INTERPRETATIVE SUMMARY. Validation of luteolysis monitoring tool for dairy cows.

Adriaens.

In this study, the performance of two monitoring algorithms to detect luteolysis using milk

progesterone measurements was validated on a simulated dataset of realistic milk progesterone

profiles. The synergistic control-based algorithm, PMASC, was able to identify luteolysis almost

simultaneously with its occurrence. It was found to be more robust against missing samples and less

dependent on the absolute milk progesterone values compared to a multiprocess Kalman filter

combined with a fixed threshold. This research showed that implementation of PMASC could

improve progesterone-based fertility monitoring on farm.

Validation of a novel milk progesterone-based tool to monitor luteolysis in dairy cows. Timing

of the alerts and robustness against missing values

ABSTRACT

Automated monitoring of fertility in dairy cows using milk progesterone is based on the accurate

and timely identification of luteolysis. In this way, well-adapted insemination advice can be

provided to the farmer to further optimize the fertility management. To properly evaluate and

compare the performance of new and existing data-processing algorithms, a test dataset of

progesterone time-series that fully covers the desired variability in progesterone profiles is needed.

Further, the data should be measured with a high frequency to allow rapid onset events, such as

luteolysis, to be precisely determined. Collecting this type of data would require a lot of time, effort

and budget. In the absence of such data, an alternative was developed using simulated progesterone

profiles for multiple cows and lactations, in which the different fertility statuses were represented.

To these, relevant variability in terms of cycle characteristics and measurement error was added,

resulting in a large cost-efficient dataset of well-controlled but highly variable and farm-

representative profiles. Besides the progesterone profiles, information on (the timing of) luteolysis

was extracted from the modelling approach and used as a reference for the evaluation and

comparison of the algorithms. In this study, two progesterone monitoring tools were compared: a

multiprocess Kalman filter combined with a fixed threshold on the smoothed progesterone values to

detect luteolysis, and a progesterone monitoring algorithm using synergistic control 'PMASC',

which uses a mathematical model based on the luteal dynamics and a statistical control chart to

detect luteolysis. The timing of the alerts and the robustness against missing values of both

algorithms were investigated using two different sampling schemes: one sample per cow every

eight hours versus one sample per day. The alerts for luteolysis of the PMASC algorithm were on

average 20 hours earlier compared to the ones of the multiprocess Kalman filter, and their timing

was less sensitive to missing values. This was shown by the fact that, when one sample per day was

used, the Kalman filter gave its alerts on average 24 hours later, and the variability in timing of the

alerts compared to simulated luteolysis increased with 22%. Accordingly, we postulate that

implementation of the PMASC system could improve the consistency of luteolysis detection on

farm and lower the analysis costs compared to the current state of the art.

Key words. milk progesterone, fertility, dairy cow, simulation, monitoring tool

INTRODUCTION

Monitoring of milk progesterone (**P4**) in dairy cows allows identification of a cows'

reproduction status. Because P4 is fat-soluble and transfers from the blood into the milk, the

concentration of P4 in milk is 4 to 5 times higher than in blood. High P4 concentrations, produced

by an active corpus luteum (**CL**) on the ovaries are associated with the luteal phase of the cycle or

pregnancy, while low P4 concentrations are known to occur during the follicular phase of the P4

cycle and in the postpartum anestrus phase after calving. Luteolysis, under influence of the uterine

$PGF_{2\alpha}$ signal and defined as the regression of the CL, is accompanied with a steep and fast decrease

in P4, seen as a drop in milk P4 from over 15 ng/mL to below 5 ng/mL in approximately 12 to 24

hours. This drop in P4 is necessary to allow for a LH surge that induces rupture of a pre-ovulatory

follicle (ovulation). Estrus detection based on milk P4 dynamics therefore relies on the accurate and

timely identification of luteolysis preceding ovulation. Since recently, it is possible to automatically

measure milk P4 on farm, in which regular milk analyses clearly show the P4 dynamics during an

estrous cycle (Adriaens et al., 2017; Bruinjé et al., 2017). The current state-of-the-art in P4-based

fertility monitoring is to smooth the raw measured values with a multi-process Kalman filter

(**MPKF**), after which a fixed threshold (**T**) to these smoothed values is applied to detect luteal

activity and luteolysis (Friggens and Chagunda, 2005; Friggens et al., 2008). The MPKF hereby

ensures that no alerts are triggered for a single low measurement. The set threshold's value might

depend on the P4 measurement technique or the calibration method, but is generally taken between

4 and 6 ng/mL (Friggens et al., 2008; Bruinjé et al., 2017). In contrast, the P4 monitoring algorithm

using synergistic control (**PMASC**) enables the identification of fertility events on farm using the

underlying physiological basis of the related P4 dynamics (Adriaens et al., 2017, 2018a). It employs

a combination of mathematical functions to describe the development and regression of the CL and

a statistical control chart for detection of luteolysis. Until now, this system was designed, optimized

and evaluated on high-frequent P4 measurements in which milk P4 was analyzed *post-hoc* via

ELISA-testing in the lab. This did not yet represent on-farm measured data for which the

measurement error is representative, the time series are sufficiently long and in which all the

variability in P4 profiles on farm is included. Before the PMASC algorithm can be used on farm, it

should therefore also be validated as such.

In the ideal scenario, this validation would be performed on a large dataset representative for

on-farm measurements and containing numerous milk P4 profiles with as much variability as

possible, not only in fertility and profile characteristics (e.g. including follicular and luteal cysts,

early and late pregnancy and embryonic losses within a lactation) but also in cycle shapes (e.g.

height, baseline and slopes of each P4 cycle). The frequency of measurement should be as high as

possible (e.g. once per milking) in order to be able to vary sampling schemes and test all possible

scenarios. Moreover, to validate a luteolysis monitoring algorithm, the actual moment of luteolysis

should ideally be known in order to use this as the 'gold standard'. To our knowledge, and

especially with respect to time of luteolysis measures, a dataset does not exist that meets all these

criteria.

Alternatively, a convenient and more efficient way to obtain an appropriate dataset is through

simulations, which allow generation of extensive datasets while avoiding analysis costs both in

terms of measurements and time. Recently, a systemic white box model representing a virtual cow

(GARUNS, Martin and Sauvant, 2010) coupled to a model describing the reproductive functioning

(reproduction function model, **RFM**, Martin et al., 2018) was developed. This model allows

simulation of virtual cows with diverse fertility characteristics, and provides scaled P4 profiles

corresponding to the reproductive functioning of the simulated cows. The RFM outputs scaled P4

profiles, meaning that the dynamics are representative for the fertility, but need to be adjusted to

represent the targeted measurement technique and substrate (milk vs. blood), from which we know

the absolute values can vary. In this way, large datasets representing cows with sufficiently variable

fertility characteristics, for which the number of estruses and timing of luteolyses is known, can be

obtained.

In a previous validation study, PMASC was shown to be successful in correctly identifying

luteolysis using milk P4 data measured on-farm with a lateral flow immunoassay (**LFIA**) (Adriaens

et al., 2019). Nevertheless, as those P4 data originated from a commercial sensor system, the

sampling frequency was set by the system software and the effect of the measurement frequency

and timing, as well as the effect of missing values on the performance of PMASC could not be

evaluated. Additionally, the timing of the alerts generated by PMASC and MPKF+T could not be

verified as no reference information on the exact moment of luteolysis was available on those

farms. Therefore, the objective of the current study was to compare the detection performance,

robustness and consistency of alerts from PMASC and the MPKF+T method based on simulated

realistic P4 profiles. Furthermore, this approach allowed for the evaluation of the effect of missing

samples or a reduced sampling scheme during luteolysis. A good understanding of the performance

of the P4 monitoring algorithm under variable sampling conditions and schemes is important to

quantify the uncertainty in the prediction of the optimal insemination window.

MATERIALS AND METHODS

Simulating Progesterone Profiles

In a first step, 100 dairy cows were simulated using a systemic model for describing lifetime

performance in dairy cows (GARUNS), developed by Martin et al. (Martin and Sauvant, 2010;

Martin et al., 2013, 2018; Gaillard et al., 2016). The fertility characteristics of these cows were

defined by a recently developed reproduction module coupled to GARUNS, the RFM, for which a

schematic overview is shown in Figure A1. The general idea of the RFM is that a cow shifts

continuously between 11 different fertility compartments, namely 'prepubertal', 'anestrous',

'anovulatory', 'pre-ovulating', 'ovulating', 'post-ovulating', 'luteinizing', 'luteal', 'cystic',

'dysfunctional' and 'gestating'. The dynamics of these shifts are influenced by the lifetime

performance model GARUNS, for instance by the rate of hormonal clearance and the energy

balance. In turn, the RFM' outputs 'conception' and 'embryonic/fetal death' manipulate the course

of GARUNS, and thus the life of a cow, to trigger body weight changes, dry-off, initiation of a new

lactation and so on. The competence stages 'cystic' and 'dysfunctional' are modifications of the

original published work (Martin et al., 2018) that allow for interruption of cyclicity in absence of P4

and a P4-producing (luteal) cyst-like structure, respectively. The first can be either sudden anestrus

(no activity on the ovaries) or a follicular cyst (large, fluid filled follicular structure on the ovaries)

(Ranasinghe et al., 2011; Jeengar et al., 2014). The latter results in intermediate P4 concentrations

during the luteal phase as described by Braw-Tal et al., (2009), Peter et al., (2009) and Rosenberg,

(2010). The parameters of the model (Table A1) were chosen to obtain cows with a large range of

fertility characteristics, both in terms of length of the postpartum anestrus period, number and

length of the cycles, occurrence of interrupted cyclicity due to follicular and luteal cysts and the

interval to successful pregnancy.

Each simulated cow had 6 to 7 lactations with different fertility features reflected in the scaled

P4 profiles (example in Figure 1, red). A subset of lactations was selected based on the variability in

P4 profile characteristics. For this, the profiles were successively sorted by postpartum anestrus

length, number of cycles and incidence of interrupted cyclicity, after which each time the 50 most

variable lactations were selected. This resulted in a dataset of 150 profiles (i.e. the consecutive

dynamics over 1 lactation) containing in total 731 scaled estrous cycles. The dataset characteristics

are summarized in Table 1.

The outputs of the GARUNS/RFM simulations are scaled P4 profiles (i.e. representing

reproduction performance over a lactation) of cows reflecting realistic fertility characteristics and

with a measurement frequency of 1 sample per 2 hours (Martin et al., 2018). However, as these

profiles are scaled, they do not represent the variability at cycle level (de-scaling), nor do they

contain measurement noise associated with the P4 measurement in milk. Accordingly, two

additional steps were required. The first step was to allow variability in the length and the relative

P4 concentrations of the follicular and luteal phases. To this end, and to ensure maximal variability,

the following properties of each cycle were adjusted according to a value randomly sampled from a

uniform distribution, chosen according to the characteristics described by Meier et al. (2009a),

Gorzecka et al. (2011) and Blavy et al. (2016):

(1) The rate of decrease in P4 during luteolysis. In this step, the duration of the drop in P4 from

maximum to minimum concentration was adjusted to last between 0.5 and 3 days (Gorzecka

et al., 2011; Bruinjé et al., 2017). The uniform distribution used was thus U[0.5;3].

(2) Adjustment of cycle height and shape. Meier and colleagues reported three different types of

serum P4 profiles: 'peaked' profiles without a clear platform, 'flat-top' profiles with a

distinguishable platform of constant high P4 production, and 'structured' profiles in which

the P4 seems to rise in two phases (Meier et al., 2009b). To simulate these different types,

the maximum P4 value in cycle was adjusted with a certain percentage varying from 40 to

100% (distribution U[0.4;1]) by either cutting off the data higher than this percentage or by

multiplying the whole cycle with this percentage. The first procedure results in a 'flat top'

shaped cycle, the second in a 'peaked' cycle. A structured shape was not considered,

because in contrast to P4 in serum, this shape was not yet reported in milk.

(3) The last step was to adjust the length of the baseline of each cycle from 3 to 8 days

(Friggens and Chagunda, 2005; Blavy et al., 2016).

This procedure was repeated for each of the 731 cycles in the simulated dataset. An example of a

(de-)scaled milk P4 profile is shown in black in the upper panel of Figure 1. For each simulated

cycle, the reference moment of luteolysis was defined as the time (days in milk) at which the P4

level decreased below 70% of the difference between maximum and minimum P4 concentration

within that cycle, further referred to as **REF$_{LUT}$**. This moment of REF$_{LUT}$ was chosen based on the

assumption that the P4 concentration has to be sufficiently low before the dominant follicle can

become LH sensitive. However occasionally, high-P4 estruses exist and thus full clearance of the

P4 is not required (Friggens et al., 2008).

The second step entailed the addition of measurement noise corresponding to the on-line LFIA

technique (resulting profile shown in lower panel of Figure 1). The characteristics of this

measurement noise were defined from an available dataset containing 10,958 on-line measured P4

measurements collected at the Hooibeekhoeve in Geel, Belgium, which was described in (Adriaens

et al., 2019). The P4 data in this LFIA dataset was smoothed using a second order Savitzky-Golay

filter with a span of 7 measurements. Subsequently, the smoothed curve was subtracted from the

data and the residuals were sorted based on their smoothed value, in which 28 classes of 1 ng/mL

were created. For example, all measurements with a smoothed level between 0 and 1 ng/mL were

assigned to the first class. Next, the standard deviation of the data in each class was calculated, and

a second order polynomial was fitted to these standard deviation data, shown in Figure 2. This

figure shows that the on-line measured P4 data is heteroscedastic, with less variability at the

extremes than at intermediate values. The level of each simulated P4 measurement was obtained by

multiplying the scaled simulated value with 28 ng/mL, while the second order polynomial fitted on

the residuals was used to determine the standard deviation corresponding to this level. Next, a

measurement was sampled from a normal distribution ~N(level, standard deviation). To introduce

outliers in the dataset caused by e.g. a sampling error, one outlier on average each 8 days of

measurements was sampled from a normal distribution with the maximum variance (i.e. a standard

deviation of 5 ng/mL). This outlier represents e.g. milkings in which the sampling did not represent

the whole milking (e.g. failed milkings or problems with the sampling unit). Accordingly, there was

a chance of about 4% [= 1/ (8*3)] for each milking that the actual milk P4 value was replaced by an

outlier sampled from a normal distribution with the maximum variance. A fixed milking interval of

8 hours (i.e. 3 samples per day) was chosen because the additional variability introduced by using

realistic milking intervals (6 – 20 hours) would not have different results (own unpublished data).

An overview of the cycle characteristics of the resulting dataset is given in the right part of Table 1.

Progesterone-based monitoring algorithm using synergistic control

The first algorithm tested in this paper, PMASC, consists of a mathematical model describing

the luteal dynamics (Adriaens et al., 2017), and a statistical process control chart to detect luteolysis

(Adriaens et al., 2018a). The mathematical model consists of two sigmoidal functions, a

symmetrical Hill function to characterize the increase in P4 during luteal development, and a

Gompertz function to describe the decrease during luteolysis. The control chart detects strong

negative residuals from the predicted luteal P4 concentration, while taking the variability in P4

measurements into account. The decreasing function is only added after the detection of luteolysis,

and can be used to calculate model-derived indicators that can be employed to inform the farmer on

relevant actions to be taken (e.g. inseminations). It was shown before that the estimation of timing

of luteolysis precedes the preovulatory LH surge by about 55 to 65 hours (Adriaens et al., 2018b).

In this study, two outputs of PMASC were tested for their accuracy to relate to luteolysis. The first

is the timing of the first measurement detected to be out-of-control (**OOC**), i.e. the exact time in

hours that a first drop in P4 lower than expected is detected, followed by the confirmation of

luteolysis in the two successive measurements. The second output '**TB85'** is an indicator calculated

from the model as follows: the moment that the model describing the drop in P4 during luteolysis

(i.e. the Gompertz function) decreases below 85% of the difference between maximum P4 model

concentration minus the baseline; both calculated from the current P4 cycle characteristics

(Adriaens et al., 2018b).

Multi-process Kalman filter

To benchmark PMASC against the current state-of-the-art for on-line P4-based fertility

monitoring, the simulated P4 values were smoothed using a MPKF as described in Friggens and

Chagunda, (2005); Friggens et al., (2008); Løvendahl and Chagunda, (2010). More specifically,

posterior mean estimates for the raw P4 values (i.e. the smoothed values) were calculated based on

a 'mixture' of 4 local linear dynamic models. These local linear models represent the 4 possible

'states' in which the P4 time-series can be: steady state, encountering a slope or a level change, or

an outlier. The mixture is calculated using the likelihood to be in a certain state taken from a

predefined prior, and the one-step-back and two-steps-back posterior probabilities. This means that

the reaction of the MPKF on a slope or level change increases with the extent of evidence for this

state. For example, when the P4 values rapidly decrease from luteal to follicular concentrations, a

first low measurement will be seen as very unlikely ('outlier'), and the smoothed value will only

decrease by a small amount. However, when the next sample is low again, there is more 'evidence'

that this is a slope change, and an increased probability will be given to the 'slope' or 'level' change

models, resulting in a larger decrease in the smoothed value.

The framework for the MPKF was set up based on the information provided in Smith and West,

(1983), West and Harrison, (1997), Korsgaard and Løvendahl, (2002) and Friggens et al., (2007).

The parameters were estimated based on the raw and smoothed P4 values of the same P4 dataset

described before and in (Adriaens et al., 2019). The mean squared difference between our

implementation of the MPKF and the smoothed values obtained from the on-line device was 0.094

ng/mL which was considered to be sufficiently low to compare results and derive relevant

conclusions.

To provide a decision on when luteolysis has happened, the smoothed P4 values are combined

with a fixed threshold to extract information from the time series. The threshold currently

considered reasonable for estrus detection alerts based on milk P4 lies in between 4 and 6 ng/mL,

and therefore in this study was taken 5 ng/mL (Friggens et al., 2008; Bruinjé et al., 2017). The

MPKF+T algorithm gave an estrus alert when the smoothed value undercut the threshold value for

the first time having previously exceeded this threshold value. To avoid multiple alerts within the

same follicular period, a minimum time-interval of 5 days between two alerts was applied.

Once initiated and trained, this method does not need adjustments nor tuning to detect

luteolysis. However, this user-friendly approach is at the cost of not including between-cow

variation in responsiveness to P4. Moreover, the MPKF results in a time-lag between actual and

detected luteolysis which is strongly dependent on luteolysis speed and the absolute P4 level

measured (Friggens and Chagunda, 2005). A solution for this can be the implementation of a smart

sampling scheme in which more samples are taken during the expected moment of luteolysis (e.g.

from 16 days after the previous luteolysis on) and the calibration of the device to favor

discrimination between high and low values.

Detection performance

The simulated milk P4 dataset was analyzed using both algorithms (PMASC and MPKF+T)

using 2 different sampling schemes. In the first sampling scheme, a milk P4 measurement was taken

at each simulated milking (i.e. 3 times a day, sampling scheme 'ALL'). For the second, only 1

sample per day (a i.e. 24h interval between samples) was provided to the algorithms (sampling

scheme '1D'), which corresponded to a sample or data reduction of 66%. The latter mimics the

effect of missing samples during luteolysis or a sampling scheme in which only 1 sample is taken

per day during luteolysis to minimize the analysis costs. This is still a very high sampling rate,

especially during the growth phase of the CL which is less of interest. Nevertheless, it gives an

indication of what the performance can be with a sampling rate of only 1 sample per day in the

period of expected luteolysis, while previously described studies sample once per milking in that

period (Bruinjé et al., 2017). Next, the number and timing of simulated luteolyses was compared

with the number of alerts given by each algorithm, and based hereon, the sensitivity, precision, and

false negative rate (**FNR**) were calculated as follows (Eq. 1 to 3):

$$Sensitivity = true\ positive\ rate = \frac{TP}{TP+FN} \qquad \textbf{(Eq. 1)}$$

$$Precision = positive\ predictive\ value = \frac{TP}{TP+FP} \qquad \textbf{(Eq. 2)}$$

$$False\ Negative\ rate\ (FNR) = \frac{FN}{TP+FN} \qquad \textbf{(Eq. 3)}$$

With **TP** being the true positives, i.e. the times PMASC or MPKF+T gave a luteolysis alert within a

window of 2 days before (i.e. 6 samples for the ALL, and 2 samples for the 1D sampling scheme) to

4 days after (i.e. 12 samples for ALL and 4 samples for the 1D sampling scheme) a luteolysis was

simulated (REF$_{LUT}$). This window was chosen based on its practical relevance: detection later than

4 days would imply that ovulation had occurred by the time of detection, and the alert would be of

no relevance for insemination (Roelofs, 2005; Adriaens et al., 2018b). False positives (**FP**) were

alerts given by an algorithm which were not associated with a REF$_{LUT}$. The false negatives (**FN**)

were defined as cases where no alert was given at all or it was given later than 4 days after REF$_{LUT}$.

For this study, we chose not to include the specificity for a combination of reasons: (1) the

specificity of the algorithms in this study is not fixed, unambiguously defined, but dependent on

both the sampling rate and the window in which alerts are considered 'true' or 'false'; (2) the

specificity is not a measure where the farmer can do something with, as it is generally accepted that

sensor systems should output as much as possible 'farmers' actions', rather than raw data. Both

concepts are further clarified in Hogeveen et al., (2010).

Timing of the Alerts and Consistency and Robustness against Missing Samples

Besides sensitivity and accuracy measures, also the timing and variability in timing of the

luteolysis alerts (i.e. P4 decrease) are of interest for an on-farm monitoring system. The first aspect,

timing of the alert, is important because early alerts allow for correct planning of the insemination

moment in order to achieve the highest chance of successful conception (Roelofs, 2005). The

second aspect, variability in timing, is mainly of importance when a fixed insemination advice is

coupled to the alerts. To this end, both the timing of the alerts and their variability compared to

REF_{LUT} were evaluated for both sampling schemes. For PMASC, the first out-of-control

measurement as well as the model-based indicator TB85 were included. The latter is calculated as

the moment the decreasing Gompertz function reaches 85% of the difference between the between

maximum and baseline P4 value of the model for that cycle, and thus takes the absolute milk P4

values of a cycle into account. This was shown previously to be the most consistent model-based

decision criterion in relation to the LH surge (Adriaens et al., 2018b). Accordingly, 6 different

groups were obtained, 3 for each sampling scheme: (1) the difference between REF_{LUT} and the first

out-of-control measurement detected by PMASC, further referred to as OOC_{ALL} and OOC_{1D}

respectively; (2) the difference between REF_{LUT} and TB85, referred to as $TB85_{ALL}$ and $TB85_{1D}$; and

(3) the difference between REF_{LUT} and the timing of the milking that MPKF+T generated an alert,

further indicated as $MPKF+T_{ALL}$ and $MPKF+T_{1D}$ for each of the sampling schemes, respectively.

Because of the unequal variances between the 6 different groups, we could not perform normal

analysis of variance to compare their means. Therefore, the Wilcoxon Signed Rank Test was used

to assess differences in median timing of the alerts, and the Brown-Forsythe test was used to

investigate differences in variability. The latter tests the mean absolute difference from the median,

which makes it robust for non-normality. However, because multiple comparison tests are not

available for these statistical tests, it was decided to test each group against each other group in

single pairwise comparisons. To avoid capitalization of chance due to multiple tests, a Bonferroni-

correction on the significance level α=0.05 was applied by dividing it by the number of tests run,

being 15 (each of the 6 groups compared to the 5 other groups). Differences were thus considered

significant if the *p*-value was below 0.05/15 = 0.0033.

RESULTS AND DISCUSSION

Simulated data

The simulated dataset contained 150 milk P4 profiles and 731 individual cycles. Eighty-two

cycles had a prolonged follicular phase ($\geq$ 9 days), 53 cycles had a prolonged luteal phase ($\geq$ 17

days) and 17 cycles had both. The average cycle length was 23.6 $\pm$ 7.6 days (mean $\pm$ SD) when all

cycles were included, and 20.6 $\pm$ 1.9 days when cycles with prolonged phases were excluded. The

average length of the follicular phase was 4.5 $\pm$ 1.7 days and the average duration of the P4 drop

during luteolysis was 1.8 $\pm$ 0.7 days. The average baseline and maximum P4 concentrations were

2.1 $\pm$ 0.9 ng/mL and 18.8 $\pm$ 5.2 ng/mL, respectively. The characteristics of these profiles correspond

to those obtained in a real on-farm setting and are in line with reported characteristics in the

literature (Blavy et al., 2016). As such, the described methodology is a valuable way to generate

large datasets while avoiding measurement costs and controlling both fertility and cycle

characteristics while having a more precise reference for luteolysis. This study included in total 731

simulated luteolyses. Technically, simulating many more (e.g. a million) cycles was possible, but

because of computational limitations, this current size was considered large enough number to show

all possible difference between the groups (MPKF/PMASC and the 2 sampling schemes).

Detection performance

In Table 2, the detection performance statistics for PMASC and MPKF+T are summarized for

the different sampling schemes. When one measurement per milking was considered, PMASC and

MPKF+T both had high sensitivities of 99.2% and 98.6%, respectively. For PMASC, also the

precision of the alerts was high (95.3%), with only 4.7% of the 766 alerts being FP. With 23.0% FP

alerts, the MPKF+T algorithm was more sensitive to variations in the data. More specifically, these

false positive alerts can be classified as (1) outliers in the follicular phase (respectively 40 and 34%

of the FP for 1D and ALL); (2) coincidentally successive measurements below the threshold,

triggering the MPKF to low levels (respectively 43 and 49% of the FP for 1D and ALL); (3) cycles

with intermediate maximal P4 concentration varying close to the threshold (17% of the FP for both

1D and ALL), which is often the case during e.g. luteal cysts (Yimer et al., 2018). To solve the first

problem, an additional requirement in the MPKF+T model was that P4 had been above 15 ng/mL

since the preceding estrus. The latter two situations are associated with the dependency of MPKF+T

on the absolute measured P4 values, and are therefore not easily solved from a detection

perspective. The MPKF+T of Friggens and Chagunda, (2005) gives an indication of the 'goodness'

of the shape of the preceding cycle as information to aid the farmer in deciding whether to

inseminate, which effectively flags these FPs (Friggens et al., 2008).

Reducing the sampling frequency to one sample per day decreases the sensitivity for estrus

detection of PMASC with 0.3% to 98.9%, and of MPKF+T with 2.2% to 96.4% (Table 2). The

number of false detections were halved to 2.6% and 12.7%, respectively for PMASC and MPKF+T

compared to the maximal sampling scheme, mainly because the number of outliers and

coincidentally successive low values decreased. Correspondingly, the precision of MPKF+T

increased with 10.3%. This shows the sensitivity of MPKF+T to the actual entered data and their

absolute values. For PMASC, the FNR was very similar to that for the 'ALL' sampling scheme

(1.1% and 0.8% respectively for '1D' and 'ALL'), which shows that the algorithm can work with

less samples, as also presented in Adriaens et al., (2019). The MPKF+T seems to be more sensitive

to this as the FNR increased from 1.4 to 3.6% when using less samples. The FN cases can be

attributed to high-P4 estruses, in which samples close to the threshold were selected by coincidence.

As a result, the smoothed values do not cross the threshold, or do not cross it in time (within a

window of 4 days after simulated luteolysis). This phenomenon also shows the dependency of the

MPKF+T on the actual absolute values. For example, when the P4 concentration drops

significantly, e.g. from 25 ng/mL to 4.9 ng/mL, the MPKF tends to be conservative and will not

drop to a value lower than the thresholds. Accordingly, at least 1 additional sample with a low P4

concentration has to be taken to trigger an alert. This time lag thereby ensures that real outliers do

not immediately trigger an alert, which is important to guard the farmers' trust. The advantage of

PMASC is that its control limits are independent of the exact raw P4 values measured, and that the

average value during the luteal phase is indirectly taken into account to monitor the drop during

luteolysis. A similar observation was made by Friggens et al., (2008) when evaluating the luteolysis

detection based on the model and algorithm described in Friggens and Chagunda, (2005). Although

the authors started with a fixed threshold of 4 ng/mL, they had to implement another threshold of

6 ng/mL in order to detect high P4 estruses (Friggens et al., 2008). Because of the quite large

measurement error for determining P4 in milk, it is not yet known whether the differences in P4

concentrations during estrus (and during the luteal phases) are due to inaccurate measurement and

calibration methods, or due to real elevated P4 concentrations, e.g. due to increased P4 production

by the adrenal cortex. When an improved P4 detection method becomes available, the inclusion of

other information (e.g. health status, parity, fat content of the milk) might become possible and

might improve the detection algorithms, but to date this is not yet available.

We did not test detection performance with other, more intelligent sampling schemes, because

this was considered outside the scope of this study. First of all, other regular sampling schemes (e.g.

1 sample per 2 days) are irrelevant as detection would likely be too late for timely insemination,

even if a follicular phase was detected. More specifically, PMASC was designed not just to 'detect',

but also to 'timely detect' estruses in order to increase the chance for successful insemination.

Timing of the Alerts: Variability and Robustness against Missing Samples

In Figure 3, the results of the timing of the alerts using all samples and one sample per day

compared to REF_{LUT} are presented. The Wilcoxon signed rank test showed that not all medians are

equal ($p < 0.001$), which can also be seen in Figure 3. Using all samples, the median difference

between REF_{LUT} and the alerts generated by PMASC (TB85 and OOC) was close to 0, and their

individual comparison test had a p-value larger than 0.44. More concretely, a median of zero for the

OOC group means that the first indication of luteolysis (i.e. first sample out-of-control) is obtained

almost simultaneously with the actual luteolysis REF_{LUT}. This 'early' first indication allows to

estimate the moment of luteolysis precisely, and has two large advantages: (1) it allows to organize

the insemination at the best moment; and (2) it allows to wait for additional proof of real estrus or

luteolysis in case of doubt, either by taking additional P4 samples, or by checking for external

estrous symptoms. The latter can be of added value for example when farmers are skeptical about

the reliability of new technologies. As expected, the most consistent insemination advice will be

derived from a model-based indicator as can be calculated from PMASC, which allows

determination of the moment of luteolysis independently of the sampling rate (when comparing 3

versus 1 sample per 24 hours). This paves the way to provide more consistent information to the

farmer.

For the OOC_{1D} group (first out-of-control measurement detected by PMASC for the one-

sample-per day scheme), the first indication of estrus is obtained on average 10 hours later

(significantly different from all other groups, $p < 0.001$). However, using $TB85_{1D}$, (i.e. the model-

based indicator using the maximum and minimum model P4 value) estimating the actual moment of

luteolysis in a consistent way close to REF_{LUT} remains possible. The alerts of $MPFK+T_{ALL}$ and

$MPKF+T_{1D}$ came respectively on average 18 and 48 hours after REF_{LUT}, which also were

significantly different from all other medians ($p < 0.001$). Accordingly, the MPKF+T algorithm has

a time lag in detection of about 2 milkings when no samples are missed during luteolysis, while this

lag increases to approximately 2 days when only one sample per day is taken. As a result, it

becomes difficult to provide the farmer with a reliable estimation of optimal insemination time,

which is not only dependent on the number of samples missed, but also on how fast P4 decreased

(and thus, the MPKF reacts), the moment of luteolysis compared to the timing of the milkings and

milking intervals.

Table 3 shows that the Brown-Forsythe test for differences in variability in the interval alert to

REF_{LUT} was highly significant. The variability for $TB85_{ALL}$ was the smallest, with a standard

deviation respectively 35.3% and 15.8% smaller than OOC_{ALL} and $MPKF+T_{ALL}$. The OOC_{ALL} and

$MPKF+T_{ALL}$ groups had an equal variability (p-value = 0.017 > 0.0033). Furthermore, individual

comparisons pointed out that the variability does not differ between the OOC and TB85 group when

one sample per day was considered (p-value = 0.047 > 0.0033). In contrast, we see that missing

samples during luteolysis have a larger effect on the consistency of alerts given by the MPKF+T

algorithm than on those obtained from OOC and TB85, resulting in a significantly larger variability

than all other groups (p-value < 0.0033). We can therefore conclude that OOC and TB85 are less

sensitive to missing samples both in terms of median timing of alerts and in terms of variability,

making it a more robust algorithm for missing samples during luteolysis compared to MPKF+T.

Part of the variability within the groups is caused by the timing of the milkings relative to the

P4 profiles. For example, in this study a sample could have been taken in a window of 0 to 8 hours

after REF_{LUT}. Accordingly, the effect of the timing of milking relative to REF_{LUT} seems to overrule

the effect of the algorithm for the scheme in which milk P4 is measured every 8 hours. Although

taking only one sample per day might not seem a 'random' way to mimic missing samples during

luteolysis, the variability in luteolysis length and the independency of the P4 profiles to the

simulated time of REF_{LUT} ensures that the timing of missed samples compared to luteolysis was

variable. In a real on-farm setting, it is more probable that not in all cows samples are skipped,

which would make the variability in alerts compared to real luteolysis for OOC and MPKF+T even

larger (see also Adriaens et al., 2019). Furthermore, based on the results of this study, we can

448 assume that the TB85 indicator remains consistent in its estimation of the timing luteolysis,

449 independent of the sampling scheme or interval, which supports its use for monitoring purposes. A

450 robust indicator is important when a fixed rule is used for decision making.

451             **CONCLUSIONS**

452    The detection performance of PMASC and the MPKF+T in terms of sensitivity, precision, false

453 negative rate, false detection rate, robustness for sampling frequency and missing samples during

454 luteolysis were studied on a simulated dataset of 150 highly variable P4 profiles containing 731

455 luteolyses preceding estrus. Both PMASC and MPKF+T had a high luteolysis detection rate, but

456 MPKF+T was more sensitive to the absolute values of the P4 data, shown by its higher false

457 detection rate. This illustrates the value and limitations of both algorithms for on-line fertility

458 monitoring. Using a PMASC-based model indicator taking into account the luteal and follicular P4

459 concentrations, a more robust estimation of the timing of luteolysis was obtained, which was less

460 sensitive to missing values compared to the current state-of-the-art MPKF+T both in terms of

461 detection rate and variability. Accordingly, PMASC has shown its potential to improve consistency

462 and robustness of progesterone-based, cost-effective detection of luteolysis on farm.

Figure 1 Upper panel: example of a simulated progesterone (P4) profile before (RFM, red) and

after adding variability in profile characteristics (RFM_C, black). Lower panel: resulting simulated

P4 profile after descaling and adding measurement noise.

Figure 2 Distribution of measurement noise for when progesterone (P4) is determined via an on-

farm lateral flow immune assay (LFIA) device. This device is optimized to discriminate between

high and low P4 values and accordingly, has a low standard deviation at the extremes. The blue bars

represent the standard deviation per smoothed progesterone concentration bin (e.g. 1-2 ng/mL),

calculated from a real on-farm measured dataset and smoothed using a second order Savitzky-Golay

filter with a span of 7 measurements. The red thick line is the fitted second order polynomial fitted

on these standard deviations, and used to determine the simulated measurement noise for each

progesterone measurement.

Figure 3 Boxplots for the differences between alerts given by the 2 algorithms included in this

study (progesterone monitoring algorithm using synergistic control, PMASC and a multiprocess

Kalman filter plus threshold, MPKF+T) and the simulated luteolysis (reference timing of luteolysis,

REF_{LUT}). A difference of zero means that luteolysis is detected on the moment it is simulated,

which is seen for the first out-of-control sample of PMASC using all samples (first out-of-control,

milk progesterone simulated 3 times a day, OOC_{ALL}) and for alerts based on the model-derived

indicator TB85, even when samples during luteolysis are missed ($TB85_{ALL}$ and $TB85_{1D}$). '1D'

hereby means that only 1 sample per day was taken, also during the period in which luteolysis

occurred.

APPENDIX

Figure A1 Model structure of the Reproduction Function Model and the adaptations made to allow

for simulation of interrupted cyclicity by prolonged luteal (DYSF and PRLP, indicated in blue) and

follicular phases (CYST, indicated in red), adapted from Martin et al., (2018).

Adriaens, Figure A1

Adriaens, Table A1. Parameters for the reproduction function model (RFM) model as described in

Martin et al., (2018). The variability in genetic scaling parameters allows to alter individual

performance of cows at the level of GARUNS. To allow for additional variability in fertility

performance of the simulated cows, two sets of parameters (set 1 and set 2) were entered in the

model. Using this table, new progesterone profiles can be simulated in a similar way as done in this

study.

Parameter name RFM[1]	Set 1	Set 2	Effect
h_CYCL[2]	**-7.0**	**-15.0**	Adjust postpartum anestrus length
Risk_CYST[3]	**1.6**	**2.0**	Incidence of follicular cysts
Risk_DYSF[4]	**1.6**	**2.0**	Incidence of luteal dysfunction
EMO[5]	**2.1**	**2.5**	Incidence early embryonic mortality (conception failure)
GSP_cv[6]	0.05	0.05	Variability between cows & characteristics (genetic scaling parameters)
RFM_h_impregnation[4][7]	0.10	0.10	Ensure restart of cyclicity after R_CYST
RFM_k09[8]	0.10	0.10	Ensure restart of cyclicity after R_CYST
RFM_k10[9]	0.12	0.12	Duration follicular cyst / ovarian anestrus
RFM_k11[10]	0.12	0.12	Duration follicular cyst / ovarian anestrus
RFM_k13[11]	0.3	0.3	Duration luteal dysfunction
RFM_EMO[2][12]	4.6	4.6	Avoid occurrence late embryonic mortality
RFM_EMO[3][13]	8.0	8.0	Avoid occurrence fetal death
