

1 **Title: Coping with multiple enemies: pairwise interactions do not predict**
2 **evolutionary change in complex multitrophic communities**

3 **Abstract**

4 Predicting the ecological and evolutionary trajectories of populations in multispecies
5 communities is one of the fundamental challenges in ecology. Many of these
6 predictions are made by scaling patterns observed from pairwise interactions. Here,
7 we show that the coupling of ecological and evolutionary outcomes is likely to be
8 weaker in increasingly complex communities due to greater chance of life-history
9 trait correlations. Using model microbial communities comprising a focal bacterial
10 species (*Bacillus subtilis*), a bacterial competitor, protist predator and phage
11 parasite, we found that increasing the number of enemies in a community had an
12 overall negative effect on *B. subtilis* population growth. However, only the competitor
13 imposed direct selection for *B. subtilis* trait evolution in pairwise cultures and this
14 effect was weakened in the presence of other antagonists that had a negative effect
15 on the competitor. In contrast, adaptation to parasites was driven indirectly by
16 correlated selection where competitors had a positive and predators a negative
17 effect. For all measured traits, selection in pairwise communities was a poor
18 predictor of *B. subtilis* evolution in more complex communities. Together, our results
19 suggest that coupling of ecological and evolutionary outcomes is interaction-specific
20 and generally less evident in more complex communities where the increasing
21 number of trait correlations could mask weak ecological signals.

25 **Introduction**

26 Species do not exist in isolation, but rather are embedded in a complex network,
27 linked to other species through a diverse set of trophic and non-trophic interactions
28 [Thompson 2005]. The ecological and evolutionary dynamics of many focal species
29 have been detailed using both theory and empirical approaches, yet we have
30 remarkably little insight into the effects of community complexity on shaping these
31 dynamics [Lytle 2001; Koskella 2014; Barraclough 2015]. Predicting the outcome of
32 these interactions on the density and traits of a given species within a multi-species
33 community is vital for understanding the long-term effects of environmental and biotic
34 change on the biodiversity and stability of communities [e.g. Yoshida 2003; Johnson
35 2007; Post 2009; Lawrence 2012; Loreau 2013; Donohue 2016; Mrowicki 2016].
36 Strong, consistent interspecific interactions also have the potential to impose heavy
37 selection pressures on species [Koskella 2011; Lawrence 2012; Friman 2013], with
38 significant implications for evolutionary trajectories [Yoshida 2003]. This predicts that
39 the selection pressures facing an organism in a complex multi-species system are
40 likely to be contingent upon the composition of that community and, moreover, that
41 the addition of species may dampen or promote evolutionary responses to individual
42 selection pressures [e.g. De Mazancourt 2008; Collins 2014; Betts 2015].

43 Predation [Sherr 2002; Friman 2013; McClean 2015], parasitism [Vos 2009;
44 Penczykowski 2016] and competition [Gause 1934; Hardin 1960; Foster 2012;
45 Friman 2014] are three major sources of antagonistic interactions for organisms.
46 These interactions act to reduce population densities both directly, by increasing
47 mortality and reducing recruitment, and indirectly, through competition for space and
48 resources. How these different types of interactions separately and importantly

49 collectively affect the population densities of focal species and trait evolution is still
50 relatively unexplored. First, it is possible that increasing the number of antagonistic
51 interactions in the community will have additively negative effects on the population
52 density of the focal species. Alternatively, increasing the number of antagonists
53 could weaken effects on focal species if they show negative effects on each other
54 via, for example, intraguild predation [Friman 2016]. Further, the number and type of
55 interactions could also affect the rate and trajectory of focal species evolution.
56 Selection pressures exerted by multiple antagonistic interactions may, for example,
57 result in trade-offs in terms of evolutionary outcomes [Stearns 1989; Friman 2013,
58 2016]. Adaptations that may be beneficial in one context may be harmful in another,
59 reducing the fitness benefit and, by extension, the rate of evolutionary change
60 [Stearns 1989; Thompson 1994; Friman 2013; Garland 2014]. For example,
61 predation tends to slow down the rate of host-parasite interactions [Friman 2013]
62 and selection by multiple predator species can change the evolutionary trajectory of
63 prey via trade-offs and correlated selection [Friman 2016]. This is because, even
64 though predators [Pernlather 2005; Estes 2011; O'Connor 2015] and parasites [Kutz
65 2005; Hudon 2006] exert strong selection for prey survival, the targets and
66 mechanisms under predator and parasite selection are likely to differ. Similarly,
67 evolution of defense against one antagonist might lead to increased susceptibility to
68 another [Friman 2009].

69 In addition to predatory and parasitic enemies, competitive interactions are a
70 pervasive force of selection and can be indirect or direct, mediated by shared
71 resources or, in the case of bacteria, through antimicrobials [Wang 2017] or
72 bacteriocins [Ghoul 2015]. Recent evidence from bacterial communities suggests
73 that interference competition and parasitism can act synergistically to suppress

74 bacterial growth due to evolutionary trade-offs, where one selection pressure makes
75 focal species more susceptible to the other [Wang 2017]. Furthermore, evolving
76 resistance to strong antagonistic interactions has often been shown to come at a
77 fitness cost [Tollrian 1995; Sheldon 1996; Van Buskirk 2000; Maclean 2004] that
78 might limit the level of resistance or adaptation to the abiotic environment [Scanlan
79 2015]. While most of the evidence to date suggests that parasites, predators and
80 competitors impose strong selection that often leads to clear fitness trade-offs, trait
81 correlations may also be positive or neutral [e.g. Wright 1999; Ackerly 2007;
82 Chamberlain 2014]. Adaptations selected in one ecological context might therefore
83 have unexpected consequences in other ecological contexts.

84 Pairwise interactions such as those among competing species have been shown to
85 predict those in more complex communities within single trophic levels [Foster 2012;
86 Rivett 2016]. However, relatively little is known about how different interactions
87 across trophic levels within a community alter evolutionary trajectories. A recent
88 study conducted with multiple predatory protists and a focal bacterial prey suggest
89 that increasing the number of antagonists in the community can weaken pairwise
90 evolutionary dynamics by increasing antagonism between different predator species
91 [Friman 2016]. Similarly, the presence of both specialist and generalist consumers
92 has been shown to change both coexistence and defence evolution in two competing
93 prey species [Hiltunen 2017]. Here, we explore whether predictions from different
94 types of antagonist pairwise interactions scale in communities with increasing
95 complexity. To this end, we manipulated the composition of multitrophic microbial
96 microcosm communities and examined how community complexity moderates the
97 dynamics of a focal bacterium species – *Bacillus subtilis* – and, critically, its ability to
98 evolve resistance to parasites (bacteriophage SPP1) and predators (*Paramecium*

99 *caudatum*) and to compete for resources with another bacterium (*Serratia*
100 *marcescens*). We also examined whether exposure to multiple enemies modified *B.*
101 *subtilis* growth adaptation in abiotic environments in the absence of other species.
102 We found that increasing the number of enemies in a community had an overall
103 negative effect on *B. subtilis*. However, only competitors imposed direct selection in
104 antagonist monocultures, while both parasites and predators imposed only indirect
105 correlated selection for resistance evolution in antagonist co-cultures. Crucially,
106 ecological and evolutionary outcomes were coupled only under direct selection by
107 competition, whereas no direct ecological or evolutionary signal was observed
108 regarding *B. subtilis* resistance trait evolution. Together, our results suggest that eco-
109 evolutionary outcomes might be interaction-specific and weakly coupled in more
110 complex communities due to increased chance of coincidental life-history trait
111 correlations.

112 **Methods**

113

114 ***Experimental design***

115 Our experiment consisted of seven sets of species combinations of *Bacillus subtilis*
116 (NCIB3610) with (1) *SPP1* phage parasite in isolation; (2) *Paramecium caudatum*, a
117 generalist [Johnson 1936; Thurman 2010; Banerjii 2015] bacterial predator in
118 isolation; (3) *Serratia marcescens* (ATCC 29632), a competitor of *B. subtilis*, in
119 isolation; (4) *P. caudatum* and *SPP1* phage; (5) *S. marcescens* and *SPP1* phage;
120 (6) *S. marcescens* and *P. caudatum*; and (7) *S. marcescens*, *P. caudatum* and
121 *SPP1* phage, resulting in a total of 7 experimental treatments, each replicated seven
122 times.

123

124 **Community assembly**

125 Culture methods followed closely those outlined in McClean *et al.*, Lawler and Morin,
126 and Leary *et al.* . Microcosms consisted of loosely capped 200 ml glass bottles with
127 15 g glass microbeads providing spatial habitat structure. The addition of the glass
128 beads allows for species to interact and behave in a more naturally complex
129 environment. Each microcosm received 100 ml medium consisting of one protist
130 pellet (Carolina Biological Supply, Burlington, NC, USA) per 1 litre spring water and
131 two wheat seeds to provide a slow release nutrient source. All media were sterilised
132 before use. Microcosms were maintained at 22 °C and under a 12:12 h light: dark
133 cycle. Nutrients in the microcosms were replenished on day 7 with a replacement of
134 7 ml of the microcosm volume with sterile medium and one additional sterile wheat
135 seed. *Paramecium caudatum* were obtained from Blades Biological UK. Bacterial
136 strains and SPP1 phage were taken from frozen laboratory stock cultures.

137

138 *P. caudatum* washing protocol

139 The *P. caudatum* protist cultures used for this experiment were laboratory cultures
140 and therefore, while not inoculated with any bacterial populations, were not entirely
141 sterile. To account for this, *P. caudatum* cultures were washed with sterile media
142 before addition to the microcosms to minimise contamination. In addition, the
143 remaining media from the washing process (minus *P. caudatum*) was combined,
144 mixed thoroughly and a similar volume to the protist treatments was added to all
145 microcosms to ensure that any bacteria present in the medium had an equal chance
146 of colonising each microcosm in every treatment. We identified a single bacterial
147 contaminant from this protist media, *Klebsiella sp.*, which colonised all microcosm

148 units in this manner in low frequencies and was treated as a standard ‘background’
149 member of the community [McClellan 2015]. At the end of the experiment, the
150 density of the *Klebsiella sp.* did not vary with experimental treatment over the course
151 of the experiment (repeated measures ANOVA; $F_{2,46} = 1.23$, $P = 0.3$).

152

153 *Bacterial cultures*

154 Overnight cultures of strains *B. subtilis* (NCIB3610) and *S. marcescens* (ATCC
155 29632), grown in a tryptone yeast (TY) medium (Luria-Bertani broth supplemented
156 with 10 mM MgSO₄ and 100 M MnSO₄ after autoclaving [Wach 1996]), were diluted
157 into fresh TY medium at an optical density at 600 nm (OD₆₀₀) ~ 0.03 and grown at 37
158 °C until late exponential phase (OD₆₀₀ ~ 1.0), at which time 1 ml of each bacterial
159 culture was inoculated into 100 ml microcosm medium, as required for experimental
160 treatments. A sample of both the *B. subtilis* and *S. marcescens* cultures were also
161 frozen at -80°C as the ancestral populations for later evolutionary comparisons.
162 Microcosms were left for 24 hr at 37 °C to facilitate growth of the bacteria prior to
163 addition of the phage. 1 ml of a 10⁻³ dilution (in sterile Phosphate Buffer Saline
164 [PBS]) of the phage stock solution (1.7×10^4 pfu ml⁻¹) was added to each microcosm
165 as required. Microcosms were then left for a further 24 hr at 37 °C to facilitate
166 bacterial growth and ensure sufficient numbers before the addition of the
167 bacterivorous *P. caudatum*. Microcosms were inoculated with washed *P. caudatum*
168 (approx. 50-70 individuals), as required for experimental treatments and allowed to
169 settle for two days at 22 °C.

170

171 *Community sampling and population density measurements*

172 The point of addition of the predators is considered as Day 0 of the experiment which

173 then ran for ten days. Samples of bacteria, phage and protists were taken every day
174 for the duration of the experiment after carefully homogenising microcosms by
175 shaking. A 0.1 ml sample was taken to count protist numbers using stereo (Olympus
176 SZX9) and compound (Olympus BX60) microscopes. Bacterial densities were
177 measured through direct colony counts (identified by colony morphology) on plates
178 from appropriately diluted samples. Phage numbers were measured through direct
179 plaque counts on plates from appropriately diluted samples. Prior to plating, 3 ml of
180 standard TY medium was inoculated with a stock of ancestral *B. subtilis* and
181 incubated at 37 °C for a minimum of 4 hr or until an OD₆₀₀ of 0.9-1.0 was achieved;
182 200 µl of the *B. subtilis* culture was added to 10 ml tubes followed by 200 µl of the
183 microcosm sample, mixed gently by hand and incubated at 37 °C for 15 min. Next, 3
184 ml of soft agar (0.5%) were added to each tube, swirled, and then poured onto pre-
185 set 1.5% TY agar plates and incubated overnight at 37 °C. The number of plaques
186 on each plate was then counted.

187

188 ***Measuring evolutionary changes in the life-history traits of focal species B.***

189 ***subtilis***

190 Eight colonies of *B. subtilis* were isolated from each microcosm via agar plating on
191 the final day of the experiment after microcosms were homogenised and vortexed to
192 strip biofilm and ensure representative sampling. The resistance of *B. subtilis* was
193 then assessed against the ancestral populations of SPP1 phage ($n = 8$ populations
194 per microcosm), ancestral *S. marcescens* competitor ($n = 3$ populations per
195 microcosm) and ancestral predatory *P. caudatum* ($n = 3$ populations per microcosm).

196

197 ***Competitive ability***

198 The competitive ability of *B. subtilis* from each treatment against the ancestral
199 competitor *S. marcescens* was assessed in direct competition as a deviation from an
200 initial 50:50 abundance ratio in co-culture experiments in 96-well plates containing
201 200 µl of microcosm medium over a 24 hr period at 22 °C. This was accomplished
202 through counting proportions of the two bacteria based on differences in colony
203 morphologies.

204

205 *Predator defence*

206 The strength of predator defence evolution of *B. subtilis* from each treatment was
207 assessed through biofilm formation in 96 well-plates, which is frequently used as a
208 proxy of bacterial defence strategy based on bacterial cell aggregates that cannot be
209 consumed by protists because they are too large or attached to surfaces [Böhme
210 2009; Chavez-Dozal 2012; Friman 2015]. To this end, evolved and ancestral
211 *Bacillus* bacteria were grown over 24 hr in 96-well plates containing 200 ml of
212 microcosm medium at 22°C with the addition of approximately 10 washed *P.*
213 *caudatum* cells. At the end of the 24 hr, *P. caudatum* cell number was counted and
214 biofilm assays were done to test predator defence [Böhme 2009; Chavez-Dozal
215 2012; Friman 2015] as follows. The liquid medium was decanted and all unattached
216 cells were removed through a water rinse. Next, 100 µl of a 0.1% crystal violet
217 solution was added to the wells to stain the biofilm attached on microplate well walls.
218 The wells were then left for 15 min and rinsed with deionised water. Plates were left
219 to dry overnight before 125 µl of 30% acetic acid (in water) were added to each of
220 the wells and incubated at room temperature for 15 minutes to solubilize the crystal
221 violet. The supernatant from each well was then transferred to wells in a new plate

222 and biofilm production was quantified by measuring the absorbance at 540 nm using
223 30% acetic acid as the blank.

224

225 *Parasite defence*

226 We used short-term growth assays in liquid media to assess the resistance of *B.*
227 *subtilis* populations to the ancestral SPP1 phage [Moulton-Brown 2018]. To this end,
228 10 µl of evolved *B. subtilis* isolates from each treatment was added to 200 µl
229 microcosm media in 96-well plates and allowed to grow independently for 20 hr at
230 22°C in both the presence and absence of 10 µl of the ancestral SPP1 phage (10^{-4}
231 titre). Bacterial density was then quantified by measuring the OD₆₀₀ to attain a proxy
232 of parasite resistance (the higher the OD, the higher the phage resistance).
233 Resistance was thus measured as reduction in density due to the parasite compared
234 to when the *B. subtilis* populations were grown alone without the parasite.

235

236 *Growth assays of B. subtilis*

237 We compared the growth of evolved and ancestral *B. subtilis* isolates to assess
238 whether the populations from different ecological contexts differed in their adaptation
239 to the growth medium [Scanlan 2015], or if adaptations against different enemies
240 might have incurred costs in terms of trade-offs with growth [Friman 2014; 2015;
241 2016]. We measured differences in two bacterial growth parameters that are
242 indicative of their ability to compete for resources: maximum growth (population
243 density after 15 hr of growth, by which time they had reached stationary phase), and
244 maximum growth rate (i.e. maximum rate of population growth per hour). Briefly,
245 ancestral and evolved *B. subtilis* isolates were grown independently over a 15-hour

246 period (OD₆₀₀ measured at 10 minute intervals) in the microcosm medium using 96-
247 well plates to assess differences in growth parameters.

248

249 ***Statistical analyses***

250 All densities were log (x+1) transformed prior to analysis to reduce bias caused by
251 different population sizes. Repeated measures analysis of variance (ANOVA) was
252 used to assess population density changes in each of *B. subtilis*, *S. marcescens*, *P.*
253 *caudatum* and SPP1 phage according to community complexity with post-hoc Tukey
254 honest significant difference (HSD) tests to highlight specific differences among
255 treatments. ANOVA and *t*-tests were used to examine the evolution of resistance in
256 *B. subtilis* isolates from each of our microcosm communities against each of the
257 competitor (based on density ratios), predator (biofilm density) and parasite (based
258 on density). Finally we used one-sample *t*-tests to test whether the ecological or
259 evolutionary outcomes from two-species communities could reliably predict the
260 outcomes in more complex communities. . Predicted values were calculated as the
261 mean (\pm s.e.) across antagonist monoculture treatments; For example, the predicted
262 value for the competitor + parasite treatment was estimated by merging the
263 competitor alone and parasite alone treatments and calculating their combined
264 mean. All analyses were carried out in R (version 3.4.4; R Developmental Core
265 Team 2018). All data available as supplementary files.

266

267

268 **Results**

269

270 *Population density dynamics of B. subtilis focal species*

271 The density of *B. subtilis* varied significantly with the number of enemy species
272 present in the community (repeated measures ANOVA: $F_{2, 46} = 8.07$, $P < 0.01$; Figure
273 1). Though addition of a second enemy did not alter the density of *B. subtilis* (Tukey
274 contrasts: 2 enemies present – 1 enemy present; $P = 0.25$; Figure 1), regardless of
275 antagonist identity (Table S1), *B. subtilis* densities were significantly lower when all
276 three antagonistic species were present together in the community (Tukey contrasts:
277 3 enemies present – 1 enemy present; $P < 0.05$, 3 enemies present – 2 enemies
278 present; $P < 0.05$; Figure 1). The observed density of *B. subtilis* in multispecies
279 communities was consistently lower than that predicted based on densities observed
280 in two species co-cultures (Table S1; Figure 3a). Together, these results
281 demonstrate that pairwise communities did not predict the density regulation effects
282 observed in the three-enemy community.

283

284 *Population density dynamics of competitor, parasite and predator*

285 The bacterial competitor species *S. marcescens* reached higher population densities
286 compared to *B. subtilis* when co-cultured in the absence of other antagonists (Figure
287 1a). This is indicative of competitive advantage. However, when either the specialist
288 parasite of *B. subtilis* (phage SPP1), a generalist predator species (*P. caudatum*), or
289 both, were added to the microbial community, this competitive advantage was
290 diminished, as evinced in a greater reduction in *S. marcescens* relative to *B. subtilis*
291 densities (repeated measures ANOVA: $F_{2, 25} = 10.34$, $P < 0.001$; Tukey contrasts; 2
292 enemies – 1 enemy and 3 enemies – 1 enemy, $P < 0.05$ in all cases; Figure 1). This
293 suggests that the presence of parasites and predators, either separately or together,
294 evened out the competitive difference between the two competing bacterial species.

295

296 Parasite densities varied with community richness (repeated measures ANOVA: $F_{2,25} = 4.1$, $P < 0.05$). Parasite density was unaffected by the presence of other
297 antagonists (Tukey contrasts: 3 enemies – parasite, $P = 0.8$; 2 enemies– parasite, $P = 0.1$; Figure 1b, g), except in the presence of both the competitor and predator of *B.*
298 *subtilis*, which decreased parasite density relative to either species present in
299 isolation (Tukey contrasts: 3 enemies – 2 enemies, $P < 0.05$; Figure 1). Parasite
300 densities dropped below the detectable limit by the end of the experiment (Figure 1g)
301 in the presence of both competitor and predator (Tukey contrasts: All species
302 present – every other parasite treatment, $P < 0.05$ in all cases; Figure 1). This
303 suggests that the competitor and predator had relatively small effects on parasite
304 densities in communities containing two enemies but additive negative effects in
305 three-antagonist communities.
306
307

308
309 Although predator densities in general increased over time, they did not vary with
310 antagonist richness (repeated measures ANOVA, $F_{2,25} = 0.63$, $P = 0.5$; Figure 1).
311 Thus, the predator was the least affected by the presence of other interacting
312 antagonistic species in the community.
313

314 *Evolution of B. subtilis competitive ability and resistance against parasite and* 315 *predator*

316 Evolutionary change in the competitive ability of *B. subtilis* was assessed by
317 comparing the growth of ancestral and evolved *B. subtilis* clones in direct
318 competition with the ancestral competitor species, *S. marcescens*, at the end of the
319 experiment. We found that the competitive ability of *B. subtilis* increased only if it had
320 been exposed to *S. marcescens* in the absence of other antagonists (Figure 2a;

321 ANOVA: $F_{6, 19} = 4.58$, $P = 0.005$; Tukey contrasts; $P < 0.05$ for each treatment
322 compared to *B. subtilis* + *S. marcescens* alone, except for *B. subtilis* + SPP1 phage
323 parasite, where $P = 0.08$). The presence of any other enemy limited the evolution of
324 *B. subtilis* competitive ability and no difference was observed relative to the ancestral
325 strain (Tukey HSD; $P > 0.05$ between all other treatment pairs, Figure 2a). The
326 observed changes in *B. subtilis* competitive ability were lower than predicted based
327 on pairwise co-cultures, except for the predator-parasite treatment (Table S1; Figure
328 3b). These results therefore indicate that evolutionary changes in *B. subtilis*
329 competitive ability were weakened in the presence of additional species.

330

331 Evolution of resistance to the parasite was measured as the difference in the growth
332 of ancestral and evolved *B. subtilis* isolates in the presence and absence of the
333 ancestral SPP1 phage (Figures 2b, S1). Overall, resistance to the ancestral parasite
334 varied strongly depending upon community composition (ANOVA: $F_{6, 38} = 7.46$, $P <$
335 0.001 ; Figure 2b). Prior exposure to the parasite alone did not affect *B. subtilis*
336 resistance to the ancestral parasite (t -test; $t_{8,14} = 0.98$, $P = 0.35$; Figure 2b, S1). In
337 contrast, the correlated evolutionary response to *S. marcescens* alone led to high
338 ancestral parasite resistance (t -test; $t_{7,3} = 5.1$, $P = 0.001$; Figures 2b, S1), while this
339 effect disappeared with the addition of other antagonists (t -tests; parasite: $t_{11,03} =$
340 0.57 , $P = 0.58$; predator: $t_{9,9} = 0.74$, $P = 0.48$; Figures 2b, S1). Moreover, prior
341 exposure to the predator alone (t -test; $t_{8,89} = -3.7$, $P < 0.01$; Figures 2b, S1), or in
342 combination with the phage parasite (t -test; $t_{9,52} = 8.58$, $P < 0.001$; Figures 2b, S1),
343 reduced *B. subtilis* resistance to the parasite. When all three enemy species were
344 present together, there was no effect on *B. subtilis* resistance to the ancestral SPP1
345 parasite (t -test; $t_{9,99} = 1.27$, $P = 0.23$; Figures 2b, S1). No major differences were

346 observed between predicted and observed parasite resistance values largely
347 because only weak parasite resistance was observed in general (Figure 3).
348 However, when both predator and parasite were present together, the resistance of
349 *B. subtilis* was lower than expected based on pairwise co-culture predictions (Table
350 S1; Figure 3c). Together, these results suggest that both competitors and predators
351 exerted opposing, correlated selection for *B. subtilis* parasite resistance and that
352 they cancelled the effect of each other out in competitor-predator co-cultures.

353

354 Resistance to the predatory protist *P. caudatum* was measured as the difference in
355 the extent of biofilm formation between ancestral and evolved *B. subtilis* isolates in
356 the presence and absence of a stock culture of *P. caudatum*. As expected, all
357 isolates produced a greater amount of biofilm in the presence of the predator
358 (Figures 2c, S2). However, all evolved isolates produced less biofilm than the
359 ancestral *B. subtilis* strain in the presence of the predator (grey line on Fig 2c), and
360 no difference in biofilm formation was observed between evolved isolates from
361 different antagonist communities (ANOVA: $F_{5, 34} = 0.77$, $P = 0.58$; Figures 2c, S2).
362 As a result, only weak predator resistance evolution and a good agreement between
363 predicted and observed evolutionary outcomes was observed, except for the
364 competitor-predator treatment, where observed evolutionary changes were less than
365 those predicted (Table S1; Figure 3d).

366

367 *Determining B. subtilis adaptation to the growth media and the cost of resistance*

368 We quantified the growth of ancestral vs. evolved *B. subtilis* isolates to assess
369 whether populations from different antagonist communities differed in their
370 adaptation to the growth medium and to identify the potential cost of resistance.

371 None of the evolved selection lines showed improved growth relative to the ancestral
372 *B. subtilis* strain, which suggests that no adaptation to the growth media occurred
373 and that changes are likely due to some costs of resistance (Figure S3a). The
374 maximum population density of evolved *B. subtilis* isolates was unaffected by
375 previous evolutionary history with either the competitor *S. marcescens* or parasite
376 (ANOVA; main effect of *S. marcescens*: $F_{1,38} = 0.64$, $P = 0.43$; main effect of SPP1
377 phage: $F_{1,38} = 1.5$, $P = 0.23$; Figure S3a). The maximum population density of *B.*
378 *subtilis* was, however, reduced significantly if it had previously been exposed to
379 antagonist communities that included the predator (ANOVA; main effect of *P.*
380 *caudatum*: $F_{1,38} = 36.12$, $P < 0.001$; Figure S3a), and this reduction was the
381 strongest in the predator-parasite treatment. In line with this, the observed maximum
382 densities were lower than predicted in more complex communities that included the
383 predator (Table S1; Figure 3e).

384
385 The growth rate of evolved *B. subtilis* isolates was much lower compared to the
386 ancestral strain (Figure S3b) and only *B. subtilis* that had evolved in the presence of
387 all three enemies had growth rates comparable with the ancestral strain. In general,
388 reduction in *B. subtilis* growth rate was lower in antagonist communities that included
389 the *S. marcescens* competitor species (ANOVA; main effect of *S. marcescens*: $F_{1,38}$
390 $= 16.44$, $P < 0.001$; Tukey contrasts $P < 0.05$; Figure S3b) and *P. caudatum* predator
391 (ANOVA; main effect of *P. caudatum*: $F_{1,38} = 8.21$, $P = 0.007$; Tukey contrasts $P <$
392 0.05 ; Figure S3b). In contrast, the presence of the SPP1 phage parasite had no clear
393 effect on *B. subtilis* growth rate (ANOVA; main effect of SPP1 phage: $F_{1,38} = 2.54$, P
394 $= 0.12$; Figure S3b). Due to similar evolutionary trajectories in pairwise co-cultures,
395 good agreement was found between predicted and observed evolutionary outcomes

396 (Figure 3). However, the observed reduction in *B. subtilis* growth rate was much less
397 than predicted in the three-antagonist community (Table S1; Figure 3f). Together,
398 these results suggest that evolved isolates had generally lowered maximum growth
399 and growth rates compared to the ancestral strain and that these changes were
400 driven mainly by the presence of the predator.

401

402

403 **Discussion**

404

405 In this study, we set out to test whether pairwise interactions observed both within
406 and among trophic levels scale with increasing complexity in multitrophic microbial
407 communities. We found that, while increasing the number of enemies in a community
408 had an overall negative effect on the densities of our focal bacterium, *B. subtilis*, only
409 the competitor imposed direct selection for *B. subtilis* trait evolution in pairwise
410 cultures. Further, this effect was weakened in the presence of other antagonists that
411 had a negative effect on the competitor. As a result, ecological (population density)
412 and evolutionary (trait evolution) outcomes were coupled only in the case of *B.*
413 *subtilis* competitive ability. However, both predators and parasites affected *B. subtilis*
414 trait evolution indirectly in antagonist co-cultures, having either positive or negative
415 effects respective to the ancestral strain. In case of both ecological and evolutionary
416 outcomes, selection in pairwise communities was a poor predictor of outcomes in
417 more complex communities, and often led to overpredictions. Overall, our findings
418 indicate that the coupling of eco-evolutionary outcomes is both trait- and interaction-
419 specific and harder to predict in more complex communities where the increasing

420 number of trait correlations can mask weak ecological signals and alter predictions
421 based on pairwise co-cultures.

422

423 Only the competitor bacterium *S. marcescens* selected for clear evolutionary change
424 in *B. subtilis* in single-enemy monocultures. Under experimental conditions, *S.*
425 *marcescens* attained higher densities than *B. subtilis*, indicating a competitive
426 advantage. This manifested as a strong driving force for evolutionary change in *B.*
427 *subtilis*, where isolates from the competitor monoculture treatment demonstrated
428 much greater competitive ability towards their ancestral competitor in comparison to
429 both ancestral *B. subtilis* and evolved *B. subtilis* isolated from multi-enemy co-
430 cultures. In contrast, neither the parasitic phage nor predatory protist caused such a
431 magnitude of evolutionary change against ancestral enemies in *B. subtilis*. One
432 explanation for this is that the duration of the experiment (10 days) was not
433 sufficiently long for the resistance to sweep through *B. subtilis* bacterial populations
434 and become fixed. Also, the nutrient concentration of our experimental conditions
435 was relatively low, which has been shown previously to slow down both parasite
436 [Friman 2015] and predator [Friman 2011] resistance evolution. In the case of
437 predator resistance evolution, we observed a very strong plastic defence response,
438 which decreased with evolved compared to ancestral *B. subtilis* strains. While this is
439 indicative of defence evolution, it was uniform among antagonist treatments,
440 suggesting that it was perhaps driven independent of the presence of the predator
441 (e.g. adaptation to growth media). It is less clear why no clear signs of parasite
442 resistance were observed. It is possible that *B. subtilis* evolved resistance to its
443 contemporary parasite without clear effects on resistance to the ancestral parasite.
444 Also, phage densities were quite low in our experimental system, which could also

445 have reduced the likelihood of resistance evolution [Lopez-Pascua 2008; Friman
446 2008].

447

448 The observed competitive advantage and selective force of the competitor bacterium
449 on *B. subtilis* was weakened substantially in the presence of other enemies. The
450 presence of either predator or parasite, alone or in combination, led to a reduction in
451 *S. marcescens* density, negating the effect of the competitor on driving selection in
452 *B. subtilis* competitive ability. Alternatively, it is possible that selection by parasites or
453 predators somehow conflicted with the selection by competitors. For example, the
454 presence of multiple enemies can weaken the respective effects via trade-offs where
455 selection by one antagonist makes the focal species more susceptible to the other
456 antagonists [Friman 2009]. This is, however, an unlikely explanation in our study, as
457 selection by the competitor alone did not make *B. subtilis* more susceptible to the
458 predator or parasite.

459

460 We found no evidence of evolutionary change in *B. subtilis* response to either
461 predator or parasite in monocultures. In contrast, adaptation to the parasitic
462 bacteriophage was driven indirectly by selection in multispecies communities, where
463 the presence of competitors had a positive, and predators a negative, effect. The
464 density of parasites was lowest in the presence of both other antagonists but this
465 does not appear to have altered the strength of their evolutionary selective pressure
466 on *B. subtilis*. This implies that adaptations conferring a competitive advantage
467 against *S. marcescens* also conferred a level of resistance against bacteriophage
468 SPP1. There are several potential mechanisms through which bacteria may develop
469 resistance against both a competitor and a bacteriophage parasite simultaneously.

470 For instance, the production of extra-cellular compounds – including matrices and
471 competitive inhibitors– are known to confer both competitive advantages [Hibbing
472 2010] and resistance [Labrie 2010] against host-specific bacteriophage parasites.
473 Only plastic defensive response to predation through biofilm production was
474 observed and this was not affected by antagonist community composition. When
475 both competitor and predator were present together, with or without the parasite, the
476 resistance of *B. subtilis* to the ancestral parasite was similar to that of the ancestral
477 *B. subtilis*. As the predator appeared to feed non-preferentially on all bacteria
478 present, it had a negative effect on the densities of both *B. subtilis* and *S.*
479 *marcescens*, which likely evened out some of the competitive interactions between
480 the two species. In addition, it is likely, though not directly measured here, that
481 predation selected for *S. marcescens* defence evolution which may have altered
482 competitive interactions between the bacteria [Hiltunen 2017]. Together, these
483 results suggest that competitors and predators impose opposing selection but that,
484 when present in the community together, cancel each other out indicative of cryptic
485 evolution [Yoshida 2007].
486
487 Our focal bacterium, *B. subtilis*, adapted differentially to the growth media depending
488 on the species that it was co-cultured with. The presence of single enemies did not
489 increase or reduce the maximum growth obtained by the *B. subtilis* populations
490 relative to their ancestral strain. This implies that changes in maximum growth would
491 likely be due to costs of resistance against multiple enemies. However, the presence
492 of predator and phage together, with or without the competitor, led to lowered
493 maximum growth. This suggests that the predators and parasites had additive
494 negative effects on the growth of the bacterium. We also found that all populations of

495 single- or two-enemy communities had lower growth rates than the ancestral strain.
496 In contrast, the presence of all three enemies at once led to increased growth rates
497 in the growth medium relative to the other populations. It has been shown previously
498 that evolution of defensive traits can impose costs in terms of reduced growth rates
499 [Ford 2016; Ashby 2017]. The effects of community complexity on a given species
500 depend upon the growth environment that they find themselves in, how each species
501 is adapted to it and, thus, the relative costs of defensive resistance evolution.
502 However, we found that resistance evolution did not increase clearly with community
503 complexity and is thus unlikely to explain the lowest growth rate cost in the most
504 complex community.

505

506 Neither the ecological nor the evolutionary outcomes of our focal bacterium *B.*
507 *subtilis* could be predicted reliably based on pairwise interactions. We found that
508 observed densities of *B. subtilis* populations in complex communities were
509 consistently lower than predicted from pairwise cultures across all treatments. This is
510 suggestive of synergistic interactions among enemy communities. Similarly, the
511 evolutionary outcomes of *B. subtilis* were more varied and often in disagreement
512 between observed and predicted outcomes in general. However, these mismatches
513 depended upon the composition of specific enemy communities and the given traits
514 measured. Most of the discrepancies between predicted and observed evolutionary
515 outcomes were associated with competitive ability and the growth parameters of our
516 evolved isolates, while no clear pattern was found with increasing community
517 complexity. The greatest magnitude of evolutionary response in monoculture was
518 observed with the competitor bacterium *S. marcescens*, an effect which was no
519 longer observed with increasing complexity. This could suggest that the greater the

520 magnitude of pairwise interactions, the greater the extent that increased complexity
521 will modify that response in natural communities.

522

523 The coupling of eco-evolutionary outcomes were also trait-specific: evolutionary
524 changes in the competitive ability of *B. subtilis* were linked strongly with ecological
525 dynamics, whereas the evolution of parasite resistance did not exert a clear
526 ecological signal. When species are dealing with a single or few strong interactions it
527 might be expected that ecological dynamics are tightly coupled with evolutionary
528 trajectories, such that relative species densities may indicate the strength of
529 selection. Ecological parameters such as biomass are frequently used to elucidate
530 shifts in evolutionary outcomes (such as changes in the ability to resist parasites)
531 within populations [Yoshida 2007]. Shifts in a population's evolutionary strategy in
532 terms of growth rates and resistance to enemies have the potential to greatly alter
533 the ecological interactions within a community. Detecting such evolutionary signals
534 of change within a population in different ecological contexts is of great importance
535 for predicting the impact of changing environments and biodiversity loss. When
536 considering the impact of global change on species evolution, our results suggest
537 that competitive interactions may play a far stronger role than appreciated
538 previously. Competition in microbial communities is a known driver of many species
539 traits [Schutler 2015; Ashby 2017; Niehus 2017] and our study shows that
540 exploitative competitive interactions may be even more important for predicting
541 responses to other biotic stressors than strong trophic interactions.

542

543 In conclusion, our findings demonstrate that predicting ecological and evolutionary
544 dynamics of complex systems based on pairwise interactions is extremely

545 challenging. If we are to better predict eco-evolutionary outcomes in large
546 multispecies ecosystems, we must endeavor to scale up empirical experiments to
547 incorporate a greater range of more realistic interaction networks, incorporating
548 multiple trophic levels. Moreover, our results suggest that selection in one context
549 can have unexpected consequences for species interactions in another context due
550 to negative and/or positive trait correlations. It is thus crucial to try to understand
551 targets of selection more mechanistically in order to predict how different selection
552 pressures might shape species evolution in complex communities. Incorporating
553 these approaches into current eco-evolutionary dynamics frameworks will help to
554 achieve much greater insight into the evolution and mechanisms of trait correlations
555 and, therefore, enhance our capacity to understand and predict species response to
556 global change in complex communities.

Figures and Legends:

811

812 **Figure 1.** Abundance (log-transformed, mean \pm std. dev., $n = 7$) of the focal species

813 *B. subtilis* (orange circles), competitor bacterium *S. marcescens* (red circles),

814 predator *P. caudatum* (green circles) and *B. subtilis*-specific parasite phage SPP1

815 (purple circles) in each treatment over the duration of the experiment (Days 1-10).

816

817

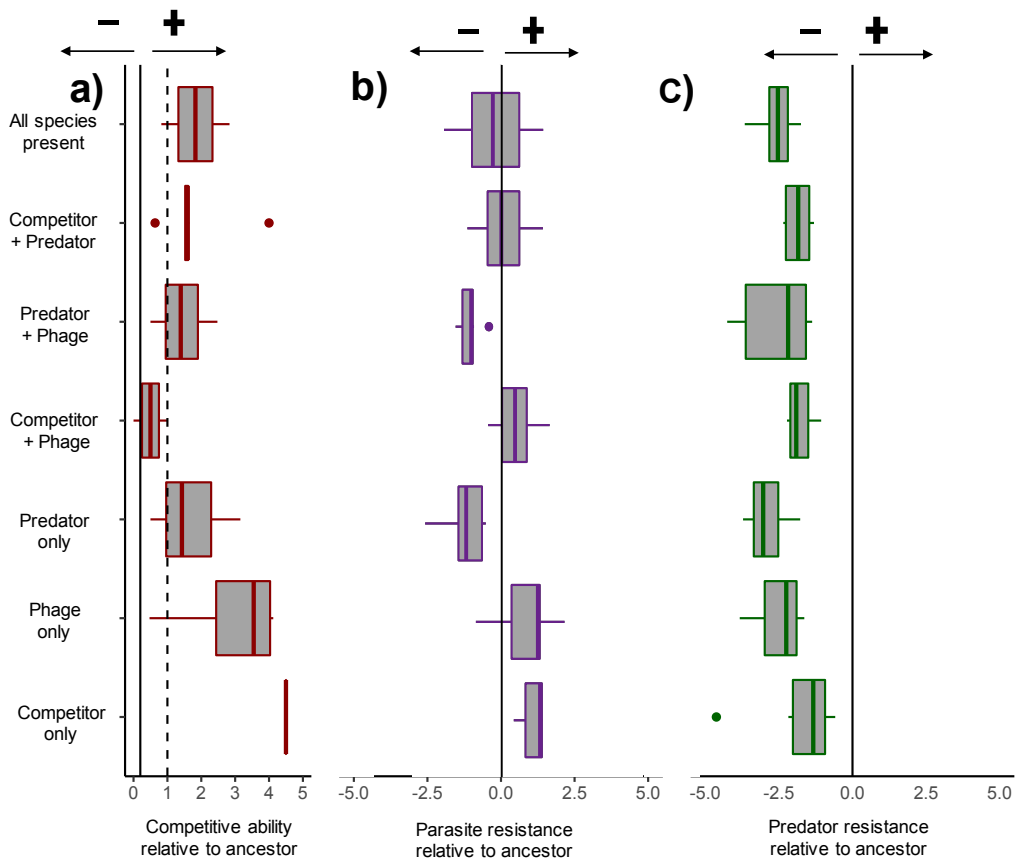

818

819

820

821

Direction of evolutionary change relative to ancestral *B. subtilis*

822

823

824 **Figure 2.** The effect of community composition on *B. subtilis* evolution relative to the

825 ancestral strain (solid line). **a.** Competitive ability of *B. subtilis* isolates, measured as

826 the ratio of *B. subtilis* to *S. marcescens* (dashed line indicates a 1:1 ratio, solid line

827 represents ancestral resistance). **b.** Relative resistance to parasite in *B. subtilis*

828 across treatment groups. Resistance to phage SPP1 was measured as the

829 difference in growth (optical density) of *B. subtilis* in the presence or absence of the

830 ancestral phage parasite. The solid line represents the resistance of ancestral *B.*

831 *subtilis* and the resistance of our experimental treatment isolates relative to ancestral

832 parasite resistance. **c.** Growth of *B. subtilis* isolates in the presence of the predator

833 *P. caudatum* (measured as \log_{10} optical density of biofilm production). Solid line

834 indicates resistance of the ancestral *B. subtilis* grown in the presence of *P.*

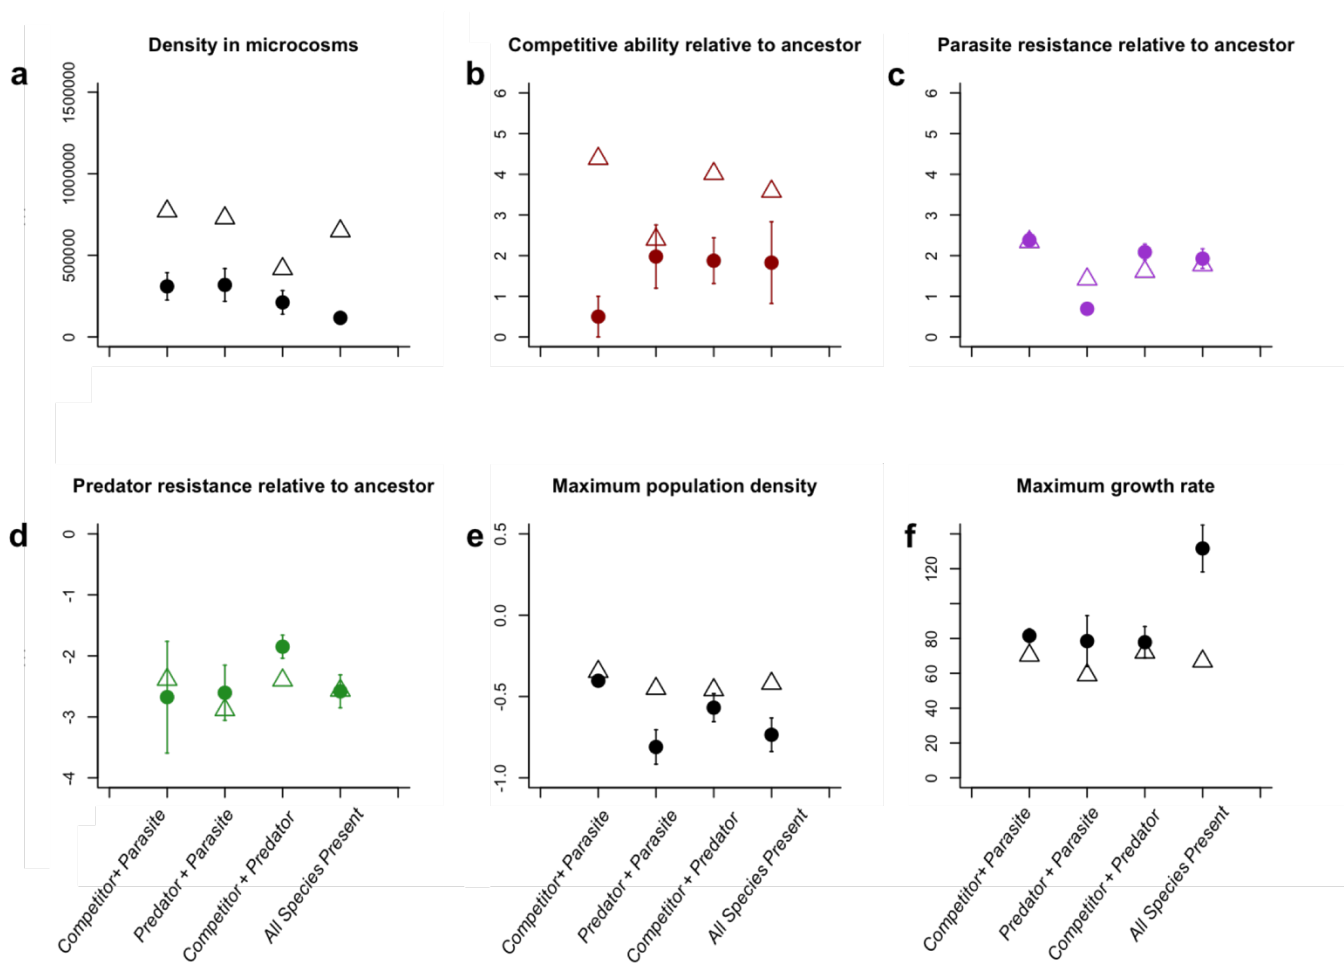

835 *caudatum*). In all cases, values to the right of the solid lines indicate higher relative
836 resistance than the ancestral strain, values to the left of the solid line indicate lower
837 resistance relative to ancestral strain of *B. subtilis*.

838

839

840

841

842

843 **Figure 3.** Predicted (open triangles) and observed (closed circles) measurements of

844 *B. subtilis* in multispecies communities. **a.** Density of *B. subtilis* per 1 ml microcosm

845 medium. **b.** Maximum population density. **c.** Maximum growth rate of evolved

846 isolates **d.** Competitive ability of *B. subtilis* isolates, measured as the ratio of *B.*

847 *subtilis* to *S. marcescens*. **e.** Relative resistance to parasites of *B. subtilis* across
848 treatment groups. **f.** Growth of *B. subtilis* isolates in the presence of the predator *P.*
849 *caudatum*. Predicted values were calculated as the mean (\pm s.e.) across antagonist
850 monoculture treatments; For example, the predicted value for the competitor +
851 parasite treatment was estimated by merging the competitor alone and parasite
852 alone treatments and calculating their combined mean.
