ABSTRACT

The heterogeneous stock (**HS**) is an outbred rat population derived from eight inbred rat strains.

The population is maintained with the goal of minimizing inbreeding and maximizing the genetic

diversity of the stock. To effectively utilize this rat strain for fine-scale genetic mapping, genotype

data is necessary for large numbers of animals. A few genotyping microarrays have been created

for rats; however, they were expensive and are no longer in production. Thus, to obtain high-

density genome-wide marker data for genetic mapping, we have adapted genotype-by-sequencing

(**GBS**) for use in rats. Here, we outline the laboratory and computational steps we took to design

and optimize an efficient double digest genotype-by-sequencing (**ddGBS**) protocol for rats. We

include a detailed protocol to perform ddGBS in rats. To analyze the ddGBS sequencing data, we

evaluated multiple existing computational tools and designed a workflow that allowed us to call

and impute over 3.7 million SNPs genome-wide in the HS. We also compared various rat genetic

maps for use in imputation, including a recently developed map specific to the HS. Using the

pipeline, we obtained concordance rates of 99% with data from a rat genotyping array. The

computational pipeline that we have developed can be easily adapted for use in other species.

INTRODUCTION

Advances in next-generation sequencing technology over the past decade have enabled the

discovery of high-density, genome-wide single nucleotide polymorphisms (**SNPs**) in model

systems. Comprehensive assays of the standing genetic variation in these organisms has allowed

for the identification of quantitative trait loci (QTL) and the application of numerous population

genetic and phylogenetic methods. However, due to the high degree of linkage disequilibrium

(**LD**) in many structured breeding populations, sequencing whole genomes is not necessary. SNPs

are frequently in strong LD with adjacent loci, effectively 'tagging' nearby variation, and thereby

reducing the number of sites that need to be genotyped. Several reduced-representation

sequencing approaches that take advantage of LD structure have been previously described (Miller

et al. 2007; van Orsouw et al. 2007; Van Tassell et al. 2008; Baird et al. 2008; X. Huang et al.

2009; Davey et al. 2011; Elshire et al. 2011; Poland et al. 2012; Peterson et al. 2012; Sun et al.

2013; Scheben, Batley, and Edwards 2017). Thousands of SNPs can be identified in large numbers

of samples for a fraction of the price of whole-genome sequencing methods (Chen et al. 2013; He

et al. 2014). The advantages of these methods are especially attractive when applied to less

commonly utilized species or strains for which genotyping microarrays are not available.

Of the existing reduced-representation protocols, the genotyping-by-sequencing (**GBS**)

approach developed by Elshire et al. (Elshire et al. 2011) has been frequently modified to

accommodate non-model species, such as: soybean (Sonah et al. 2013), rice (Furuta et al. 2017),

oat (Fu and Yang 2017), chicken (Pértille et al. 2016; Wang et al. 2017), mouse (Parker et al.

2016), fox (Johnson et al. 2015), and cattle (De Donato et al. 2013), among others. The greatly

varying genomic composition among organisms necessitates a diverse and customized set of

approaches for obtaining high-quality genotypes. As such, both the GBS protocol and

computational pipeline require modifications when applied to a new species. Recent work from

our group showed that GBS can be effectively applied to outbred mice (Parker et al. 2016;

Gonzales et al. 2017; Zhou et al. 2018) and rats (Fitzpatrick et al. 2013). However, those

publications used protocols that had not been optimized, leaving significant room for improvement

in genotype quality and marker density. Additionally, although several tools and workflows for

the analysis of GBS data have been described, including Stacks (Catchen et al. 2013), IGST-GBS

(Sonah et al. 2013), TASSEL-GBS (Glaubitz et al. 2014), Fast-GBS (Torkamaneh et al. 2017),

and GB-eaSy (Wickland et al. 2017), the majority were developed and optimized for use in plant

species and given the lack of well-developed genomic resources in these species, do not leverage the wealth of genomic data available for model organisms such as rats. Here we describe the customized computational and laboratory protocols for applying GBS to HS rats.

The HS is an outbred rat population created in 1984 using eight inbred strains and has been maintained since then with the goal of minimizing inbreeding and maximizing the genetic diversity of the colony (Johannesson et al. 2008; Woods and Mott 2017). After more than 80 generations of accumulated recombination events, their genome has become a fine-scale mosaic of the inbred founders' haplotypes. The breeding scheme and the number of accumulated generations has made the HS colony attractive for genetic studies. Additionally, extensive deep sequencing data exists for the eight progenitor strains, allowing for accurate imputation from sites directly captured by GBS to millions of additional SNPs.

Detailed here are the steps we have taken to optimize a rat GBS protocol and computational pipeline. Drawing on existing protocols (Elshire et al. 2011; Peterson et al. 2012; Poland et al. 2012; Parker et al. 2016) as templates, we redesigned our GBS approach and have developed a novel, reference-based, high-throughput workflow to accurately and cost-effectively call and impute variants from low-coverage double digest GBS (**ddGBS**) data in HS rats. This publication is intended as a resource for others who might wish to perform GBS in rats and should provide a roadmap for adapting GBS for use in new species. We demonstrate that with a suitable reference panel, applying reduced representation approaches and imputation in model systems can provide high-confidence genotypes on millions of genome-wide markers.

MATERIALS AND METHODS

Tissue samples and DNA extraction

Samples for this study originated from three sources: an inhouse advanced intercross line (**AIL**)

derived from LG/J and SM/J mice (Gonzales et al. 2018), Sprague Dawley (**SD**) rats from Charles

River Laboratories and Harlan Sprague Dawley, Inc. (Gileta et al. 2018), and an HS rat colony

(Woods and Mott 2017; Chitre et al. 2018). Early stages of ddGBS optimization utilized AIL

genomic DNA extracted from spleen by a standard salting-out protocol. Later optimization steps

were performed using genomic DNA from SD rats extracted from tail tissue using the PureLink

Genomic DNA Mini Kit (Thermo Fisher Scientific, Waltham, MA). HS rat DNA was extracted

from spleen tissue using the Agencourt DNAdvance Kit (Beckman Coulter Life Sciences,

Indianapolis, IN). All genomic DNA quality and purity was assessed by NanoDrop 8000 (Thermo

Fisher Scientific, Waltham, MA). Interestingly, we observed that rat genomic DNA appears to

degrade faster than mouse genomic DNA following extraction; therefore, we recommend storing

rat genomic DNA at -20° and using it within weeks of extraction whenever possible.

***In silico* digest of rat genome**

We used *in silico* digests to aid in the selection of restriction enzymes, with the goal of maximizing

the proportion of the genome captured at sufficient depth to make confident genotype calls We

used the *restrict* function in EMBOSS (version 6.6.0) (Rice, Longden, and Bleasby 2000) in

conjunction with the REBASE database published by New England BioLabs (NEB; version 808)

(Roberts and Macelis 1999) to perform *in silico* digest of the current release of the Norway brown

rat reference genome, designated rn6. For the primary restriction enzyme, we chose PstI, which

had been successfully used in numerous project (Fitzpatrick et al. 2013; Parker et al. 2016;

Gonzales et al. 2018). We performed the digest with PstI alone and then with PstI paired with each

of 7 secondary enzymes: AluI, BfaI, DpnI, HaeIII, MluCI, MspI, and NlaIII. We only considered

fragments with one PstI cut site and one cut site from the secondary enzyme because the adapter

and primer sets are designed to only allow these fragments to be amplified. The final choice of

enzyme (NlaIII) was determined empirically and is detailed in the Results.

Restriction enzyme selection

Initial criteria for selecting a secondary restriction enzyme were: a 4bp recognition sequence, no

ambiguity in the recognition sequence (i.e. N's), compatibility with the NEB CutSmart Buffer, and

an incubation temperature of 37°C. The list of enzymes meeting these criteria at the time included:

AluI, BfaI, DpnI, HaeIII, MluCI, MspI, and NlaIII. Using the *in silico* digest data, we looked to

maximize the portion of the genome contained within a fragment size range of 125-275bp (250-

400bp with annealed adapters and primers) (Figure 1; Table 1). We excluded enzymes that

produced blunt ends, both because it would be more difficult to anneal adapters to blunt ended

fragments and because our adapters would then also anneal to blunt ends produced by DNA

shearing. We also excluded methylation-sensitive enzymes, as we did not want to limit the breadth

of our sequencing efforts, accepting the possibility of read pileup in repetitive regions. Based on

these criteria, NlaIII, BfaI, and MluCI were selected for further testing.

ddGBS library preparation and sequencing

The full ddGBS protocol is available in File S1. In brief, approximately 1µg of DNA is used per

sample. Sample DNA, PstI barcoded adapters, and NlaIII Y-adapter are combined in a 96-well

plate and allowed to evaporate at 37°C overnight. Sample DNA and adapters are re-eluted on day

two with a PstI/NlaIII digestion mix and incubated at 37°C for two hours to allow for complete

digestion. Ligation reagents are then added and incubated at 16°C for one hour to anneal the

adapters to the DNA fragments, followed by a 30-minute incubation at 80°C to inactivate the

restriction enzymes. Sample libraries are purified using a plate from a MinElute 96 UF PCR

Purification Kit (QIAGEN Inc., Hilden, Germany), vacuum manifold, and ddH$_2$O. Once re-eluted,

libraries are quantified in duplicate with Quanit-iT PicoGreen (Thermo Fisher Scientific, Waltham,

MA) and pooled to the desired level of multiplexing (i.e. 12, 24, or 48 samples per library). Pooled

libraries are concentrated to obtain the desired volume for use in the Pippin Prep. The concentrated

pool is quantified to ensure the gel cassette will not be overloaded with DNA (>5µg). The pool is

then loaded into the Pippin Prep for size selection (300-450bps) using a 2% agarose gel cassette

on a Pippin Prep (Sage Science, Beverly, MA). Size-selected libraries were then PCR amplified

for 12 cycles to increase the quantity of DNA, concentrated, and checked for quality on an Agilent

2100 Bioanalyzer with a DNA 1000 Series II chip (Agilent Technologies, Santa Clara, CA).,

Bioanalyzer results were used to assure sufficient DNA concentration and to identify excessive

primer dimer peaks.

An initial 96 HS samples were sequenced, 12 samples per library, at Beckman Coulter

Genomics (now GENEWIZ) on an Illumina HiSeq 2500 with v4 chemistry and 125bp single-end

reads. Subsequently, we began using a set of 48 unique barcoded adapters (File S2) to multiplex

48 HS samples per ddGBS library. Each library was run on a single flow cell lane on an Illumina

HiSeq 4000 with 100bp single-end reads at the IGM Genomics Center (University of California

San Diego, La Jolla, CA).

158 **Figure 2. ddGBS sequencing data analysis workflow.** Each step of the workflow is described
159 in the text.

160
161

Evaluation of ddGBS pipeline performance

We present the steps required to call and impute genotypes from raw ddGBS sequencing data in

Figure 2. During optimization of the pipeline, performance was assessed by two primary metrics:

(1) the number of variants called and (2) genotype concordance rates for calls made in 96 HS rats

that had both ddGBS genotypes and array genotypes from a custom Affymetrix Axiom MiRat

625k microarray (Part#: 550572). There were two checkpoints in the GBS pipeline where genotype

quality (measured by concordance rate) was assessed: after internal imputation within Beagle

(Browning and Browning 2009, 2016) and again after imputation to the reference panel with

IMPUTE2 (B. N. Howie, Donnelly, and Marchini 2009; B. Howie et al. 2012). A third, additional

metric we checked was the transition to transversion ratio (T_ST_V), which is expected to be ~2 for

intergenic regions.

Demultiplexing

The PstI adapter barcodes were used to demultiplex FASTQ files into individual sample files.

Three demultiplexing software packages were tested: FASTX Barcode Splitter v0.0.13 [RRID:

SCR_005534] (Hannon Lab 2010), GBSX v1.3 (Herten et al. 2015), and an in-house Python script

(Parker et al. 2016). Reads that could not be matched with any barcode (maximum of 1 mismatch

allowed), or that lacked the appropriate enzyme cut site, were discarded. Samples with less than

two million reads after demultiplexing were discarded. Data concerning demultiplexing are shown

in Table S1 are from a single HS rat sequenced in a 12-sample library on one lane after

demultiplexing and adapter/quality trimming.

Barcode, adapter, and quality trimming

183 Read quality was assessed using FastQC v0.11.6 (Andrews 2017). We compared the efficacy of

184 two rapid, lightweight software options for trimming barcodes, adapters, and low-quality bases

185 from the NGS reads: Cutadapt v1.9.1 (Martin 2011) and the FASTX Clipper/Trimmer/Quality

186 Trimmer tools v0.0.13 (Hannon Lab 2010) (Table S2). A base quality threshold of 20 was used

187 and reads shorter than 25bp were discarded.

Read alignment and indel realignment

Rattus norvegicus genome assembly rn6 was used as the reference genome for read alignment with

the Burrows-Wheeler Aligner v0.7.5a (BWA) [RRID: SCR_010910] (H. Li and Durbin 2009)

using the *mem* algorithm. We then used GATK IndelRealginer v3.5 [RRID: SCR001876]

(McKenna et al. 2010) to improve alignment quality by locally realigning reads around a reference

set of known indels in 42 whole-genome sequenced inbred rat strains, including the eight HS

progenitor strains (Hermsen et al. 2015).

Variant calling

Variants were called, and genotype likelihoods were computed at variant sites using ANGSD

v0.911, under the SAMtools model for genotype likelihoods (Korneliussen, Albrechtsen, and

Nielsen 2014; Durvasula et al. n.d.). Further, using ANGSD, we inferred the major and minor

alleles (-*domajorminor* 1) from the genotype likelihoods, retaining only high confidence

polymorphic sites (-*snp_pval* 1e-6), and estimated the allele frequencies based on the inferred

alleles *(-domaf* 1). We discarded sites missing read data in more than 4% of samples (–*minInd*).

Additionally, we tested multiple thresholds for minimum base (-*minQ*) and mapping (-*minMapQ*)

qualities.

Internal imputation

Beagle v4.1 (Browning and Browning 2009, 2016) was used to improve the genotyping within the

samples without the use of an external reference panel. Missing and low quality genotypes were

imputed by borrowing information from other individuals in the dataset with high quality

information at these same variant sites. . It must be noted that before settling on the combination

of ANGSD and Beagle for genotype calling and internal imputation, we also experimented with

GATK's UnifiedGenotyper and HaplotypeCaller (McKenna et al. 2010) with various parameter

settings, but with unsatisfactory results.

Quality Control for genotypes before imputation using and external reference panel

To verify the quality of the "internally" imputed genotypes prior to imputing SNPs from the 42

inbred strain reference panel (Hermsen et al. 2015), we checked concordance rates for the 96 HS

animals with array genotypes, examined the T_ST_V ratio, and assessed whether the sex as recorded

in the pedigree records agreed with the sex empirically determined by the proportion of reads on

the X-chromosome out of the total number of reads (Figure S1). We also identified Mendelian

errors using the --mendel option in *plink* and known pedigree information for 1,136 trios from 214

families within the HS sample. Using the fraction of the trios that were informative for a given

SNP and the formula $1-(1-2p(1-p))^3$, where p represents the minor allele frequency of the allele,

we formed curves for the distributions of the expected number of Mendelian errors for both SNPs

and samples and chose the inflection points as thresholds for the number of Mendelian errors

allowed.

Data preparation for phasing with external reference panel

First, in our study sample of 96 samples, we only retained variants previously identified in

the 8 HS founder strains because we expected the polymorphisms in our samples to be limited to

the variation present in the founders (Hermsen et al. 2015; Ramdas et al. 2018). Further, to improve

imputation accuracy and computational efficiency, we employed a pre-phasing step with

IMPUTE2 (*prephase_g*) (B. Howie et al. 2012) prior to imputation. A flowchart outlining the pre-

phasing protocol is presented in Figure S2.

Genetic maps

Genetic maps are required for phasing and imputation with IMPUTE2. When we began this

project, no strain-specific recombination map was available for HS rats. Thus, we considered a

sparse genetic map for SHRSPxBN (Steen et al. 1999). We also tested two types of linearly

interpolated genetic maps, with recombination rates set at either 1cM/Mb or the chromosome

specific averages for rats, as reported by Jensen-Seaman et al. (Jensen-Seaman 2004). Lastly, late

in the course of this project, we experimented with an HS-specific genetic map developed by

Littrell et al. the Medical College of Wisconsin (Littrell et al. 2018).

Imputation to reference panel

We used a combination of existing sequencing and array genotyping data from the HS rat founder

and other inbred laboratory rat strains (Hermsen et al. 2015) as reference panel for imputation.

Genotype data underwent QC and were phased by Beagle into single chromosome haplotype files.

Haplotype files were then created using the workflow detailed in Figure S2. Imputation by

IMPUTE2 was performed in 5Mb windows using the aforementioned reference panels and genetic

maps.

Data availability

Genotype data will be available at

https://figshare.com/articles/Heterogeneous_Stock_Genotype_Data/8243222 and the code

necessary to run the steps outline in the publication are provided at

https://figshare.com/articles/ddGBS_Pipeline_Commands/8243156. Supplementary Files are

available at https://figshare.com/articles/Supplementary_Files/8243129. Additional data is

available upon request.

253   RESULTS

ddGBS optimization

Previous projects utilizing GBS in mice and rats (Fitzpatrick et al. 2013; Parker et al. 2016;

Gonzales et al. 2018) often encountered an issue where certain regions of the genome experienced

high pileups of reads per sample (>100x), while other regions were covered by just 1-2 reads. This

read distribution imbalance can be caused in part by PCR amplification bias, where a subset of

fragments are preferentially amplified until they dominate the final library (Kanagawa 2003; Aird

et al. 2011). These previous protocols utilized 18 cycles of amplification. We tested reducing this

to 8, 10, 12, or 14 cycles and found that below 12 cycles, there was insufficient PCR product to

accurately quantify and pool for sequencing. The reduction in the number of PCR cycles was

expected to reduce PCR bias, though this was not explicitly tested.

Another concern regarding previous sequencing results was an excess of long fragments

(>700bps as determined by *in silico* digest), which do not provide sufficient reads to make

confident genotype calls (< 5 reads per sample) and are therefore wasteful. We tested three

methods of combating this issue, including: increasing the digestion time or enzyme concentration,

performing size selection on the libraries, and using a two-enzyme restriction digest.

We considered the possibility that the restriction enzyme digests might not be running to

completion. To address this possibility, we increased the duration of the digestion from 2 hours to

3 or 4 hours. We also tried increasing the number of units of PstI enzyme added, to ensure complete

digest. Neither of these modifications impacted the final fragment length distribution of the library,

indicating that the digest was reaching completion after 2 hours using the original concentration

of PstI (File S3 – wells 1-6).

Our previous GBS protocol did not have an explicit library fragment size selection step.

The final library was purified using a MinElute PCR Purification Kit (QIAGEN Inc., Hilden,

Germany), which isolates PCR products 70bp-4kb in length, leaving a wide range of fragment

sizes in the final library, under the assumption that only shorter fragments would bridge amplify

on the flow cell. This method was imprecise and had low reproducibility, negatively impacting our

ability obtain reads at consistent sites across libraries. Rather than attempt size selection by gel

extraction, we chose to utilize a Pippin Prep, which automates the elution of DNA libraries of

desired fragment size ranges. By using this automated size selection, we reduced the proportion of

the genome targeted for sequencing, and because restriction enzymes make the consistent cuts

across samples, ensure the same fragments are sequenced in the majority of libraries. Since the

clustering process involves a bridge amplification step that preferentially amplifies library

fragments with shorter insert sizes (Illumina, Inc. 2014), we kept the size selection window narrow

(250-400bps) to avoid introducing a bias in which fragments were sequenced. A comparison of

the fragment size distributions for the protocols before and after introduction of the Pippin Prep is

shown in File S4.

To increase the proportion of the genome captured within the fragment size window, we

pursued a double digest of the genome using a secondary enzyme with a more frequently occurring

recognition sequence. When used alone, *in silico* digest of the rn6 reference genome by PstI

(Figure 1; Table 1) showed that only ~0.5% of the genome would have fallen within a 150bp

fragment size window selected on the Pippin Prep. Previously, we performed GBS in CFW mice

using the single-enzyme approach and observed that large regions of the genome that were not

covered by sequencing reads (Parker et al. 2016). Therefore, we sought to increase the fraction of

the genome that was accessible to GBS, so that there would be sufficient SNPs to tag majority of

the variation in the rat genome. Additionally, we were concerned about potential biases in

coverage, heterozygosity, and the minor allele frequency (**MAF**) spectrum that may be introduced

by incomplete capture of the genome (Flanagan and Jones 2018).

The number of fragments with one of each of the cut sites were summed for all observed

lengths and the results summarized in Figure 1 and Table 1. BfaI, MluCI, and NlaIII were chosen

for further testing due to their compatibility with PstI digestion reagents and temperatures, sticky

ends, and the proportion of the genome falling in the size selection window. We ruled out BfaI

because it only had a 2bp overhang after cleavage, which led to a high concentration of adapter

dimer in the sequencing libraries (S5 File). NlaIII was chosen because it contained the greatest

portion of the genome in the size selection window.

Table 1. Restriction enzyme options for double digest.

Restriction Enzyme(s)	Recognition sequence	Length of Overhang (bp)	% Genome in 250-400bp Region[+]	% Genome in 300-450bp Region[+]
PstI	CTGCA^G	4	0.48%	0.56%
PstI + AluI	AG^CT	0	3.06%	2.88%
PstI + BfaI	C^TAG	2	3.10%	3.25%
PstI + DpnI*	GA^TC	0	2.69%	3.00%
PstI + HaeIII	GG^CC	0	2.71%	2.79%
PstI + MluCI	^AATT	4	3.32%	3.21%
PstI + MspI	C^CGG	2	1.16%	1.24%
PstI + NlaIII	CATG^	4	3.45%	3.31%

310 The percent genome in region columns indicate the percentage of the genome that falls within the
311 provided fragment size ranges and can therefore be captured by GBS.

313 * Restriction enzyme is methylation sensitive.

314 [+] Calculated using rn6 genome length of 2,870,182,909bps.

318   **Figure 1.** *In silico* **digest fragment distributions for PstI and potential secondary restriction**
319   **enzymes.**

320

321

322

323   Each panel represents an independent digest of rn6 with the listed enzyme(s). Regions highlighted
324   in blue are fragments that would be selected by the Pippin Prep (125-275bp) after annealing
325   adapters and primers. These regions are quantified in Table 1 by multiplying the length of the
326   fragments by the number of fragments to estimate the portion of the genome captured.

327

In our previous GBS protocol, all fragments were cut on both ends by PstI. By using a substantially lower concentration of the barcoded PstI adapter than the common PstI adapter, we ensured the barcoded adapter would be the limiting reagent and the majority of fragments with an annealed barcoded adapter would have a common adapter on the other end. This is crucial, as having one of each of the adapters is required for proper amplification of the fragments on the flow cell. However, when using both PstI and NlaIII, the library is predominantly composed of fragments cut on both sides by NlaIII (File S6), which will amplify during PCR with a common adapter, but not on the flow cell. Therefore, we employed a Y-adapter (Poland et al. 2012) to control the direction of the first round of PCR and prevent two-sided NlaIII fragments from dominating the final sequencing library (File S2).

We tested numerous quantities of PstI and NlaIII adapters in an attempt minimize the amount used and avoid adapter dimers in the final libraries. For the barcoded PstI adapters, we tested 120pmol, 60pmol, 20pmol, 4.0pmol, 2.67pmol, 1.60pmol, 0.53pmol, and 0.20pmol; for the NlaIII Y-adapter, 30pmol, 10pmol, 5.0pmol, 4.0pmol, and 1.0pmol (Files S7 & S8). We found that 0.20pmol of PstI adapter and 4pmol of NlaIII Y-adapter yielded sufficient library and minimized the presence of adapter dimers.

We sequenced a trial flow cell with 8 pooled ddGBS libraries of 12 SD rat samples each (96 total) on a HiSeq 2500 (Illumina, San Diego, CA) with 125bp reads and v3 chemistry, obtaining an average of 15.3 million reads per sample. Given the NlaIII *in silico* digest results suggested we were capturing ~3.4% of the genome and that we were using 125bp reads, this corresponded to approximately 20x coverage of captured sites. We subsequently increased the number of samples to 48 per library for the HS rats because we hypothesized 5x would be sufficient coverage per sample when utilizing imputation to a reference panel. We also discovered that a

portion of the reads contained sequence fragments of the NlaIII adapter sequence, indicating there were fragments with insert sizes smaller than 125bps in the final library. To avoid this, we increased the fragment size range to 300-450bps (Table 1), which corresponds to a 175-325bp insert size once the adapters and primers are accounted for. Due to the high concentrations of our libraries after pooling, the library size distribution obtained from the Pippin Prep was uniformly shifted towards higher fragment lengths (Figure S3).

The final ddGBS protocol can be found in File S1 and the necessary primer and adapter sequences in File S2. This protocol was used for the sequencing of all HS rats included in the following computational optimization steps.

Demultiplexing

The number of base pairs of sequencing data retained after demultiplexing was fairly consistent across demultiplexing software (Table S1). We ultimately decided to use FASTX Barcode Splitter because it yielded the greatest number of reads after quality/adapter trimming and had faster run times. An average of 330 million 100bp reads were obtained per library, resulting in ~7 million reads per sample. Figure S4 shows the distribution of reads counts for all samples after demultiplexing.

Adapter and quality trimming

Read quality was substantially improved after trimming the barcode and adapter sequences and low-quality base pairs at the ends of reads (Figure S5). Overall read counts were only marginally reduced by quality trimming (Table S1). We observed that the number of called variant sites and the genotyping rate were both greater when using reads initially processed by cutadapt (Martin, 2011) than reads processed by the FASTX_Toolkit (Table S2). Importantly, a large portion of the

additional identified variants were known variant sites from the 42 inbred strains reference set

(Figure S6), indicating the elevated call rate was at least in part due to capturing more true variant

sites. We viewed this as sufficient support for proceeding with cutadapt for adapter removal and

quality trimming.

Mapping quality

The number of called variants and genotype call rates were identical at read mapping quality

(mapQ) thresholds of either 20 or 30 (Table S3) within ANGSD. As the ANGSD mapQ threshold

was raised to 45, there was a small reduction in the number of called variants, and then much

greater losses at thresholds of 60 or 90. Fortunately, genotype concordance rates at both low and

high mapQ thresholds were stable, despite the putatively higher quality of the alignments (Figure

S7). This permitted us to select a lower mapQ threshold (mapQ = 20), maximizing the number of

variants called without sacrificing genotyping accuracy.

Variant calling

Figure 3 shows that across all levels of genotype discordance rates (with the array genotyping

data), the combination of the ANGSD (*samtools* model) with BEAGLE produced more SNPs, at

various genotyping concordance thresholds, than GATK's HaplotypeCaller (McKenna et al. 2010;

DePristo et al. 2011). This observation held when variants were limited only to biallelic sites and

SNPs with an MAF > 0.05 (Figure S8).

Figure 3. Genotype discordance rates between array data and variants called by GATK or

ANGSD.

The figure compares the number variants called by combination of ANGSD and Beagle or GATK

HaplotypeCaller and Beagle at various thresholds of genotype discordance with array data. Calls

were made using the 96 HS rats with array data. (A) The x-axis represents the genotype

discordance rate thresholds and the y-axis is the number of variants that surpass that threshold for

each genotype calling method. (B) Additional filters were applied to the original SNP sets and the

plot zooms in on a smaller range of acceptable discordance rates. Blue lines represent the unfiltered

SNP set. Yellow lines have been filtered for singletons. Red lines have further excluded SNPs with

an MAF < 0.05. Each line contains the same number of points.

ANGSD supports four different models for estimating genotype likelihoods: SAMtools,

GATK, SOAPsnp and SYK. We compared the methods to determine which produced the most

SNPs with the lowest error rates. The SOAPsnp model demonstrated an advantage in genotype

accuracy and number of variants called post-imputation with Beagle (Figure S9). However,

SOAPsnp requires considerably more time (1.7x for 96 samples) and memory and scales poorly

with sample size. With greater than 2,000 samples, we were unable to allocate sufficient memory

for the SOAPsnp model to successfully run, even after dividing the chromosomes into several,

smaller chunks. The marginal benefits of SOAPsnp in accuracy and number of variants were far

outweighed by its limitations when applied to a large sample set. The GATK model showed a

greater number of variants for more lenient genotype discordance rate threshold, but as stringency

increased, the number of variants converged across the remaining 3 models. We proceeded with

the SAMtools model for genotype likelihood estimation due to its previous support in the GBS

literature (Torkamaneh et al. 2017), accepting a nominal decrease in highly concordant variants

(Figure S9) for a large reduction in run time and memory usage.

Imputation to reference panel

Imputation is use in two ways in our protocol. As described above, we use imputation to assign

missing genotypes at SNPs called in only a subset of individuals. In addition, we use imputation

in this section to call genotypes at sites where GBS that were inaccessible to ddGBS sequencing.

Thus, our second application (described here) is similar to the human genetics application in which

imputation using 1000 Genomes increases the number of SNPs beyond those included on a given

microarray platform.

Before starting this imputation step, we observed an inflated transition/transversion ratio

(Table S4) in our ANGSD/Beagle SNPs. This issue was ameliorated when the SNP set was filtered

for only "known" variants that were previously identified in either the 42 inbred strains (Hermsen

et al. 2015) or the 8 deep-sequenced HS founders (Ramdas et al. 2018). For imputation, we

therefore only provided IMPUTE2 with previously identified variant sites from our

ANGSD/Beagle output. Prior to running IMPUTE2, we also filtered the variants for biallelic sites

with a genotype call in at least two individuals. Using pedigree data for the HS rats, we further

removed samples showing an order of magnitude higher level of Mendelian error than the sample

mean. We further removed SNPs that had an error rate surpassing a threshold of ~0.005 (Figure

S10; inflection point). There were 4 samples and 4,179 SNPs removed from subsequent analyses.

Lastly, we removed any samples where the sex chromosome read ratio was incompatible with their

reported sex (Figure S1).

To determine which reference set to use for imputation, we tested six different possible

combinations of available reference data (Table 2). The most accurate imputation was observed

for the reference set containing only the 8 deep-sequenced HS founder strains (Ramdas et al. 2018);

however, imputation to this set had the lowest genotyping rate of all panels. In contrast, using the

42 rat inbred strains displayed a balance of high accuracy and low missingness, leading us to

choose this as our reference set. To better understand the role of the 8 founder strains, which were

part of the 42 strains reference panel, we created a reference panel that included only the 34 non-

HS founder strains. As expected, discordance rates were much higher when only considering non-

founders. However, the genotype missingness was lower for the 34 than the 8 founders alone,

suggesting a combination of the two was the optimal set.

Table 2. Imputation accuracy based on different variant reference panels for IMPUTE2.

The table includes six different possible reference panels for imputation. The 42 inbred strains, 34 non-founder inbred strains, and 8 HS founders from the 42 inbred strains all were derived from Hermsen et al. 2015 (Hermsen et al. 2015). The UMich 8 HS founders were obtained from Ramdas et al. 2018 (Ramdas et al. 2018). The final set of 8 HS founder was taken from Baud et al. 2013 (Rat Genome Sequencing and Mapping Consortium et al. 2013).

		Chr1	Chr2
42 inbred strains	**Discordance rate**	0.011	0.010
	# Variants	790,659	882,993
	Genotyping Rate	0.85	0.81
All 34 non-founder inbred strains	**Discordance rate**	0.035	0.030
	# Variants	812,550	912,749
	Genotyping Rate	0.84	0.80
8 HS founders only from the 42 inbred strains	**Discordance rate**	0.012	0.011
	# Variants	805,424	902,061

UMich 8 HS founders only	**Discordance rate**	0.0059	0.008
	# Variants	865,514	898,621
	Genotyping Rate	0.42	0.41
Baud et. al 2013 8 HS founders only	**Discordance rate**	0.0095	0.0096
	# Variants	507,909	540,844
	Genotyping Rate	0.43	0.40

IMPUTE2 requires a genetic map. As described in the methods section, we considered four different genetic maps, two that were empirically derived and two that were linear extrapolations based on the physical map (Figure S11). All genetic map performed similarly (Table S5). Surprisingly, the linear genetic maps performed just as well as the HS-specific map (Littrell et al.

468   2018). Thus, for simplicity, we chose to use the chromosome-specific values initially published by

469   Jensen-Seaman (Jensen-Seaman 2004).

470   To obtain our final set of ~3.7 million variants, a final round of variant filtering was

471   performed after imputation to the 42 strain reference panel. We removed SNPs with MAF < 0.005,

472   a post-imputation genotyping rate < 90%, and SNPs that violated HWE with $p<1x10^{-10}$.

473   DISCUSSION

The use of microarrays and WGS for genotyping large samples in model organisms remains cost-

prohibitive. There is therefore an urgent and wide-spread need for high-performance and

economical methods of obtaining genome-wide genotype data. While reduced-representation

approaches have been utilized in numerous species of plants and animals, including rodents

(Peterson et al. 2012; Fitzpatrick et al. 2013; Parker et al. 2016; Gonzales et al. 2017; Zhou et al.

2018), there has yet to be a published protocol optimized specifically for rats. Prior to sequencing

thousands of HS samples with GBS for our mapping efforts, we wanted to ensure we were

capturing the greatest possible number of high-quality variants at the lowest possible cost. The

protocol we present here is the culmination of careful testing and optimization of each step of the

GBS protocol for rats. We have now applied the approach to 4,973 HS rats, as well as 4,608

Sprague Dawley rats (Gileta et al. 2018).

Our previous GBS protocol (Parker *et al*, 2016), which was designed for use with CFW

mice, was unsuitable for our current genotyping efforts in HS rats, due to the much higher levels

of genetic diversity in the HS population. There are multiple reasons we chose to develop our own

computational pipeline for GBS rather than using existing workflows. Foremost, the prominent

GBS analysis pipelines were developed and optimized for use in crop species (Sonah et al. 2013;

Catchen et al. 2013; Glaubitz et al. 2014; Torkamaneh et al. 2017; Wickland et al. 2017), which

are polyploid and have differing levels of variation and LD than outbred rodent populations.

Additionally, there were elements of each pipeline that did not meet our needs or lacked

customizability. For instance, TASSEL-GBS v2 (Glaubitz et al. 2014) trims all reads to 92 base

pairs; however, other projects underway in our lab utilized up to 125bp reads, leading to a ~20%

reduction in data. TASSEL-GBS also ignores read base quality scores, which are informative in

probabilistic frameworks for estimating uncertainty in alignments and variant calls (H. Li, Ruan,

and Durbin 2008; DePristo et al. 2011; Nielsen et al. 2011), and uses a naïve binomial likelihood

ratio method for calling SNPs. Stacks has previously shown poor performance in demultiplexing

(Herten et al. 2015; Torkamaneh et al. 2017) and does not make use of the reference genome for

priors when calling SNPs (Catchen et al. 2013). Fast-GBS relies on Platypus (Rimmer et al. 2014)

for variant calling (WGS500 Consortium et al. 2014; Torkamaneh et al. 2017), which employs a

Bayesian method of constructing candidate haplotypes that works poorly with low-pass

sequencing data and does not scale well to large sample sizes (Z. Li, Wang, and Wang 2018).

Lastly, none of these pipelines included an imputation step, which is crucial for filling in missing

genotypes in GBS data and can provide millions of additional SNPs given an appropriate

composite reference panel (B. Howie, Marchini, and Stephens 2011; G.-H. Huang and Tseng

2014).

Though we have not explicitly tested each alternate GBS pipeline for the purposes of this

publication, this has been recently done by Wickland et al. (Wickland et al. 2017). Their pipeline

GB-eaSy, which ours most closely resembles, was found to be superior by a number of metrics to

Stacks, TASSEL-GBS, IGST, and Fast-GBS. Similar to GB-eaSy, our pipeline utilizes a double-

digest GBS protocol, aligns reads to the reference genome with *bwa mem*, and uses the SAMtools

genotype likelihood model for calling SNPs (H. Li 2011). The combination of bwa mem and

SAMtools algorithm was independently shown to have the best performance for calling SNPs from

Illumina data (Hwang et al. 2015), further supporting our choice of these programs for read

alignment and variant calling. Additionally, using the ANGSD wrapper provided us with the

ability to convert the posterior genotype probabilities into genotype dosages for mapping studies

(Korneliussen, Albrechtsen, and Nielsen 2014).

A minor difference between GB-eaSy and our pipeline is the use of cutadapt (Martin 2011)

rather than GBSX (Herten et al. 2015) for demultiplexing, though both performed equally well

(Table S1). The primary improvement is our extension of the pipeline with the implementation of

effective internal and reference-based imputation steps using the 42 inbred rat genomes (Hermsen

et al. 2015) and 8 deep-sequenced HS founders from UMich (Ramdas et al. 2018). There are two

stages of imputation in our pipeline: the first one is accomplished by Beagle and aims to fill in

missing genotypes at called variants using information from other samples; this raising the

genotype call rate to 100%, but it may also introduce errors due to insufficient information,

emphasizing the need for careful filtering steps. The second stage of imputation made use of

IMPTUE2 and an external reference panels of variants called from WGS data on the 8 inbred HS

founders, as well as 34 additional inbred rat strains. We decided to include the 34 additional strains

because of the elevated genotyping rate we observed upon their inclusion in the IMPUTE2

reference panel. We attribute this to the presence of haplotypes that exist in both the 8 the HS

founder strains and a subset of the 34 additional strains in this panel. The benefits of using a

composite reference panel have been previously noted (Zhang et al. 2013; G.-H. Huang and Tseng

2014); there is increased accuracy and decreased missingness in the imputed genotype data.

In summary, we have adapted a GBS protocol and genotyping and imputation pipeline to

obtain dense genotypes on genome-wide markers in highly-multiplexed HS rats. After quality

filtering on the level of SNP and sample, over 3.7 million were called with a concordance rate of

99%. The ddGBS protocol and bioinformatic methods used to produce this data are publicly

available, easy to handle, and cost-effective. The presented workflow could be feasibly followed

with marginal modifications for application in other species.

Figure S1. Ratio of reads on X-chromosome to total sequencing reads.

The color of the points indicates the pedigree-recorded sex of the samples. Females are expected to have approximately twice as many reads for the X-chromosome. Samples that did not cluster with their pedigree-recorded sex were removed from the study for possible sample mix-up.

820

Figure S2. Data preparation workflow for imputation with IMPUTE2.

Figure S3. Programmed vs. empirical Pippin Prep fragment size range.

This plot comes from the Bioanalyzer output for a pooled HS library. The x-axis shows the library
fragment sizes in base pairs, and the y-axis is in fluorescent units, which represent the quantity of
the fragments on the gel chip. There is approximately a 50-75bp shift in the empirical library
distribution compared to expectation due to the high quantity of fragments loaded into the Pippin
Prep gel cassette.

Figure S4. Raw read counts grouped by shipment batch.

Raw read counts are on a per-sample basis after demultiplexing FASTQ files with FASTX Barcode Splitter.

872
Figure S5. FASTQC results pre- and post-filtering with Cutadapt.

FASTQC results are from a single sample from the original set of 96 HS samples prepared in 12-plex
and sequenced on the Illumina HiSeq 2500 with 125bp reads.

Figure S6. Overlap of called SNPs with known variants after read trimming with FASTX or Cutadapt.

Figure S7. Mapping quality thresholds.

Genotyping error rate and number of variants by men depth per sample per variant site for mapping quality thresholds of 20, 30, and 60.

Figure S8. ANGSD vs GATK HaplotypeCaller, filtered calls.

The panel compares the number variants called by combination of ANGSD and Beagle or GATK
HaplotypeCaller and Beagle at various thresholds of genotype discordance with array data. Calls
were made using the 96 HS rats with array data. The x-axis represents the genotype discordance
rate thresholds and the y-axis is the number of variants that surpass that threshold for each
genotype calling method. Additional filters were applied to the original SNP sets and the plot
zooms in on a smaller range of acceptable discordance rates compared to Figure 3. Blue lines
represent the unfiltered SNP set. Yellow lines have been filtered for singletons. Red lines have
further excluded SNPs with an MAF < 0.05. Each line contains the same number of points.

950 **likelihood models.**

954
955

Figure S10. Mendelian error rates

The plot shows the Mendelian error rate for all SNPs. A threshold was set at the inflection point
of the curve (~0.005) and all SNPs above that threshold were removed from the data set.

Figure S11. Available rat genetic maps.

Plotted physical and genetic distances are for chromosome 12.

Table S1. Demultiplexing performance.

All methods began with the same number of reads from the original FASTQ. Final read and base pair counts are from after the reads have been trimmed of adapter, barcode, and restriction site sequences, as well as low-quality base pairs (< Q20).

	In-house Python Script	GBSX	FASTX Barcode Splitter
Reads with NlaIII adapter sequence	545,177 (3.07%)	475,581 (2.67%)	547,697 (3.07%)
Total bps processed	2,061,523,464	2,116,436,361	2,227,542,500
Total bps written to file	2,059,714,312	2,114,841,934	2,225,724,833
Proportion of bps retained	99.91%	99.92%	99.92%
Reads post-processing	17,771,754	17,786,280	17,820,340
