPE samples from 229 oropharyngeal origin. In practice, the automatic Seegene software interpretation should be 230 used with caution for negative or invalid FFPE biopsies.

Our observations indicate that IL as well as AP28 assays could be used in clinical
laboratory to detect and genotype HPV in FFPE OPSCC biopsy samples. To our knowledge,

10

233 only one study compared the performance of the AP28 assay and the CLART system from 234 Genomica (Madrid, Spain) on only 3 FFPE HNSCC samples (27). In our series, the IL assay 235 appeared as sensitive as in-house HPV16 qPCR, in keeping with previous reports showing 236 that IL is highly reliable on FFPE archival samples. Nevertheless, the AP28 technic could be 237 preferred depending on the recruitment of the laboratory, particularly if the number of 238 samples is important. Indeed, AP28 relies on real-time PCR, which allows easier and faster 239 procedure as compared with IL technic which appears more cumbersome and requires 240 specific material for hybridization on membrane following PCR amplification. In addition, the 241 risk of cross contamination between samples is less important with AP28 than with IL. 242 However, it should be kept in mind that misdetection of HPV16-positive biopsies could occur 243 with AP28 assay. Since HPV16 is known to be the most prevalent HPV genotype in OPSCC, 244 diagnosed in 85% of cases (26), one could strongly recommend confirming the negative 245 results by AP28 with HPV16 genotype-specific molecular assay validated on FFPE samples. 246 In our laboratory, we have chosen to screen first for HPV16 by in-house HPV16 qPCR, and 247 then to test further the negative samples with IL or AP28 to potentially detect less common 248 genotypes in OPSCC, or confirm the negativity for HPV.

In conclusion, our observations demonstrate that both commercially available IL and AP28 assays could be used in clinical laboratories with similar performances in routine on OPSCC FFPE samples, in order to address the recent recommendations for direct HPV testing in OPSCC (12). Nevertheless, low HPV viral load in FFPE biopsy samples could be a limiting factor, rendering in medical practice the diagnosis of HPV in OPSCC sometimes difficult. Finally, HPV diagnosis and genotyping in OPSCC may necessitate several complementary technics, to overcome the limitation of some commercially available assays.

401 Legend for the figure

402 **Figure 1.** Comparison of HPV16 viral loads (in-house qPCR) and HPV16 AP28 semi-403 quantitative results. HPV16 semi-quantitative results are presented as negative, +, ++ and +++ 404 according to the cycle at which the signal is detected (no detection, detection at 50, 40 and 30 405 cycles respectively). The Spearman's rank correlation test is shown on the figure (R=0.54, 406 p=0.0058).
