ABSTRACT

The TIR1/AFB auxin co-receptors mediate diverse responses to the plant hormone auxin. The Arabidopsis genome encodes six TIR1/AFB proteins representing three of the four clades that were established prior to angiosperm radiation. To determine the role of these proteins in plant development we performed an extensive genetic analysis involving the generation and characterization of all possible multiply mutant lines. We find that loss of all six TIR1/AFB proteins results in defects in embryogenesis as early as the 8-cell stage, and possibly earlier. Mutant embryos progress but exhibit frequent cell division errors followed by proliferation of the suspensor, and eventually seed abortion. Despite this dramatic phenotype, a single wild-type allele of *TIR1* or *AFB2* is sufficient to support growth throughout plant development. Further, gametophytic expression of the *TIR1/AFB* genes is not essential for development of the male or female gametophyte. Our analysis reveals extensive functional overlap between even the most distantly related *TIR1/AFB* genes except for *AFB1*. Surprisingly, the AFB1 protein has a specialized function in rapid auxin-dependent inhibition of root growth and early phase of root gravitropism. This activity may be related to a difference in subcellular localization compared to the other members of the family.

INTRODUCTION

The phytohormone auxin regulates diverse processes throughout the entire plant life cycle. Auxin acts as a signal to promote cell differentiation during morphogenetic events such as embryogenesis, root development, and shoot organ formation. Auxin also mediates responses to environmental cues such as light, gravity, water availability, and

pathogens. Auxin regulation of transcription involves three families of proteins; AUXIN

RESPONSE FACTOR (ARF) transcription factors, Aux/IAA transcriptional repressors,

and TRANSPORT INHIBITOR RESPONSE1 (TIR1)/AUXIN-SIGNALING F-BOX (AFB)

proteins. Auxins, of which indole-3-acetic acid (IAA) is the predominant natural form, are

perceived by a co-receptor complex consisting of TIR1/AFB and Aux/IAA proteins.

Formation of the co-receptor complex leads to degradation of the Aux/IAA protein and

activation of ARF-dependent transcription (Reviewed in (Lavy and Estelle 2016). In

addition to this established pathway, recent studies demonstrate that the TIR1/AFB

proteins are required for very rapid auxin responses in the root and in developing root

hairs that are independent of transcription (Dindas et al. 2018; Fendrych et al. 2018).

The details of TIR1/AFB function in these rapid responses are currently unknown, but in

the root, the response is thought to be important for early events in gravitropism.

Members of the TIR1/AFB protein family are encoded by three pairs of paralogs in the

Arabidopsis genome. Each protein contains an amino-terminal F-Box followed by

eighteen leucine-rich repeats (LRRs). Only *tir1*, *afb2*, and *afb5* mutants have been

identified in forward-genetic screens (Ruegger et al. 1997; Ruegger et al. 1998; Alonso

et al. 2003; Walsh et al. 2006; Parry et al. 2009), but reverse-genetic analyses revealed

functional redundancies between *TIR1*, *AFB2*, and *AFB3* as well as between *AFB4* and

AFB5 (Dharmasiri et al. 2005; Prigge et al. 2016).

Gene duplication events provide the primary source material for the evolution of

biological innovation. In plants, whole genome duplication (WGD) events have been

especially important with events preceding the radiation of several key plant lineages

including seed plants, flowering plants, and core eudicots (Jaillon et al. 2007; Jiao et al.

2011; Clark and Donoghue 2018). Following duplication, the paralogs are often

redundant, allowing one copy to degenerate into a pseudogene (Lynch and Conery

2000). In Arabidopsis, the average half-life of a duplicate gene has been estimated at

17.3 million years (Lynch and Conery 2003). In many cases, however, both duplicates

are retained for one or a combination of reasons (reviewed in (Panchy et al. 2016).

Occasionally, one of the paralogs evolves a novel function (neofunctionalization), but

often the two paralogs fulfill different aspects (enzymatically, temporally, or spatially) of

the role of the ancestral gene (subfunctionalization). Following subfunctionalization,

there may be changes in selective pressure allowing each paralog to evolve specialized

functions without affecting functions carried out by the other paralog. This mechanism

likely played a prominent role in the evolution of plant gene families and, in turn, in the

radiation and diversification of land plants.

The *TIR1/AFB*, *Aux/IAA*, and *ARF* gene families expanded during land plant evolution

after the divergence of bryophytes and vascular plants (Remington et al. 2004; Rensing

et al. 2008; Mutte et al. 2018). Because auxin has a central role in many important

adaptations that occurred during land plant evolution, such as vascular development,

lateral root formation, and organ polarity; it seems likely that the acquisition of new roles

for auxin was enabled by the duplication and diversification of these three gene families.

Here we present the comprehensive genetic analysis of the *TIR1/AFB* gene family of

Arabidopsis which revealed extensive functional overlap between even distantly related

members as well as an essential role for the TIR1/AFB pathway in early embryos. In

contrast the AFB1 protein appears to have adopted a special role in a rapid auxin

response in the root.

RESULTS

Major lineages of auxin receptors diverged prior to the fern–seed plant split

To better understand the timeframe during which the auxin receptor family diversified,

we built upon previous phylogenetic analyses (Parry et al. 2009; Mutte et al. 2018) with

more taxon sampling at key nodes. As shown earlier (Hori et al. 2014; Mutte et al.

2018), the *TIR1/AFB* genes likely evolved from a gene encoding an F-Box/LRR protein

similar to those present in the genomes of extant streptophyte algae. These algal

proteins form a sister clade to three distinct land plant F-Box families, the TIR1/AFB

auxin receptors, the COI1 jasmonate-Ile (or dinor-OPDA) receptors, and the 'XFB' clade

of unknown function conserved in the genomes of mosses and some lycophytes but not

in other land plants (Prigge et al. 2010; Bowman et al. 2018). While the last common

ancestors of land plants and of vascular plants had only one *TIR1/AFB* gene, three

clades of auxin receptors were established prior to the radiation of euphyllophytes (ferns

plus seed plants) over 400 million years ago (Morris et al. 2018) (Figure 1—figure

supplement 1A). Another gene duplication event prior to angiosperm radiation split the

TIR1/AFB1 clade from the AFB2/AFB3 clade. Receptors from each of the four clades

are not retained in the genome of every flowering plant. For example, *AFB6* orthologs

are not present in the genomes of core Brassicales species—including Arabidopsis—

nor those of Poaceae species including rice and maize. The gene duplication event

establishing the distinct TIR1 and AFB1 clades is coincident with the At-β WGD event at

the base of Brassicales, while both the AFB2/AFB3 and the AFB4/AFB5 duplication

events coincide with the more recent At-α WGD prior to divergence of the Brassicaceae

family (Figure 1—figure supplement 1A) (Schranz and Mitchell-Olds 2006).

One noteworthy aspect of the phylogenetic tree is the pronounced branch-length

asymmetry within the TIR1+AFB1 clade (Figure 1—figure supplement 1). Since the last

common ancestor of *Arabidopsis* (Brassicaceae) and *Tarenaya* (Cleomaceae), the

AFB1 gene has accumulated over three times as many non-synonymous changes as

TIR1 (Figure 1—figure supplement 1B) despite being under selection based on the ratio

of non-synonymous and synonymous substitutions (Delker et al. 2010; Wright et al.

2017). AFB1 also differs from the other TIR1/AFBs in that it contains two of three

substitutions in the first α-helix of the F-Box that were each previously shown to weaken

TIR1's interaction with CUL1 (Yu et al. 2015). The substitution with the largest effect,

Glu8Lys (equivalent to Glu12Lys in TIR1), appeared shortly after the At-β WGD that

produced AFB1, and the Phe14Leu substitution appeared prior to the crown group of

the Brassicaceae family (Figure 1—figure supplement 1C). Interestingly, *AFB1*

orthologs from members of the *Camelina* genus—*C. sativa* (all three homeologs), *C.*

laxa, *C. hispida*, and *C. rumelica*—additionally contain the third substitution (Figure 1—

figure supplement 1C).

Genetic analysis of the *Arabidopsis TIR1/AFB* gene family revealed extensive functional overlap

Previous studies have assessed the functional overlap between the *TIR1*, *AFB1*, *AFB2* and *AFB3* genes (Dharmasiri et al. 2005; Parry et al. 2009) and separately between the *AFB4* and *AFB5* genes (Prigge et al. 2016). To study the genetic interactions between all members of the family, and to determine the effects of the complete absence of TIR1/AFB-mediated auxin signaling, lines with strong loss-of-function mutations in the six *TIR1/AFB* genes were intercrossed to generate all sixty-three mutant combinations. We used the following alleles *tir1-1, afb1-3, afb2-3, afb3-4*, *afb4-8*, and *afb5-5* (Figure 1—figure supplement 2A; (Ruegger et al. 1998; Parry et al. 2009; Prigge et al. 2016). The *tir1-1* allele, which causes an amino acid substitution within the leucine-rich repeat domain of the protein, has been reported to act as a dominant-negative allele (Dezfulian et al. 2016; Wright et al. 2017). However, we found that the root elongation phenotype of plants heterozygous for the *tir1-1*, *tir1-10*, and *tir1-9* alleles were not significantly different from each other and each displays a semi-dominant phenotype (Figure 1— figure supplement 2B). These results argue against a dominant negative effect for *tir1-1* since neither *tir1-9* or *tir1-10* produce detectable levels of transcript (Ruegger et al. 1998; Parry et al. 2009). Nevertheless, because it is possible that a dominant-negative effect might be revealed in higher-order mutants and because the *afb2-3* allele may not be a complete null allele (Parry et al. 2009), we generated selected mutant combinations also using the *tir1-10* (Parry et al. 2009) and the *afb2-1* (Dharmasiri et al. 2005) T-DNA insertion alleles. The *afb2-1* allele was introgressed from the Ws-2 background into the Col-0 background through at least eight crosses. For brevity,

mutant line names will be simplified such that "*tir1afb25*" corresponds to the *tir1-1 afb2-*

3 afb5-5 triple mutant line, for example, unless other allele numbers are specified.

The sixty-three mutant combinations displayed a wide range of phenotypes from

indistinguishable from wild type to early-embryo lethality (Figure 1—figure supplement

3). The non-lethal higher-order mutant combinations displayed a cohort of phenotypes

associated with mutants defective in auxin signaling: smaller rosettes, reduced

inflorescence height, reduced apical dominance, fewer lateral roots, and partially or

wholly valveless gynoecia (Figure 1; Figure 1—figure supplements 3 and 4). The three

viable quintuple mutants—*tir1afb1245*, *tir1afb1345*, and *afb12345*—had rosettes

approximately half the diameter and inflorescences less than half the height of WT Col-

0. Despite being smaller, these lines produced approximately twice as many branches

as WT (Figure 1A; Figure 1—figure supplement 4). Remarkably, lines retaining only one

copy of *TIR1* (*tir1/+ afb12345*) or one copy of *AFB2* (*afb2/+ tir1afb1345*) were viable.

The rosettes of these two lines were much smaller than those of WT plants with the

tir1/+ afb12345's rosette phenotype being slightly more severe (Figure 1B). In contrast,

afb2/+ tir1afb1345 plants developed shorter primary inflorescences and appeared to

completely lack apical dominance as all axillary meristems became active upon

flowering. The *afb2/+ tir1afb1345* and *tir1/+ afb12345* plants rarely produced seeds.

Lines containing the alternate alleles—*afb2-1/+ tir1-10 afb1345* and *tir1-10/+ afb2-1*

afb1345—displayed phenotypes indistinguishable from the corresponding lines (Figure

1B).

Auxin plays an important role in many aspects of root development. To begin to assess

the role of the *TIR1/AFBs* during root growth, we measured the effect of exogenous IAA

on primary root growth in the mutant lines. The responses ranged from indistinguishable

from WT to nearly insensitive to 0.5 µM IAA (Figure 1—figure supplement 4E), where

the roots of lines containing the *tir1* and *afb2* mutations displayed strong IAA resistance

(Dharmasiri et al. 2005; Parry et al. 2009). In addition, we found that the *afb3* and *afb5*

mutations had substantial effects on auxin response, while the *afb4* mutation had a

more modest effect. The mutant lines also responded similarly to exogenous auxin with

respect to lateral root production. The lines more resistant to IAA in the root elongation

assay tended to produce fewer lateral roots (Figure 1—figure supplement 4D, 4E).

Combinatorial mutant analyses revealed roles for *TIR1/AFB* family members

except *AFB1*

Each of the *tir1/afb* mutations, except for *afb1*, affected the above-described

phenotypes but to varying extents. To appraise the effects of each mutation on several

plant phenotypes, we plotted the mean values for each phenotype minus that of the

corresponding line without that mutation. Larger effects are indicated by greater

deviations from zero. For both the root elongation assay and the induction of lateral root

primordia, the *tir1* allele had the largest effect with the *afb2*, *afb5*, *afb3*, and *afb4*

mutations having smaller median effects (Figures 2A and 2B). The *afb1* mutation had

little or no effect on root elongation but, surprisingly, had an opposite effect on lateral

root formation.

Only *tir1* and, to a lesser degree, *afb2* affect rosette diameter in most contexts with the

median effects for *afb3*, *afb4*, and *afb5* being very close to zero (Figure 2C). However,

they have huge collective effects, where the *afb2345* quadruple mutant is over 6 cm

smaller than each of the four triple mutants (blue arrowheads; Figures 2C). Consistent

with previous reports that *AFB5* plays a key role in regulating inflorescence branching

and height (Prigge et al. 2016; Ligerot et al. 2017), the *afb5* mutation has the largest

effect on these phenotypes, although each mutation, except for *afb1*, had some effect

(Figures 2D and 2E).

While the *afb1* mutation had minimal effect on most aspects of plant growth, it

suppressed the lateral root phenotype of some mutant lines both with and without auxin

treatment (Figure 2B; below). We found that the *afb1* mutation suppressed the

phenotype of both the *afb234* (2.15±0.13 versus 1.75±0.10 lateral roots/cm) and *afb345*

triple mutants (3.10±0.13 versus 1.96±0.14 lateral roots/cm) measured after 12 days on

media not supplemented with IAA. This behavior was not observed in an otherwise WT

background (2.76±0.11 for *afb1* versus 3.23±0.15 lateral roots/cm for Col-0) nor in a

tir1-1 background (1.75±0.08 versus 2.34±0.09 lateral roots/cm for *tir1*). Each of the

pairs were significantly different (two-tailed *t*-test, $p < 0.03$).

Penetrance of *tir1/afb* embryonic root formation defects are temperature sensitive

The *tir1afb23* and *tir1afb123* lines were previously shown to display a variably penetrant

phenotype in which seedlings lack roots, lack both roots and hypocotyls, or fail to

germinate (Dharmasiri et al. 2005; Parry et al. 2009). All lines homozygous for both *tir1*

and *afb2* plus either *afb3*, *afb4*, or *afb5* display these defects to some degree ranging

from 1% in *tir1afb24* to 99% in *tir1afb1234* (Figure 1—figure supplements 3 and 5).

We had noticed a sizeable difference in the proportion of seedlings lacking roots from

different batches of seeds. To test whether the temperature at which the seeds mature

affects the penetrance of the rootless seedling phenotype, we grew *tir1afb23*,

tir1afb123, *tir1afb245* and WT in parallel at 17°C, 20°C, and 23°C and scored the

progeny seedling phenotypes (Figure 1—figure supplement 5). The penetrance of the

phenotype for all three lines was significantly lower at 20°C than at either 17°C or 23°C

for all with the exception that the difference with *tir1afb245* at 17°C was not significant

using the Fisher's exact test. This suggests that aspects of the auxin regulatory system

are sensitive to temperature.

The *tir1afb12345* mutant line exhibits defects early in embryogenesis

Because *tir1afb235* seedlings were not identified among the progeny of *tir1/+ afb235* or

afb2/+ tir1afb35 plants, we examined developing embryos dissected from the siliques

from these lines. Eleven of 41 (27%) and 52 of 213 (24%), respectively, of the embryos

from each line lacked cotyledons and had over-proliferated suspensors while the rest

had a WT phenotype (Figure 3A, 3A').

Because all mutant combinations expected to produce one-quarter *tir1afb2345* progeny

were either seedling lethal or infertile, we created a transgene that hemizygously

complements these phenotype and segregates as a single locus. We assembled the

complementing genomic fragments encoding TIR1, AFB2, and AFB5, each carboxy-

terminally fused with the coding sequences for different monomeric fluorescent proteins

(mOrange2, mCitrine, and mCherry, respectively) concatenated into a single binary

plasmid (Figure 3—figure supplement 1). This construct was transformed into progeny

of *tir1/+ afb5/+ afb1234* plants, backcrossed and selfed to obtain a sextuple mutant

background, and two *TIR1/AFB5/AFB2* lines were identified that complemented the

sextuple mutant phenotype when hemizygous and segregated as a single locus. Using

this approach, one-quarter of the progeny of plants hemizygous for these transgenes

display embryo defects, while the complemented siblings are easily identified because

they expressed fluorescent TIR1, AFB2, and AFB5 fusion proteins.

The earliest potential difference between sextuple mutants and the complemented

siblings is that the initial division of the embryo proper was occasionally displaced from

vertical in sextuple 2-cell embryos (3 of 19 were >12° from vertical) compared to

complemented sibling embryos (0 of 64), however the average angles from vertical

were not significantly different (p = 0.32) (Figure 3B–C versus 3B′–C′, 3N). The third

round of divisions in the embryo proper separates the upper and lower tiers with the

lower surface of the upper tier typically being slightly convex, and this curvature is

significantly more prominent in the sextuple mutants (p = 1.4×10^{-7}; Figure 3D versus

3D′, 3O). Later, during the transition from the 8-cell to the 16-cell embryos, nearly all cell

divisions in the complemented embryos are oriented periclinally, as in WT embryos. In

contrast, 69% of these division are anticlinal in the mutant embryos (Figure 3E and 3E′,

3P). In WT 32-cell stage embryos, the hypophysis cell normally divides asymmetrically

to produce the lens-shaped cell which is required for the formation of the embryonic

root. This division was delayed in the mutant, and when it occurred, was symmetrical

(Figure 3G–H and 3G′–H′). Later, the cells of the embryo proper slow or cease dividing

and the cells of the suspensor begin to proliferate and invariably produce a radially

symmetric terminal phenotype (Figure 3I–M, 3I′–M′). Around the stage where

complemented siblings are at the bent-cotyledon stage, the cells of the sextuple mutant

senesce and seed development is aborted (Figure 3—figure supplement 2). Hence, the

sextuple mutant reveals the importance of *TIR1/AFB* auxin response machinery from

the earliest stages of embryogenesis.

Expression of embryo-patterning reporters is disrupted in the *tir1afb235*

quadruple mutant

To learn more about the early embryo defects, we introgressed marker genes into lines

segregating the *tir1afb235* quadruple mutant. This quadruple mutant displays a

phenotype indistinguishable from that of the sextuple mutant from at least the

dermatogen stage, when quadruple mutants can first be reliable distinguished from non-

quadruple mutants (Figure 4). Expression of the auxin-responsive marker

DR5$_{rev}$:3×Venus-N7 was undetectable in embryos displaying the mutant phenotype

(Figure 4E–G; compare to Figure 4A–C; 0/10 in quadruple mutants and 26/26 in non-

mutant siblings) indicating that auxin-regulated transcription through the remaining

receptors, AFB4 and AFB1, is minimal at most during embryogenesis. Similarly, the

quiescent center marker *WOX5:GFP* marker was not detected in the mutant embryos

(Figure 4H), whereas in wild type the reporter is first expressed in the hypophysis prior

to its asymmetric division then persists in the quiescent center cells (Figure 4D; 0/11 in

quadruple mutants and 28/28 in non-mutant siblings).

Auxin efflux reporter *PIN7-Venus* is normally expressed in the suspensor, hypophysis,

hypophysis-derived cells, and weakly in protodermal cells of the lower tier (Figure 4K–

L). In mutant embryos, PIN7-Venus is faintly detectable in these cells in globular-stage

embryos. Unexpectedly, the signal is much stronger in protodermal cells of the embryo

proper, especially in the lower tier, by the 32-cell stage (Figure 4O–P; 7/8 quadruple

mutants and 0/14 siblings). The same pattern was observed with the *PIN7-GFP* marker

(Figure 4U; 8/8 quadruple mutants and 0/30 siblings). The auxin efflux reporter *PIN1-*

Venus is initially expressed in a reciprocal pattern to *PIN7-Venus*, in all the cells above

the hypophysis except the lower-tier protodermal cells and is later refined to strips from

the provascular cells out to the cotyledon tips (Figure 4I–J; 12/12 of phenotypically

normal embryos). In the mutants, PIN1-Venus signal is reduced and restricted primarily

to apical protodermal cells (Figure 4M–N; 9/9 quadruple mutants). This is reminiscent

but more severe than its pattern in *monopteros* mutants where provascular expression

is merely reduced. The *NTT-YPet* marker gene is normally first strongly expressed in 8-

to 16-cell embryos in the nuclei of suspensor cells and the hypophysis and persists in

the suspensor and the hypophysis-derived cells in later embryo stages (Figure 4R–T;

58/59 phenotypically normal embryos))(Crawford et al. 2015). In mutants, NTT-YPet

appears normally in most suspensor cells, but not always including the hypophysis (2/6

32-cell quadruple mutant embryos had signal above background in the hypophysis),

and is progressively lost in the distal suspensor cells before the abnormal lateral cell

divisions occur (Figure 4V–X; 4/4 late-globular-stage mutants lacked signal in both the

hypophysis and the adjacent suspensor cell). This is very similar to NTT-YPet

expression in a *monopteros* mutant embryos (Crawford et al. 2015).

Gametophytically expressed TIR1/AFBs do not contribute to gametophytic

viability

Because the maternal supply of auxin and the endosperm both play important roles in

embryo development, it is possible that female gametophytes lacking auxin receptors

would not be viable. Although the incidence of sextuple mutant embryos shows that

gametophytically-expressed auxin receptors are not required for viability, it is possible

that they contribute to robust transmission. To test the transmission through sextuple

mutant megagametophytes and pollen, we carried out reciprocal crosses between wild

type (Col-0) and the hemizygously *TIR1/AFB5/AFB2*-complemented sextuple mutant. If

the sextuple mutant gametophyte survives and is fertilized, the progeny's embryo

lethality would be rescued by wild-type copies of each receptor provided by the Col-0

parent. The F_1 progeny were scored for the presence of the transgene to infer the

sextuple's transmission rates through both gametophytes (Figure 3—figure supplement

3). The sextuple mutant was transmitted nearly as well as without the complementing

transgene as with it through both the pollen (49.4%) and the female gametophyte

(47.9%) (χ^2 test p = 0.81 and 0.43, respectively). This indicates that gametophytically

expressed TIR1/AFBs do not contribute to gametophytic viability.

Functional TIR1/AFB-mCitrine reporters reveal contrasting patterns of spatio-temporal expression and sub-cellular localizations

To reveal whether differences in expression pattern can account for the relative importance of the TIR1/AFBs in different aspects of growth and development, C-terminal fusions with the bright, relatively fast-maturing, monomeric fluorescent protein mCitrine were produced for each TIR1/AFB protein in the corresponding single mutant background. Each transgene complemented the mutant phenotypes (Figure 5—supplement 1). The fluorescent signal in the *AFB5-mCitrine* lines was fairly uniformly distributed in shoot apices (Figure 5F), while in the *AFB3-mCitrine*, *AFB2-mCitrine*, and *TIR1-mCitrine* lines, fluorescence was more restricted to young primordia and meristem peripheral zones (Figure 5A, 5C–D). Within organ primordia, *TIR1-mCitrine* appears to be strongest in the adaxial domains of the youngest primordia. Signal for the *AFB4-mCitrine* line was barely detectable (Figure 5E), while that of *AFB1-mCitrine* was very strong and largely complementary to *TIR1-mCitrine* in that the strongest signal was in abaxial domains and in the stem (Figure 5B). The expression patterns in either primary or lateral roots for each *TIR1/AFB* gene except *AFB4* translationally fused to a YFP have been reported previously (Prigge et al. 2016; Wang et al. 2016; Rast-Somssich et al. 2017; Roychoudhry et al. 2017). TIR1-, AFB2-, AFB3-, and AFB5-mCitrine signal was uniformly detected throughout the root meristematic region and fainter signal detected in the root cap cells (Figure 5G, 5I–J, 5L; Figure 5—figure supplement 2) as shown previously. AFB1-mCitrine is very highly expressed throughout the root except for the columella, cortex, endodermis, and pericycle of the meristematic region (Figure 5H). AFB4-mCitrine signal in lines that complemented the *afb4* phenotype was barely

detectable. However, an *AFB4-mCitrine* line that is hypersensitive to the synthetic auxin

picloram line's expression pattern was comparable to that of AFB5-mCitrine (Figure 5K;

Figure 5—figure supplement 2I–L). In embryos, TIR1-, AFB2-, AFB3-, and AFB5-

mCitrine accumulate fairly uniformly throughout the embryos and suspensors while

AFB4-mCitrine's signal was close to background levels and AFB1-mCitrine was

undetectable (Figure 5T–Y).

The subcellular localization of different TIR1/AFB proteins varied substantially (Figure

5M–S; Figure 5—figure supplement 3). We quantified this variation more precisely by

measuring the relative level of each protein in the nucleus versus outside the nucleus in

epidermal cells of the root elongation zone based on mCitrine fluorescence (Figure 5S).

TIR1-mCitrine is primarily in nuclei while significant amounts of AFB2 through AFB5 are

present in the cytoplasm. Strikingly, AFB1-mCitrine appears primarily outside the nuclei.

The localizations are consistent across multiple lines and, when tested, different

fluorescent protein tags (Figure 5—figure supplement 2). Hence, despite being from the

same clade, TIR1 and AFB1 proteins exhibit contrasting patterns of primarily nuclear

and cytoplasmic subcellular localizations, respectively.

AFB1 plays a key role in the rapid auxin inhibition of root growth

Gravitropic curvature of the root is a rapid auxin-regulated growth response that

requires asymmetric distribution of auxin between the upper and lower side of the root

(Sato et al. 2015). According to the current model, auxin has two modes of action during

gravitropism: a rapid nongenomic phase, followed by a transcriptional phase that is

dependent on the TIR1/AFB proteins (Shih et al. 2015). Surprisingly, recent studies

demonstrate that rapid, nongenomic auxin inhibition of root growth is dependent on the

TIR1/AFBs (Fendrych et al. 2018). To determine the relative contribution of the

TIR1/AFB family members to the rapid response, we measured the effect of 10 nM IAA

on root growth in various *tir1/afb* lines over a 20-minute time period (Figure 6; Figure

6—figure supplements 1–3). The results in Figure 6 show that each of the TIR1/AFBs

contributes to rapid root growth inhibition but that, surprisingly, the *afb1-3* mutant is

almost completely resistant to auxin indicating that AFB1 is the dominant auxin receptor

for this response. Expression of *AFB1-mCit* under control of the *AFB1* promoter

restored the wild-level of auxin response. The behavior of the *afb1* mutant is particularly

remarkable since the mutant is not affected in any of the other auxin-regulated growth

processes that we characterized, with the possible exception of lateral root formation.

This includes long-term inhibition of root growth. Thus, the *afb1* mutant is a useful tool

to discriminate between nongenomic and transcriptional auxin responses.

As a contrast we also examined the effect of auxin on etiolated hypocotyl growth in the

mutant lines. This response is slower than the root response and depends on the

canonical nuclear TIR1/AFB pathway (Fendrych et al. 2016). Dissected hypocotyl

segments from etiolated seedlings were treated with 5 µM NAA and imaged every 10

minutes for 180 minutes. The response of the mutant lines was complex (Figure 6—

figure supplement 4). Several lines were clearly resistant to auxin, particularly

tir1afb1245 and *tir1afb245.* Notably, comparison of these lines suggests that the *afb1*

mutation did not contribute to resistance. Other lines also lacking both *AFB4* and

AFB5—afb1345, tir1345, afb1245, and *afb12345*—display a moderate level of

resistance. Finally, three lines, *tir1afb134, tir1afb23,* and *tir1afb124* are hypersensitive

to auxin in this assay (Figure 6—figure supplement 4).

AFB1 regulates the initial phase of root gravitropic response

Gravitropic root curvature is first apparent less than 10 minutes after a gravity stimulus

(Shih et al. 2015). It has been proposed that the early stage of gravitropism is mediated

by a non-genomic auxin response while prolonged root curvature requires auxin

regulated transcription (Sato et al. 2015). Since AFB1, and to a lesser extent, the other

TIR1/AFBs, contribute to nongenomic inhibition of root elongation, we wondered if they

are required for the early gravitropic response. To test this possibility, we performed

gravitropism assays on a number of *tir1/afb* lines (Figure 7; Figure 7—figure supplement

1). The gravitropic response can be divided into three phases. A slow or lag phase

which occurs over the first 90 minutes in Col-0, followed by a 3-hour linear phase and

finishing with a plateau phase. The *tir1afb345* line exhibits a slower gravitropic response

during the linear phase and a reduced angle at plateau compared to WT (Figure 7A) as

expected based on results with other *tir1/afb* mutant combinations (Dharmasiri et al.

2005). Strikingly, the *tir1afb1345* mutant exhibited an additional decrease in the

gravitropic response during the initial lag phase demonstrating that AFB1 is required for

this phase (Figure 7A Figure 7-figure supplement 1A). The *tir1afb1* line

showed a similar decrease in the lag phase compared to *tir1* (Figure 7B Figure 7-figure

supplement 1B). It seems likely that TIR1 also contributes to the early response since

the *tir1afb1* double mutant showed a stronger delay compared to either single mutant.

In addition, both *tir1* and *afb1* displayed a reduced early response in one of the two

experiments (Figure 7—figure supplement 1B). Since other members of the family also

confer low levels of auxin resistance in the rapid root growth response, these proteins

may also make a small contribution to the early phase of gravitropism (Figure 6A).

Further, both *afb1 AFB1-mCitrine* lines responded appreciably faster than the *afb1*

mutant during the first 2 hours with the brighter of the two mCitrine lines, line #7,

exhibiting a difference by 30 minutes (Figure 7C; Figure 7—figure supplement 1C).

Interestingly, both mCitrine lines started to plateau earlier and at a reduced angle

compared to wild type while *afb1* plateaued later and at an increased angle, suggesting

that AFB1 and the rapid response also play a role at later stages of the gravitropic

bending response.

DISCUSSION

The TIR1/AFB protein family has expanded through a series of gene duplication events

that began before fern–seed-plant divergence. Despite the fact that three major

subclades were established approximately 400 MYA (Morris et al. 2018), our genetic

studies reveal that for most auxin-regulated growth processes, the TIR/AFB proteins

retain largely overlapping functions. The striking exception to this general statement is

the dominant role for AFB1 in rapid auxin inhibition of root growth. In general, *TIR1* is

most important for normal growth and development, but *AFB5* and *AFB2*, and to a

lesser extent *AFB3* and *AFB4*, also play significant roles. Spatial differences are also

apparent; *TIR1* has a major role in the root while *AFB5* is relatively more important in

hypocotyl and inflorescence development.

Although all six genes are broadly expressed, it appears that the relative importance of

individual TIR1/AFB proteins in various organs are at least partly related to differences

in expression. For example, *AFB5* is more broadly expressed than the other genes in

the inflorescence while in the root, *TIR1* and *AFB2* are most highly expressed. The

AFB4 gene is expressed at a lower level in all tissues consistent with its relatively minor

role. Additional differences in patterns of expression are also apparent, particularly in

the inflorescence. Further studies will be required to determine if these differences are

important.

Our studies demonstrate that the levels of the TIR1/AFB proteins are not uniform

throughout the plant. This is true for individual members of the family and for total

TIR1/AFB levels across different tissues and cell types. Earlier experiments also

showed that TIR1/AFB levels can be dynamic in a changing environment (Vidal et al.

2010; Wang et al. 2016). These observations may have important implications for use of

DII-Venus-based auxin sensors to estimate relative auxin levels, since levels of the

sensor protein are dependent on both auxin and the TIR1/AFBs (Brunoud et al. 2012;

Liao et al. 2015). Given the debate over an auxin-response asymmetry across shoot

organ primordia (Bhatia et al. 2019; Guan et al. 2019), it is particularly interesting that

we see an asymmetric distribution of TIR1-mCitrine across flower primordia.

It is important to emphasize that individual members of the family may have functions in

particular environmental conditions. For example, the microRNA miR393 is known to

target *TIR1, AFB2*, and *AFB3* but not other members of the family (Jones-Rhoades and

Bartel 2004; Navarro et al. 2006). Regulation of miR393 abundance modulates the

levels of these three TIR1/AFBs to facilitate various growth processes, such as lateral

root formation and hypocotyl elongation in response to environmental signals (Vidal et

al. 2010; Pucciariello et al. 2018).

Previous *in vitro* studies have documented some differences in the biochemical activity

of members of the TIR1/AFB family (Calderón Villalobos et al. 2012; Lee et al. 2014).

Similarly, an auxin-induced degradation assay in yeast reveals differences in the

behavior of TIR1 and AFB2 (Wright et al. 2017). In contrast, our results do not reveal

any biochemical specificity, except for *AFB1* (see below). Thus, a single *TIR1* or *AFB2*

allele is sufficient to support viability throughout the plant life cycle albeit with

dramatically reduced fertility. This contrasts to functional diversification seen in other

well-studied gene families that diverged in a similar time frame such as the

phytochrome photoreceptors and Class III HD-Zip transcriptional regulators (Prigge et

al. 2005; Franklin and Quail 2010; Strasser et al. 2010). It is possible that the retention

of overlapping functions reflects stricter constraints on TIR1/AFB protein function. One

possibility is that the different *TIR1/AFB* paralogs have been maintained because they

contribute to the robustness of the auxin signaling system. Of course, specific functions

may be revealed in future studies.

The importance of auxin in patterning of the developing embryo is well established

(Palovaara et al. 2016). Auxin signaling, as evidenced by activity of the *DR5* reporter, is

first apparent in the apical cell of the embryo (Friml et al. 2003). The essential role of

auxin in the apical cell and later in the hypophysis is clearly demonstrated by the

defects in the division of these cells in the *tir1afb235* quadruple and *tir1afb12345*

sextuple mutant (Figure 3). Similar defects are observed in a number of other auxin

mutants including those affecting response (*monopteros* and *bodenlos*), auxin synthesis

(*yuc1 yuc4 yuc10 yuc11* and *taa1 tar1 tar2*) and transport (*pin1 pin3 pin4 pin7* and *aux1*

lax1 lax2)(Berleth and Jürgens 1993; Hardtke and Berleth 1998; Hamann et al. 1999;

Hamann et al. 2002; Friml et al. 2003; Cheng et al. 2007; Stepanova et al. 2008; Robert

et al. 2015). However, none of these lines exhibit the fully penetrant embryo-lethal

phenotype observed for the *tir1afb235* quadruple and *tir1afb12345* sextuple mutants. In

the other mutants, significant fractions of embryos escape embryo lethality and

germinate, albeit often as rootless seedlings.

The expression of key embryonic markers in the mutants also reveals profound defects

in embryonic patterning by the dermatogen stage. Although *tir1afb235* embryos form a

morphologically normal hypophysis cell, this cell never expresses *NTT-YPet* or

WOX5:GFP. The proliferation of suspensor cells in the mutant is associated with

reduced expression of the suspensor marker *PIN7-Venus* and to a lesser extent *NTT-*

YPet suggesting that the TIR1/AFB pathway is required to maintain the suspensor cell

fate, consistent with an earlier study (Rademacher et al. 2012). *PIN1-Venus* is normally

expressed in most cells distal from the hypophysis in globular embryos and in

provascular tissue in later embryos, but it was expressed primarily in apical protodermal

cells in *tir1afb235* mutants (Figure 4M–N). This is reminiscent of its pattern in the

monopteros mutant, where some protodermal expression appears although the

provascular expression is retained (Breuninger et al. 2008). Because both cotyledon

specification and *PIN1* expression are influenced by auxin perception, it is unclear

whether the mutant embryos lack the radial asymmetry that predicts cotyledon

positioning or fail to elaborate on this asymmetry. It was surprising to observe that *PIN7-*

Venus exhibits ectopic expression in the embryo proper. The reason for this is unclear

but *PIN7* expression may normally be repressed in the embryo by a TIR1/AFB-

dependent pathway. Given that PIN1 and PIN7 are normally expressed in non-

overlapping domains in the embryo (Friml et al. 2003), one possibility is that the

reduction in PIN1 expression in the mutants allows PIN7 to be expressed beyond its

normal boundaries.

In contrast to the embryo, the role of auxin in gametophyte development is uncertain.

Several reports suggest that auxin has an important role in patterning of the female

gametophyte (Pagnussat et al. 2009; Panoli et al. 2015; Liu et al. 2018). Others have

argued against a role for auxin based on theoretical considerations as well as lack of

evidence for an auxin response using several auxin reporters (Lituiev et al. 2013). Our

studies suggest that the TIR1/AFB auxin receptors are not required for gametophyte

development although we cannot rule out a minor role. It is important to note that we

have not directly examined developing sextuple gametophytes and it is possible that

there are minor defects that do not affect viability. We also can't eliminate the possibility

of perdurance of TIR1/AFB proteins from the maternal tissue. Finally, it is possible that

auxin is required, but acts through a non-canonical pathway such as that involving auxin

binding to the ETTIN protein (Simonini et al. 2016).

AFB1 is unique among the auxin co-receptors and appears to have undergone

pronounced functional changes during the diversification of the Brasssicales order since

the *TIR1–AFB1* duplication in the At-β WGD around 80 to 90 million years ago (Figure

1—supplement 1C) (Edger et al. 2018). Although AFB1 can interact with Aux/IAA

proteins in an auxin-dependent manner, it does not appear to assemble into a Skp,

Cullin, F-box containing (SCF) complex as efficiently as the other TIR1/AFBs and is not

primarily localized to the nucleus where it could directly influence transcriptional

responses (Dharmasiri et al. 2005; Yu et al. 2015)(Figure 5N and 5S; Figure 5—figure

supplement 2C–D). The F-Box substitutions in AFB1 affecting SCF assembly appeared

between approximately 45 and 65 million years ago (Figure 1—supplement 1C)(Edger

et al. 2018). It is noteworthy that unlike the other *TIR1/AFB* genes that are broadly

expressed in most cells, *AFB1* is expressed very highly in some tissues (root epidermis

and vascular tissue) and not at all in others (meristematic pericycle and early embryos).

Based on our genetic studies, AFB1 appears to have a negative effect on lateral root

initiation in the *afb234* and *afb345* lines despite the fact that AFB1 is not expressed in

the pericycle, the site of lateral root initiation, suggesting that this may be a non-cell-

autonomous effect.

We find that AFB2 through AFB5 are distributed between the nucleus and the

cytoplasm, at least in epidermal cells of the root (Figure 5S). In contrast, the paralogs

TIR1 and AFB1 differ dramatically in being highly enriched in the nucleus and in the

cytoplasm, respectively. In Arabidopsis roots, auxin treatment results in very rapid

responses including increased cytosolic Ca^{++} levels, alkalinization of the apoplast and

inhibition of root growth (Shih et al. 2015; Dindas et al. 2018; Fendrych et al. 2018).

Because these events occurred too rapidly to involve transcription, it was assumed that

they did not require the TIR1/AFB proteins. However, recent studies have demonstrated

that two rapid responses, inhibition of root growth and membrane depolymerization in

root hairs, do require the TIR1/AFBs (Dindas et al. 2018; Fendrych et al. 2018).

Surprisingly we find that the growth inhibition response is mediated primarily by AFB1.

This may reflect the high level of AFB1 in the cytoplasm. It is not currently clear how

deeply conserved the cytoplasmic localization of AFB1 is. It is possible that AFB1's

specialization is a relatively recent event and that the responsibility of mediating the

rapid response is shared by multiple TIR1/AFB proteins in other plant lineages. An

answer to this question will require further information on the molecular basis for AFB1

localization.

It has been proposed that the rapid nongenomic auxin response in the Arabidopsis root

has a role in early stages of root gravitropism (Sato et al. 2015), and our results support

this idea. Although the *afb1* mutant has only a modest effect on gravitropism by itself, in

combination with *tir1* or *tir1afb345,* it confers a clear decrease in early gravity response.

It is surprising that the *afb1* mutation has only a modest effect on root gravitropism

given the nearly complete absence of the rapid nongenomic auxin response. This may

be a reflection of the gravitropic assay we have employed. Further detailed studies of

the gravitropic response may reveal a more substantial role for the rapid response. The

fact that two *AFB1-mCitrine* lines both appear to affect the early response as well as the

angle at the plateau phase, hint at additional complexity. Although the rapid auxin

response has only been described thus far in Arabidopsis, it is probably not unique to

the Brassicales given that a relatively fast gravitropic response is common in diverse

seed plants (Zhang et al. 2019). If the rapid auxin response evolved prior to the TIR1–

AFB1 duplication event and the ancestral TIR1/AFBs contributed to both the nuclear

genomic and cytoplasmic nongenomic auxin responses, the differences between TIR1

and AFB1 represent an elegant example of subfunctionalization of AFB1 to a role in the

non-genomic response and, possibly, of TIR1 to specialize in the nuclear auxin

response. Furthermore, as AFB1 has a major role in the rapid response but little or no

function in the transcriptional response, the *afb1* mutant provides a useful tool to

separate the two responses.

METHODS

Phylogeny

The sources for the amino-acid sequences (Figure 1—figure supplement 1A) and

CDS (Figure 1—figure supplement 1C) are listed in Supplementary File 1 (Jiao et al.

2011; Goodstein et al. 2012; Johnson et al. 2012; Matasci et al. 2014; Wickett et al.

2014; Xie et al. 2014; One Thousand Plant Transcriptomes 2019). Taxa were selected

based on availability, quality, and diverse sampling at key nodes. A reduced set was

included for COI1 homologs. The *AFB1* genes from *Camelina hispida*, *C. laxa*, and *C.*

rumelica were amplified from genomic DNA using Phusion Polymerase (New England

Biolabs or ThermoFisher) and primers to regions of the 5′ and 3′ UTRs conserved in all

three *C. sativa AFB1* genes in the *C. sativa* genome (Kagale et al. 2014). The PCR

products were subcloned, and three *C. hispida* and *C. laxa* clones and a single *C.*

rumelica clone were sequenced. The *CamhiAFB1* and *CamlaAFB1* sequences included

in analysis appeared in two of the three clones (GenBank accession numbers

MK423960–MK423962).

To build the alignment of F-Box-LRR protein sequences, sequences from distinct

subclades were aligned using T-COFFEE v11.00 (Notredame et al. 2000) to identify

and trim unique unalignable regions from individual sequences before aligning the

whole set. Ambiguous regions of the full alignments were removed in Mesquite v3.5

(Maddison and Maddison 2018). The raw alignment of nucleotide CDS sequences of

Brassicales *TIR1/AFB1* genes was adjusted so that gaps fell between adjacent codons.

Phylogenetic trees were inferred using MrBayes v3.2.6 (Ronquist et al. 2012). For the

TIR1/AFB/XFB/COI1 phylogeny, a total of six runs of four chains were split between two

Apple iMac computers using the parameters aamodelpr=mixed, nst=6, and

rates=invgamma. Only four of the six runs had converged after 16 million generations,

so the analysis was restarted with three runs each starting with the best tree from one of

the initial runs and with more heating (temp=0.5) for 10 million generations. The

TIR1/AFB1 nucleotide alignments were partitioned by codon position with

ratepr=variable, nst=6, rates=invgamma with three runs of 4 chains run for five million

generations. The consensus trees were viewed using FigTree v1.4.4 (Rambaut 2018).

Mutants

The alleles used—*tir1-1, tir1-9, tir1-10, afb1-3, afb2-1, afb2-3, afb3-1, afb3-4,*

afb4-8, and afb5-5—have been described previously (Ruegger et al. 1998; Dharmasiri

et al. 2005; Parry et al. 2009; Prigge et al. 2016). Seeds from *Camelina* species were

provided by the United States National Plant Germplasm System (USDA-ARS, USA): *C.*

hispida (PI 650133), *C. laxa* (PI 633185), and *C. rumelica* (PI 650138). Unless noted,

plants were grown at 22°C long-day (16:8) conditions on ½× Murashige and Skoog

media with 0.8% agar, 1% sucrose, and 2.5 mM MES, pH 5.7, or in a 2:1 mixture of soil

mix (Sunshine LC1 or ProMix BX) and vermiculite. Leaf DNA was isolated with a

protocol adapted from (Edwards et al. 1991) to use steel BBs (Daisy Outdoor Products),

2 ml microcentrifuge tubes, and 20-tube holders (H37080-0020, Bel-Art). See

Supplementary File 2 for primers used for genotyping.

Fluorescent marker lines were described previously: *NTT-2×YPet* (Crawford et

al. 2015), *PIN7-GFP* (Blilou et al. 2005), *DR5$_{rev}$:3×Venus-N7* (Heisler et al. 2005),

WOX5:GFP$_{ER}$ (Blilou et al. 2005). The recombineered *PIN1-Venus* and *PIN7-Venus*

markers (Zhou et al. 2011) were obtained from the Arabidopsis Biological Resource

Center (CS67184 and CS67186). Previously characterized *PIN1-GFP* lines could not be

used because of tight linkage to *AFB2* (CS9362) and co-segregation with L*er*-derived

enhancers of the *afb2/+ tir1afb35* phenotype (CS23889). Each marker was introgressed

into lines segregating the *tir1afb235* quadruple mutant by two sequential crosses, PCR

genotyping, and selfing. Marker line homozygosity was confirmed in F$_1$ seedlings from

test crosses to WT. The *UBQ10:H2B-mTurquoise2* marker was assembled by

combining the pK7m34GW destination vector (Karimi et al. 2007), UBQ10prom_P4P1R

(Jaillais et al. 2011)(provided by Nottingham Arabidopsis Stock Centre, N2106315),

H2B_noStop/pDONR207 (provided by Frederic Berger), and 2×mTurqoise2/pDONR-

P2RP3 using the LR Recombinase System (Life Technologies). For

2×mTurqoise2/pDONR-P2RP3, the mTurquoise2 coding sequence (Goedhart et al.

2012); provided by Joachim Goedhart) was amplified using primers mTU2_P2RP3_F

and mTU2_P2RP3_wSTOP_R primers and recombined into pDONR-P2RP3 vector in a

BP reaction to give mTURQUOISE2/pDONR-P2RP3. This plasmid was amplified using

the INS_mTU2_P2RP3_F and INS_mTU2_P2RP3_wSTOP_R primers and the

BB_mTU2_ P2RP3_F and BB_mTU2_ P2RP3_R primers. The PCR products were

assembled by Gibson cloning (New England Biolabs) to give 2×mTurqoise2/pDONR-

P2RP3. The *UBQ10:H2B-mTurquoise2* transgene was introduced to Col-0 plants as

described (Simon et al. 2014).

Fluorescently tagged TIR1/AFB lines

Genomic regions containing each of the *TIR1/AFB* genes were amplified using

Phusion polymerase (New England Biolabs or ThermoFisher) from corresponding

genomic clones (JAtY51F08, JAtY62P14, JAtY53F15, JAtY61O12, and JAtY52F19)

except for *AFB3* which was amplified from Col-0 genomic DNA. See Supplementary File

2 for primers used. The PCR products were cloned into pMiniT (New England Biolabs),

and the stop codon was altered to create a *Nhe*I site using site-directed mutagenesis.

An *Xba*I fragment containing either mCitrine (Griesbeck et al. 2001), mOrange2 (Shaner

et al. 2008), or mCherry (Shaner et al. 2004) preceded by a short linker (either Arg-Gly$_5$-

Ala or Arg-Gly$_4$-Ala) was ligated into the *Nhe*I sites. The genomic regions including the

fluorescent protein genes were inserted in the *Mlu*I site of pMP535 (Prigge et al. 2005)

as *Asc*I fragments (*AFB5*) or as *Mlu*I-*Asc*I fragments (others). To produce the sextuple-

complementation construct, the *TIR1-mOrange2* fragment was cloned into pMP535 as

above, then *AFB2-mCitrine* was inserted into the re-created *Mlu*I site followed by *AFB5-*

mCherry into its re-created *Mlu*I site. The constructs were introduced into the following

strains by floral dip (Clough and Bent 1998): *tir1/+ afb5/+ afb1234* progeny (sextuple-

complementation construct), *tir1afb23* (*TIR1-mCitrine*, *AFB3-mCitrine*, and *AFB3-*

mEGFP), *tir1afb1245* (*AFB2-mCitrine*), *afb45* (*AFB4-mCitrine* and *AFB4-tdTomato*),

afb5-5 (*AFB5-mCitrine*, and *afb1-3* (*AFB1-mCitrine*). Basta-resistant candidate lines

were selected based on complementation of visible phenotypes (except for *AFB1-*

mCitrine) then crossed to get them into the appropriate mutant backgrounds. Once in

the sextuple-mutant background, the complementation transgene was maintained as a

hemizygote by checking siliques for aberrant embryos or aborted seeds. The *afb5-5*

AFB5-mCitrine #9 and *#19* lines were described previously (Prigge et al. 2016).

Microscopy

For confocal microscopy of the root meristem, five- to seven-day-old seedlings

were stained in a 10 µg/ml aqueous solution of propidium iodide for one minute, rinsed

in water, mounted with water, and viewed with either a Zeiss LSM 880 inverted

microscope or a Zeiss LSM 710 inverted microscope. Embryos were fixed and stained

with SCRI Renaissance 2200 (SR2200; Renaissance Chemicals, UK; (Crawford et al.

2015). Briefly, using fine forceps and a 27-gauge needle as a scalpel, developing seeds

were dissected from siliques and immediately immerged in fix solution (1×PBS, 4%

formaldehyde (Electron Microscopy Sciences, 15713), and 0.4% dimethyl sulfoxide) in a

six-well plate with 100µ-mesh strainers. A vacuum was pulled and held three times for

12 minutes each time, before rinsing twice with 1×PBS for 5 minutes. The embryos

were transferred to SR2200 stain [3% sucrose, 4% diethylene glycol, 4% dimethyl

sulfoxide and 1% SR2200 and stained overnight with vacuum pulled and released 3-4

times. Seeds were mounted (20% glycerol, 0.1×PBS, 0.1% dimethyl sulfoxide, 0.1%

SR2200, and 0.01% Triton X100) and the embryos were liberated by pressing on the

coverslip. To detect mCitrine in the shoot apices, we removed stage 5 and older floral

buds using fine forceps, fixed and rinsed (as with the embryos), soaked in ClearSee

(Kurihara et al. 2015) for seven to ten days changing the solution every two to three

days, and then stained with basic fuchsin (not shown) and Fluorescent Brightener 28

(Calcofluor White M2R) as described (Ursache et al. 2018). Confocal image channels

were merged using ImageJ or FIJI (Schindelin et al. 2012; Schneider et al. 2012).

Cleared embryos were viewed by mounting dissected ovules in a solution containing 2.5

g chloral hydrate dissolved in 1 ml 30% glycerol and viewed with a Nikon E600

microscope.

Fluorescence quantification

In order to infer the amounts of TIR1/AFB protein inside and outside the nucleus,

40× magnification images of epidermal cells in the elongation zone of each TIR1/AFB-

mCitrine lines were captured. Because the nuclei of AFB1-mCitrine-expressing cells are

not apparent, the F_1 of a cross with a plant with a *UBQ10:H2B-mTurquoise2* transgene

was used to delineate the nucleus. Using FIJI (Schindelin et al. 2012), regions of

interests including the entire cell (cell, based on propidium iodide staining), the nucleus

(nuc, based on mCitrine or mTurquoise2 signal), and a cell-sized region outside the root

(bg, background) were drawn using the freehand selections tool, and the area and

mean gray values were measured for the mCitrine channel for each. The percent

nuclear was calculated using the equation $\%_{nuc} = [Area_{nuc} \times (Mean_{nuc} - Mean_{bg})] \div$

$[Area_{cell} \times (Mean_{cell} - Mean_{bg})]$.

Phenotype comparisons

The viable *tir1afb* lines were divided based on whether they contained the *tir1*

mutation, and the two batches were grown sequentially. The *afb123* line included in the

initial batch displayed a long-hypocotyl phenotype that may have been picked up after

an earlier cross to the *afb4-2* mutant, so a third batch was made up of alternative

isolates for five lines whose pedigrees included a cross to *afb4-2*. Each batch included

Col-0 and *tir1-1*. Seeds were surfaced sterilized, stratified in water for five days, spotted

onto ½ MS medium containing 1% sucrose, and incubated in a light chamber (22°C).

Twelve five-day-old seedlings for each genotype were transferred to 120 mm square

plates containing the same medium containing either 0, 20, or 100 nM IAA (batch a), 0,

100, or 500 nM IAA (batch b), or 0, 20, 100, or 500 nM IAA (batch c). Each plate

received six seedlings from six genotypes spread out over two rows. Seedlings for each

genotype were present on the top row of one plate and the lower row on a second plate

placed in a different part of the growth chamber after marking the position of the root

tips with a marker and scanning with Epson V600 flatbed scanners. The plates were

scanned again after 72 hours (96 hours for batch c), and the growth was measured

using imageJ. The plates containing 100 nM IAA were grown for a fourth day before the

numbers of lateral roots protruding through the epidermis were counted using a

dissecting microscope. Five seedlings from the no-IAA control plates were transferred to

soil in 6cm pots and grown an additional 34 days. The genotypes for two plants per line

were confirmed by PCR. For each 42-day-old plant, the height from the rosette to the tip

of the longest inflorescence and the maximum rosette diameter were measured, and the

numbers of branches of at least 1 cm were counted. The IAA effects on root elongation

data is presented as the percent relative to the growth without IAA ± the relative

standard error of the ratio. For the gene effect analyses, the averages from each batch

were normalized using measurements for Col-0 and *tir1-1* plants that were included with

each batch.

Time lapse imaging of root growth

Seeds were sown on ½ Murashige and Skoog medium containing 1% sucrose

and 0.8% agar and stratified for 2-3 days at 4°C. Approximately fifteen 5-day-old

seedlings were transferred to culture chambers (Lab-Tek, Chambers #1.0 Borosilicate

Coverglass System, catalog number: 155361) containing the same agar medium

supplemented with DMSO or IAA 10 nM (stock solution at 10 µM in DMSO). The

transfer of seedlings was completed within 45-60 seconds. Images were acquired every

25 seconds for 20 minutes representing 50 images per root using Keyence microscope

model BZ-X810 with 4× lens.

Images obtained for one field were stacked and cropped to the region of interest

(ROI). An auto threshold using the method "Default" was applied. In addition, the

"erode", "despeckle" and "Remove outliers" (radius 10, threshold 50) functions were

used to smooth the image and remove the remaining background. Each root tip was

selected and the "Feret Distance" within the ROI (which corresponds to the longest

distance in an object) was determined for each root. Image processing was automated

with an ImageJ macro, Supplementary File 6. For each time point the "Feret Distance"

root growth was calculated by subtracting the initial "Feret Distance". The values

obtained were used to generate graphs. For each genotype, the experiment was

repeated three independent times.

To determine the effect of auxin on root growth throughout the experiment, the

area under each curve of auxin-treated roots was determined and divided by the

corresponding value for roots grown on DMSO condition to calculate the root growth

response to IAA. A response value of 1 indicates that IAA had no effect on root growth.

The effect of IAA on root growth was determined this way to account for differences in

root growth between genotypes on DMSO.

Each sample was subjected to four different normality tests (Jarque-Bera,

Lilliefors, Anderson-Darling and Shapiro-Wilk). Samples were considered as a Gaussian

distribution when at least one test was significant (p = 0.05). As a normal distribution

was observed a one-way ANOVA coupled with a post hoc Tukey Honestly Significant

Difference test was performed (p = 0.05).

Hypocotyl segment elongation assay

Measurements of etiolated hypocotyl elongation were carried out essentially as

described previously (Fendrych et al. 2016; Li et al. 2018). Seeds were sterilized and

stratified for four (set 1) or five (set 2) days before plating. After 6 hours of light

treatment, the plates were wrapped in aluminum foil and sealed in a cardboard box for

66 hours. The plates were opened in a room lit only with an LED desk lamp with six

layers of green cello film (Hygloss Products) filtering the light. Using a dissecting

microscope with its light source filtered with six sheets of green cello film, the roots and

cotyledons were excised using razor blades and the hypocotyls transferred to plates

containing depletion medium (DM: 10 mM KCl, 1 mM MES pH 6, 1.5% phytagel)

overlain with a piece of cellophane (PaperMart.com). After 30 to 80 minutes on DM, the

hypocotyl segments were transferred to treatment plates (DM plus either 5 µM NAA or

the equivalent amount of solvent (0.025% ethanol). Eight to sixteen hypocotyls were

transferred for each genotype and treatment except for there being only five control-

treated *tir1afb23*. Using Epson V600 flat-bed scanners, the plates were scanned at

1200 dpi 30-60 seconds after transfer then every ten minutes for three hours. The

segments were measured using a FIJI macro that applied "Auto Threshold" (Default),

"Despeckle," "Remove Outliers" (radius=2 threshold=50 which=Bright), then returned

the "Feret Distance" for each. For each segment at each time point, the Feret distance

was subtracted from the initial Feret distance. The lengths were converted to µm using

the conversion 21.16667 µm/pixel. In the second experiment, Col-0 hypocotyls were

dissected first and a second batch was dissected after the other genotypes to test

whether the length of time on DM affected the assay. Measurements for the two

batches were only different at the 20 minute time point ($p < 0.05$ in two-tailed *t*-test).

Gravitropism assay

In the experiments corresponding to Figure 7, six-day-old seedlings were

positioned on four 120 mm square plates such that four seedlings of each genotype

were in different positions in the four plates to reduce position effects. The plates were

placed in the growth chamber vertically for an hour, scanned with an Epson V600 flat-

bed scanners, then returned to the chamber vertically but rotated 90° from the original

orientation. Plates were re-scanned every 30 minutes for 8 hours. For each root tip at

each time point, the angle was measured in FIJI by drawing a line drawn from the

medial point two-root-widths from the root tip to the root tip. These angles were

corrected for scan-to-scan differences in plate orientation by measuring the angle of a

horizontal line on the plate in each image. The mean changes in root-tip angle from that

at time zero ± S.E.M. for each genotype at each timepoint was plotted. The experiments

corresponding to Figure 7—figure supplement 1 were carried out in the same manner

except that each plate contained a single genotype, and the seedlings were not

repositioned onto different plates prior to rotation and scanning.

Research Scholarship. RB was supported by BBSRC Discovery and Future Food

Beacon Nottingham Research Fellowships.

 FIGURES AND TABLES

Figure 1. *tir1/afb* mutant lines exhibit a range of shoot phenotypes. (**A**) The viable

quintuple mutants, *tir1afb1245, tir1afb1345*, and *afb12345,* are each approximately half

the height of Col-0 WT, but differ in other phenotypes. Note the curved silique tips of the

tir1afb1245 mutant (indicative of gynoecium defects) and the short siliques (due to poor

fertility) of the *afb12345* mutant. (**B**) Lines with only one *TIR1+* or one *AFB2+* allele

display similar phenotypes regardless of the mutant *tir1* and *afb2* alleles: left to right,

tir1-1/+ afb2-3 afb1345, *tir1-1 afb2-3/+ afb1345*, *tir1-10/+ afb2-1 afb1345*, and *tir1-10*

afb2-1/+ afb1345. (**C**) Normal siliques (Col-0, left) have two valves containing

developing seeds while 32% of *tir1afb1245* siliques have only one. The adaxial half of

the valve walls were removed to reveal the developing seeds. Scale bars are 1 mm.

Plants were grown for 42 days at 22°C and 16h daylength.

Figure 2. Relative *TIR1/AFB* gene effects. For each of the five phenotype

measurements (Figure 1—figure supplement 4), the normalized mean for each

genotype with the given mutation was subtracted from the normalized mean for the

corresponding genotype lacking that mutation and plotted (circles). The red bars

indicate the median difference attributable to the given mutation. (**A**) Effects of each

mutation on IAA-inhibition of root elongation. For each genotype, twelve five-day-old

seedlings were transferred and grown for three days on media containing 100 nM IAA,

and their average growth was divided by that of twelve seedlings grown on media

lacking added auxin. (**B**) Effects of each mutation on auxin-induced lateral root

production. Twelve five-day-old seedlings for each genotype were grown for four days

on media containing 100 nM IAA and the numbers of emerged lateral roots were

counted. (**C**) Effects of each mutation on the average rosette diameters of five 42-day

old plants. The blue arrowheads indicate difference in phenotypes between the *afb2345*

quadruple mutant and the four triple mutants, and the green arrowheads indicate those

for the *afb12345* quintuple mutant and the five quadruple mutants. (**D**) Effects of each

mutation on the average height of the primary inflorescences for five 42-day old plants.

(**E**) Effects of each mutation on the average number of inflorescence branches (≥1 cm)

on five 42-day old plants.

Figure 3. Embryo-lethal phenotypes of *tir1/afb* mutant lines. Rows of panels alternate

between defective and normal embryos. Approximately one-quarter of the chloral-

hydrate-cleared embryos from siliques of *afb2/+ tir1afb35* plants did not produce

cotyledon primordia and have over-proliferated suspensors (**A**) while the remaining

siblings from the same silique appear normal (**A'**). Embryos from *TIR1/AFB5/AFB2/+*

tir1afb12345 plants were fixed, stained with SR2200 (cell walls, magenta), and scanned

for fluorescence from the AFB2-mCitrine fusion protein (yellow). All were progeny of

"d2" transgenic line and the standard alleles except panels **C** and **D** contained the *tir1-*

10 and *afb2-1* alleles and panels **H'** and **I** were progeny of plants with the "d1"

transgenic line. The embryos in panels **B**–**M** are sextuple mutants lacking mCitrine

signal while those in **B'**–**M'** are complemented siblings. The embryo stages are 2-cell

(**B**–**C**, **B'**–**C'**), 8-cell (octant; **D**, **D'**), 16-cell (dermatogen; **E**, **E'**), early globular (**F**, **F'**),

late globular (**G**–**H**, **G'**–**H'**), late transition (**I**, **I'**), heart (**J**, **J'**), torpedo (**K**–**L**, **K'**–**L'**), and

bent cotyledon (**M**, **M'**). The yellow cytoplasmic signal in panels **I** through **M** likely

represents autofluorescence of senescing cells. (**N**) Histogram of the angles of the first

division plane with 0° defined as perpendicular to a line connecting the upper corners of

the hypophysis cell for sextuple (black) and complemented siblings (white). The

average difference was not significantly different (p = 0.32 from t-test, n = 19 and 64).

(**O**) Histogram of the angles of lines connecting the upper and lower tiers of octant

embryos from side to center to side (indicated by arrowheads in panels **D**, **D′**). The

means for the sextuple and complemented siblings were 149.1° and 169.1°,

respectively, and were significantly different (p = 1.4×10^{-7} from t-test, n = 29 and 84). (**P**)

Bar graph showing the frequencies of normal (periclinal) and aberrant (anticlinal,

arrowheads in panel **E**) divisions in 16-cell embryos. While aberrant divisions were

observed in complemented siblings, they were significantly more frequent in sextuple

mutants (p = 2.8×10^{-54} from Fisher's exact test, n = 94 and 437 divisions).

Figure 4. Marker gene expression in the *tir1afb235* embryos. Fluorescence in embryos

from both *afb2/+ tir1afb35 DR5rev:3×Venus-N7* (**A**–**C, E**–**G**) and *afb2/+ tir1afb35*

WOX5:GFP$_{ER}$ (**D**, **H**) markers was present in phenotypically normal siblings (**A**–**D**) but

absent in abnormal (presumed *tir1afb235*) embryos (**E**–**H**). Fluorescence in embryos

from *tir1/+afb235 PIN1-Venus* plants: normal-phenotype globular embryo (**I**), normal-

phenotype torpedo-stage embryo (**J**), mutant-phenotype globular embryo (**M**) and later-

stage embryo (**N**). Progeny of *tir1/+ afb235 PIN7-Venus* or *afb2/+ tir1afb35 PIN7-GFP*

plants: phenotypically normal globular embryos (**K**, **Q**) mutant globular embryos (**O**, **U**),

and normal (**L**) and mutant (**P**) torpedo-stage embryos. Progeny of *afb2/+ tir1afb35*

NTT-YPet plants: normal-phenotype globular- (**R**–**S**) and transition- (**T**) stage embryos,

and mutant embryos (**V**–**X**). Scale bars: 10 µm.

Figure 5. Expression of *TIR1/AFB-mCitrine* translational fusions. (**A**–**F**) Confocal

images of inflorescence apices from 4-week-old plants containing the specified

TIR1/AFB-mCitrine transgenes. (**G**–**R**) Confocal images of roots of 5-day-old seedlings

under lower magnification (**G**–**L**) or 7-day-old seedlings under higher magnification (**M**–

R). Images in panels **G** and **I**–**L** used similar microscope settings while those in panel **H**

used less sensitive settings. (**S**) Plot comparing the relative proportions of mCitrine

signal inside the nucleus (gray) and outside the nucleus (white). Cells were imaged and

measured for each TIR1/AFB-mCitrine line, and the averages ± standard deviations are

shown. For AFB1-mCitrine, F1 hybrids with the *UBQ10:H2B-mTurquoise2* nuclear

marker were used so that the nuclei could be delineated (Figure 5—figure supplement

3). The numbers in the bars indicate the number of cells measured and the letters

distinguish significantly different averages (two-tailed *t*-test $p < 0.05$). (**T**–**Y**) Confocal

images of dermatogen or early globular embryos. mCitrine signal is shown as yellow in

all panels, and cell walls were stained with Calcofluor White M2R (blue; **A**–**F**), propidium

iodide (magenta; **G**–**R**), and SCRI Renaissance 2200 (blue; **T**–**Y**). In panels M–R,

mCitrine fluorescence is shown with and without merging with the propidium iodide stain

image. Transgenic lines and genetic backgrounds used: (**A**, **G**, **M, S**, **T**) *tir1-10 TIR1-*

mCitrine#2; (**B**, **H**, **N**, **S**, **U**) *afb1-3 AFB1-mCitrine#7*; (**C**, **O**, **V**) *afb2-3 AFB2-mCitrine#3*;

(**I**, **S**) *afb2-3 AFB2-mCitrine#5*; (**D**, **J**, **P**, **S**, **W**) *afb3-4 AFB3-mCitrine#1*; (**E**, **K**, **Q**, **S**, **X**)

afb4-8 AFB4-mCitrine#3; (**F**, **L**, **Y**) *afb5-5 AFB5-mCitrine#19* and (**R**, **S**) *afb5-5 AFB5-*

mCitrine#23. Scale bars equal 25 µm (**A**–**F**), 50 µm (**G**–**L**), and 10 µm (**M**–**R**, **T**–**Y**).

Figure 6. The role of *AFB1* in rapid inhibition of root elongation. (**A**) Plot of the root

growth response of different genotypes to 10 nM IAA for 20 minutes. Black circles

represent the response for one single root. Red crosses indicate the mean. Black bars

indicate median. n indicates the number of roots obtained from three independent

experiments. Letters indicate statistical differences according to one-way ANOVA

coupled with post hoc Tukey honestly significant difference (HSD) test ($p = 0.05$). (**B**)

Graph of the root length in µm according to time in seconds of WT and *afb1* in DMSO

and 10 nM IAA treatments (blue, gray, orange and yellow lines, respectively). Bars

indicates standard deviation of the mean (SEM). n indicates the number of roots

obtained from three independent experiments.

Figure 7. Gravitropic response of *tir1/afb* lines. Sixteen seedlings for each line were

imaged every 30 minutes after rotating the plates 90° and the mean difference in the

root-tip angle from the original angle ± SEM are plotted versus time. Col-0 and *afb1-3*

are included in all panels for comparison. Time points at which lines differed from Col-0

are indicated by degree symbols (°) and differences between lines with and without the

afb1 mutation are indicated by asterisks (*) of the colors shown in the legend (*t*-test, $p <$

0.05). Colors: black, Col-0; red, *afb1-3*; blue, *tir1afb345*; purple, *tir1afb1345*; cyan, *tir1-*

1; lavender, *tir1-1 afb1-3*; light green, *afb1-3 AFB1-mCitrine#5*; and dark green, *afb1-3*

AFB1-mCitrine#7.

Figure 8. (Or Graphical Abstract) Summary of each *TIR1/AFB* gene's contributions to

different responses. The line weights reflect the relative importance for each gene's

roles. The blue lines represent contributions to the rapid IAA-mediated inhibition of root

elongation and the red line with the bar end indicates the antagonistic role observed for

AFB1 in lateral root production**.**

Figure 1—figure supplement 1. TIR1/AFB Phylogeny. (**A**) The MrBayes-inferred gene

tree illustrates the relationships between three F-Box-LRR protein families in land

plants. The sources of the sequences are indicated by tip label colors: *Arabidopsis*

thaliana, black; other eudicots, gray; monocots, light blue; magnoliids, dark blue; ANITA

grade angiosperms, dark purple; gymnosperms, brown; ferns, red; lycophytes, light

purple; mosses, dark green; liverworts, teal; hornworts, tan; and algae, light green. The

branches leading to the At-α and At-β WGDs are indicated by red and blue dots,

respectively. Three clades of TIR1/AFB proteins have well-supported fern sister clades

indicating that first gene duplications in the family predated euphyllophyte radiation.

Note that the position of the lycophyte TIR1/AFBs relative to those of bryophytes and

seed plants was not resolved. (**B**) The graph shows the sum of branch lengths (amino-

acid substitutions per site) from the node joining the Cleomaceae and Brassicaceae

clades to the tip for the Arabidopsis member of the clade. (**C**) Gene tree for the TIR1

and AFB1 clades with the parsimoniously inferred relative dates for the appearance of

the three substitutions in the first helix of the F-Box that were shown to interfere with

SCF assembly. The *Salvadora AFB1* transcript assembly lacked the sequence

encoding this helix so that ancestor's sequence could not be predicted.

Figure 1—figure supplement 2. Alternate *tir1/afb* alleles. **A**, Diagram of exon/intron

structure showing the locations of each mutation used in this study. T-DNA insertions

are shown as triangles with the arrowheads indicating the locations of left-border

sequences. The box in the third exons indicates the regions targeted by miR393. **B**,

Root elongation inhibition assay of seedlings homozygous or heterozygous (F_1 progeny

of Col-0 crosses) for three *tir1* alleles. Sample sizes were 20-31 per treatment. Two-

tailed *t*-test *p* values: *, ≤0.05 and **, ≤0.005 compared to Col-0; °, ≤0.05 and °°, ≤0.005

compared to *tir1-10*; and †, ≤0.05; ††, ≤0.005 compared to *tir1-10*/+. The *tir1-9* allele

(Ws-2 background) was backcrossed twice to Col-0 and an additional time for *tir1-9/+*.

C, 32-day old Col-0, *afb2-3 afb1345*, and *afb2-1 afb1345* plants. **D**, 42-day old Col-0,

tir1-1 afb1345, and *tir1-10 afb1345* plants.

Figure 1—figure supplement 3. Summary of phenotypes for mutant combinations. For

the quantitative traits (Figure 1—figure supplement 4), the ranges for each of the

phenotypes were divided into five bins, from "–" to "++++" in increasing severity. NA,

Not applicable (due to embryo or seedling lethality); ND, not determined. The "%

Rootless Embryo" column reflects the percent of rootless and inviable seedlings from

plants grown at 20°C except where noted. The % Siliques Missing Valves column

reflects those missing more than one-third of a valve (n = 53 to 81).

Figure 1—figure supplement 4. Shoot and root phenotypes of *tir1/afb* mutants. The

seedlings/plants were grown in three batches (separated by dashed lines). Average

inflorescence height (**A**) and rosette diameter (**B**) of 42-day-old plants of the given

genotypes. (**C**) Average numbers of inflorescence branches (≥ 1 cm) with the shades of

gray distinguishing branches from primary, secondary, and tertiary inflorescences. In

panels **A**–**C**, $n = 5$ plants each except for *afb2*, *tir1afb245*, and Col-0 (batch C) for which

$n = 4$**.** (**D**) Average numbers of emerged lateral roots after five days on media lacking

IAA then four days on media containing 100 nM IAA (n = 10-24 seedlings). (**E**) Inhibition

of root elongation assays. Seedlings were grown for five days on media lacking IAA

then transferred to media containing 20 nM, 100 nM, 500 nM IAA, or DMSO-only control

and grown for three days. Growth during the three days on media containing IAA is

expressed as a percentage of the growth of the same genotype on control plates (n = 7-

24 seedlings for each treatment). The lines with an asterisk included a cross to an *afb4-*

2 containing line in their pedigrees, and alternate lines never exposed to the TILLING

background were included in the third batch for five of the six such lines. The *afb123*

line included in the first batch—and none of the others—exhibited a long-hypocotyl

phenotype presumably acquired from the *afb4-2* line so it was excluded. The error bars

indicate standard error of the mean (**A**–**D**) or the relative standard error of the ratio (**E**).

Figure 1—figure supplement 5. Embryonic root formation in *tir1/afb* mutants. **A**,

representative seedlings of *tir1afb23* mutants with and without roots. **B**, four *tir1afb1245*

seedlings with (left) and without roots (three on right), **C**, four rootless *tir1afb234*

mutants. **D**, graph showing the percent of seedlings of different genotypes lacking roots

(dark gray) or not germinating (light gray). The temperatures indicate the conditions in

which the parents were grown, Percival growth chambers set to 17°C or 20°C or an

environmental room with temperatures between 22°C and 23°C. For *tir1afb234* and

tir1afb1234, adventitious roots needed to be induced with a 3-day treatment on 10 µM

NAA before transplanting to soil and growing for seed collection in a different Percival

chamber set to 22°C. Error bars indicate standard error of the mean for progeny of four

different parents of the given genotype/temperature combination. For the Fisher's exact

tests, all four families' tallies were combined, from 142–255 seeds per

genotype/condition were tested. *, Different from 20°C for the same genotype using

Fisher's exact test, $p < 0.001$. †, Different from *tir1afb23* using Fisher's exact test, $p <$

0.01.

1014

Figure 3—figure supplement 1. Transgene complementing the *tir1afb12345* sextuple

mutant. **A**, diagram of the Transfer-DNA region of pMP1855 containing genomic regions

of *TIR1*, *AFB5*, and *AFB2* fused to *mOrange2*, *mCherry*, and *mCitrine*, respectively.

BAR, Basta- (phosphinothricin-) resistance gene flanked by the *Agrobacterium nopaline*

synthase promoter and terminator. **B**–**D**, confocal images of a globular-stage embryo

from a *TIR1/AFB5/AFB2 #d2/d2* plant detecting mOrange2 (**B**), mCherry, (**C**), and

mCitrine (**D**). **E**–**F**, phenotypes of a 32-day-old WT Col-0 plant and a *tir1afb12345* plant

hemizygous for the *TIR1/AFB5/AFB2 #d2* transgene of the same age.

1023

Figure 3—figure supplement 2. Appearance of autofluorescence in sextuple mutant

embryos. Torpedo-stage transgene-complemented sextuple mutant (**A**) and sextuple

mutants equivalent to between early torpedo to bent-cotyledon stages (**B**–**D**) were

imaged using similar microscope settings for SR2200 stain (blue), mCitrine (yellow),

mOrange2 (orange), and mCherry (red). In the mutants, autofluorescence appears in all

three fluorescent protein channels in the same patterns albeit much less intensely in the

YFP channel. The settings for YFP were much less sensitive than the others because

AFB2-mCitrine was much brighter than TIR1-mOrange2 and AFB5-mCherry (likely due

to dimmer fluorescent proteins with much slower maturation rates as well as lower

expression levels). Scale bars are 10 µm.

1034

1035   **Figure 3—figure supplement 3.** Plants of the given genotype were used in crosses to

1036   wild type (Col-0) as either the pollen donor (♂) or the recipient (♀). The progeny were

1037   sprayed with herbicide to identify F_1 progeny inheriting the transgene. The Chi-squared

1038   tests compared the observed numbers of sextuple and complemented-sextuple

1039   gametophytes to the expected 1:1 ratio.

1040

Figure 5—figure supplement 1. (**A**) Comparison of 42-day old Col-0, *tir1afb23*, *afb23*,

and *tir1afb23 TIR1-mCitrine#2* plants. (**B**) Comparison of 42-day old Col-0, *tir1afb1245*,

tir1afb145, and *tir1afb1245 AFB2-mCitrine#5* plant phenotypes. (**C**) Comparison of 42-

day old Col-0, *tir1afb23*, *tir1afb2*, and *tir1afb23 AFB3-mCitrine#1* plant phenotypes.

Each of the transgenes complements the silique and inflorescence height phenotypes.

measured for seedlings grown on media containing 20 µM picloram, expressed as a

percentage of elongation on media lacking picloram. Lines *AFB4-mCitrine#3* and *AFB4-*

tdTomato#16 are more sensitive to picloram than WT indicating that the transgene is

likely expressed at higher levels than the endogenous *AFB4* locus. Sample sizes were

15-16 per line per treatment. Error bars show the SE of the ratio. Letters at top

distinguish lines with different responses to picloram (*t*-test, $p < 0.05$).

1053

Figure 5—figure supplement 2. Comparison of *TIR1/AFB-mCitrine* lines. Roots of 5-

day-old seedlings for two different lines are shown with a merged image of propidium

iodide (magenta) and the fluorescent signal of mCitrine (yellow) or mEGFP (green) on

the left and fluorescent signal alone on the right. **A**, *TIR1-mCitrine#2*; **B**, *TIR1-*

mCitrine#4; **C**, *AFB1-mCitrine#7*; **D**, *AFB1-mCitrine #5*; **E**, *AFB2-mCitrine#5*; **F**, *AFB2-*

mCitrine#3; **G**, *AFB3-mCitrine#1*; **H**, *AFB3-mEGFP#2*; **I**, *AFB4-mCitrine#1*; **J**, *AFB4-*

mCitrine#3; **K**, *AFB5-mCitrine#23*; and **L**, *AFB5-mCitrine#9.* The first line for each gene

is the same as shown in Figure 5 panels G–L. The numbers in the lower left corner

indicate similar microscope settings from 1 (least sensitive) to 4 (most sensitive). Scale

bars equal 25 μm.

1064

Figure 5—figure supplement 3. AFB1-mCitrine expression is unchanged in F_1 hybrids

used for signal quantification. Images of root epidermal cells in the elongation zone from

7-day-old seedlings are shown for the fluorescent signal of AFB1-mCitrine (yellow),

propidium iodide (magenta) and mTurquoise2 (cyan), and a merged image. In panel **C**,

the mTurquoise2 signal is included in cyan. **A**, *afb1-3 AFB1-mCitrine#7 × UBQ10:H2B-*

2×mTurquoise2 F_1 and **B**, *afb1-3 AFB1-mCitrine#7*. Scale bars equal 10 μm.

1071

Figure 6—figure supplement 1. Time courses of root elongation. Graph of the root

length in µm versus time in seconds with DMSO and 10 nM IAA treatments (blue and

orange lines, respectively) in wild type (a), *afb1* (b), *tir1afb1* (c), *tir1afb12* (d), *tir1afb13*

(e), *tir1afb135* (f), *tir1afb134* (g), *tir1afb1245* (h), *tir1afb1345* (i), *afb1 AFB1-mCitrine#7*

(j), *tir1* (k), *afb23* (l), *afb45* (m), *tir1afb2* (n), *tir1afb3* (o), *tir1afb23* (p), *tir1afb345* (q).

Bars indicate standard deviation of the mean (SEM). Blue region indicates no

differences between the length of treated and non-treated conditions while pale orange

indicates significant difference according to two ways *t*-test ($p = 0.05$). n indicates the

number of roots imaged in three independent experiments.

1081

1082 **Figure 6—figure supplement 2**. Movie of wild type root tip with mock (DMSO, left

1083 panel) and 10 nM IAA (right panel) treatments. Images were acquired every 25 seconds

1084 for 20 minutes. Scale bar 100 µm.

1085

1086 **Figure 6—figure supplement 3**. Movie of *afb1-3* root tip with mock (DMSO, left panel)

1087 and 10 nM IAA (right panel) treatments. Images were acquired every 25 seconds for 20

1088 minutes. Scale bar 100 µm.

1089

Figure 6—figure supplement 4. Graphs showing changes in length of hypocotyl

segments treated with 5 µM NAA or 0.025% ethanol (Controls) for three hours. The

genotypes shown on the right correspond to the nearest curve with NAA treatment at

the 180 minute timepoint. The curves for the control treatment are not labeled. Error

bars show standard error of the mean. For pairwise *t*-test *p* values for each treated

genotype at each time point, see Supplemental File 5. The experiments shown in

panels **A** and **B** were done on different days.

1097

Figure 7—figure supplement 1. Gravitropic response of *tir1/afb* lines, repeat

experiment. Seedlings for each line were imaged every 30 minutes after rotating the

plates 90° and the mean difference in the root-tip angle from the original angle ± SEM

are plotted versus time. Col-0 and *afb1-3* are included in all panels for comparison.

Time points at which lines differed from Col-0 are indicated by degree symbols (°) and

differences between lines with and without the *afb1* mutation are indicated by asterisks

(*) of the colors shown in the legend (*t*-test, $p < 0.05$). Colors (sample size): black, Col-0

(33); red, *afb1-3* (24); blue, *tir1afb345* (42); purple, *tir1afb1345* (41); cyan, *tir1-1* (39);

lavender, *tir1-1 afb1-3* (40); light green, *afb1-3 AFB1-mCitrine#5* (39); and dark green,

afb1-3 AFB1-mCitrine#7 (41).

Figure 1. *tir1/afb* mutant lines exhibit a range of shoot phenotypes. (**A**) The viable quintuple mutants, *tir1afb1245,* *tir1afb1345*, and *afb12345,* are each approximately half the height of Col-0 WT, but differ in other phenotypes. Note the curved silique tips of the *tir1afb1245* mutant (indicative of gynoecium defects) and the short siliques (due to poor fertility) of the *afb12345* mutant. (**B**) Lines with only one *TIR1+* or one *AFB2+* allele display similar phenotypes regardless of the mutant *tir1* and *afb2* alleles: left to right, *tir1-1/+ afb2-3 afb1345*, *tir1-1 afb2-3/+ afb1345*, *tir1-10/+ afb2-1 afb1345*, and *tir1-10 afb2-1/+ afb1345*. (**C**) Normal siliques (Col-0, left) have two valves containing developing seeds while 32% of *tir1afb1245* siliques have only one. The adaxial half of the valve walls were removed to reveal the developing seeds. Scale bars are 1 mm. Plants were grown for 42 days at 22°C and 16h daylength.

Figure 2. Relative *TIR1/AFB* gene effects. For each of the five phenotype measurements (Figure 1—figure supplement 4), the normalized mean for each genotype with the given mutation was subtracted from the normalized mean for the corresponding genotype lacking that mutation and plotted (circles). The red bars indicate the median difference attributable to the given mutation. (**A**) Effects of each mutation on IAA-inhibition of root elongation. For each genotype, twelve five-day-old seedlings were transferred and grown for three days on media containing 100 nM IAA, and their average growth was divided by that of twelve seedlings grown on media lacking added auxin. (**B**) Effects of each mutation on auxin-induced lateral root production. Twelve five-day-old seedlings for each genotype were grown for four days on media containing 100 nM IAA and the numbers of emerged lateral roots were counted. (**C**) Effects of each mutation on the average rosette diameters of five 42-day old plants. The blue arrowheads indicate difference in phenotypes between the *afb2345* quadruple mutant and the four triple mutants, and the green arrowheads indicate those for the *afb12345* quintuple mutant and the five quadruple mutants. (**D**) Effects of each mutation on the average height of the primary inflorescences for five 42-day old plants. (**E**) Effects of each mutation on the average number of inflorescence branches (≥1 cm) on five 42-day old plants.

Figure 3. Embryo-lethal phenotypes of *tir1/ afb* mutant lines. Rows of panels alternate between defective and normal embryos. Approximately one-quarter of the chloral-hydrate-cleared embryos from siliques of *afb2/+ tir1afb35* plants did not produce cotyledon primordia and have over-proliferated suspensors (**A**) while the remaining siblings from the same silique appear normal (**A′**). Embryos from *TIR1/ AFB5/AFB2/+ tir1afb12345* plants were fixed, stained with SR2200 (cell walls, magenta), and scanned for fluorescence from the AFB2-mCitrine fusion protein (yellow). All were progeny of "d2" transgenic line and the standard alleles except panels **C** and **D** contained the *tir1-10* and *afb2-1* alleles and panels **H′** and **I** were progeny of plants with the "d1" transgenic line. The embryos in panels **B**–**M** are sextuple mutants lacking mCitrine signal while those in **B′**–**M′** are complemented siblings. The embryo stages are 2-cell (**B**–**C**, **B′**–**C′**), 8-cell (octant) (**D**, **D′**), 16-cell (dermatogen) (**E**, **E′**), early globular (**F**, **F′**), late globular (**G**–**H**, **G′**–**H′**), late transition (**I**, **I′**), heart (**J**, **J′**), torpedo (**K**–**L**, **K′**–**L′**), and bent cotyledon (**M**, **M′**). The yellow cytoplasmic signal in panels **I** through **M** likely represents autofluorescence of senescing cells. (**N**) Histogram of the angles of the first division plane with 0° defined as perpendicular to a line connecting the upper corners of the hypophysis cell for sextuple (black) and complemented siblings (white). The average difference was not significantly different (*p* = 0.32 from *t* test, *n*=19 and 64). (**O**) Histogram of the angles of lines connecting the upper and lower tiers of octant embryos from side to center to side (indicated by arrowheads in panels **D**, **D′**). The means for the sextuple and complemented siblings were 149.1° and 169.1°, respectively, and were significantly different ($p=1.4\times10^{-7}$ from *t* test, *n*=29 and 84). (**P**) Bar graph showing the frequencies of normal (periclinal) and aberrant (anticlinal, arrowheads in panel **E**) divisions in 16-cell embryos. While aberrant divisions were observed in complemented siblings, they were significantly more frequent in sextuple mutants ($p=2.8\times10^{-54}$ from Fisher's exact test, *n*= 94 and 437 divisions).

Figure 4. Marker gene expression in the *tir1afb235* embryos. Fluorescence in embryos from both *afb2/+ tir1afb35 DR5rev:3×Venus-N7* (**A–C, E–G**) and *afb2/+ tir1afb35 WOX5:GFP_{ER}* (**D, H**) markers was present in phenotypically normal siblings (**A–D**) but absent in abnormal (presumed *tir1afb235*) embryos (**E–H**). Fluorescence in embryos from *tir1/+afb235 PIN1-Venus* plants: normal-phenotype globular embryo (**I**), normal-phenotype torpedo-stage embryo (**J**), mutant-phenotype globular embryo (**M**) and later-stage embryo (**N**). Progeny of *tir1/+ afb235 PIN7-Venus* or *afb2/+ tir1afb35 PIN7-GFP* plants: phenotypically normal globular embryos (**K, Q**) mutant globular embryos (**O, U**), and normal (**L**) and mutant (**P**) torpedo-stage embryos. Progeny of *afb2/+ tir1afb35 NTT-YPet* plants: normal-phenotype globular- (**R–S**) and transition- (**T**) stage embryos, and mutant embryos (**V–X**). Scale bars: 10 µm.

Figure 5. Expression of *TIR1/AFB-mCitrine* translational fusions. (**A–F**) Confocal images of inflorescence apices from 4-week-old plants containing the specified *TIR1/AFB-mCitrine* transgenes. (**G–R**) Confocal images of roots of 5-day-old seedlings under lower magnification (**G–L**) or 7-day-old seedlings under higher magnification (**M–R**). Images in panels **G** and **I–L** used similar microscope settings while those in panel **H** used less sensitive settings. (**S**) Plot comparing the relative proportions of mCitrine signal inside the nucleus (gray) and outside the nucleus (white). Cells were imaged and measured for each TIR1/AFB-mCitrine line, and the averages ± standard deviations are shown. For AFB1-mCitrine, F1 hybrids with the *UBQ10:H2B-mTurquoise2* nuclear marker were used so that the nuclei could be delineated (Figure 5—figure supplement 3). The numbers in the bars indicate the number of cells measured and the letters distinguish significantly different averages (two-tailed *t*-test *p* < 0.05). (**T–Y**) Confocal images of dermatogen or early globular embryos. mCitrine signal is shown as yellow in all panels, and cell walls were stained with Calcofluor White M2R (blue; **A–F**), propidium iodide (magenta; **G–R**), and SCRI Renaissance 2200 (blue; **T–Y**). In panels **M–R**, mCitrine fluorescence is shown with and without merging with the propidium iodide stain image. Transgenic lines and genetic backgrounds used: (**A**, **G**, **M, S, T**) *tir1-10 TIR1-mCitrine#2*; (**B**, **H**, **N**, **S**, **U**) *afb1-3 AFB1-mCitrine#7*; (**C**, **O**, **V**) *afb2-3 AFB2-mCitrine#3*; (**I**, **S**) *afb2-3 AFB2-mCitrine#5*; (**D**, **J**, **P**, **S**, **W**) *afb3-4 AFB3-mCitrine#1*; (**E**, **K**, **Q, S, X**) *afb4-8 AFB4-mCitrine#3*; (**F**, **L**, **Y**) *afb5-5 AFB5-mCitrine#19* and (**R**, **S**) *afb5-5 AFB5-mCitrine#23*. Scale bars equal 25 μm (**A–F**), 50 μm (**G–L**), and 10 μm (**M–R**, **T–Y**).

Figure 6. The role of *AFB1* in rapid inhibition of root elongation. (**A**) Plot of the root growth response of different genotypes to 10 nM IAA for 20 minutes. Black circles represent the response for one single root. Red crosses indicate the mean. Black bars indicate median. n indicates the number of roots obtained from three independent experiments. Letters indicate statistical differences according to one-way ANOVA coupled with post hoc Tukey honestly significant difference (HSD) test (p = 0.05). (**B**) Graph of the root length in µm according to time in seconds of WT and *afb1* in DMSO and 10 nM IAA treatments (blue, gray, orange and yellow lines, respectively). Bars indicates standard deviation of the mean (SEM). n indicates the number of roots obtained from three independent experiments.

Figure 7. Gravitropic response of *tir1/afb* lines. Sixteen seedlings for each line were imaged every 30 minutes after rotating the plates 90° and the mean difference in the root-tip angle from the original angle ± SEM are plotted versus time. Col-0 and *afb1-3* are included in all panels for comparison. Time points at which lines differed from Col-0 are indicated by degree symbols (°) and differences between lines with and without the *afb1* mutation or an *AFB1-mCitrine* transgene are indicated by asterisks (*) of the colors shown in the legend (*t*-test, *p* < 0.05). Colors: black, Col-0; red, *afb1-3*; blue, *tir1afb345*; purple, *tir1afb1345*; cyan, *tir1-1*; lavender, *tir1-1 afb1-3*; light green, *afb1-3 AFB1-mCitrine#5*; and dark green, *afb1-3 AFB1-mCitrine#7*.

Figure 8. (Graphical Abstract) Summary of each *TIR1/AFB* gene's contributions to different responses. The line weights reflect the relative importance for each gene's roles. The blue lines represent contributions to the rapid IAA-mediated inhibition of root elongation and the red line with the bar end indicates the antagonistic role observed for AFB1 in lateral root production.

A

Figure 1—figure supplement 1. TIR1/AFB Phylogeny. (**A**) The MrBayes-inferred gene tree illustrates the relationships between three F-Box-LRR protein families in land plants. The sources of the sequences are indicated by tip label colors: *Arabidopsis thaliana*, black; other eudicots, gray; monocots, light blue; magnoliids, dark blue; ANITA grade angiosperms, dark purple; gymnosperms, brown; ferns, red; lycophytes, light purple; mosses, dark green; liverworts, teal; hornworts, tan; and algae, light green. The branches leading to the At-α and At-β WGDs are indicated by red and blue dots, respectively. Three clades of TIR1/AFB proteins have well-supported fern sister clades indicating that first gene duplications in the family predated euphyllophyte radiation. Note that the position of the lycophyte TIR1/AFBs relative to those of bryophytes and seed plants was not resolved. (**B**) The graph shows the sum of branch lengths (amino-acid substitutions per site) from the node joining the Cleomaceae and Brassicaceae clades to the tip for the Arabidopsis member of the clade. (**C**) Gene tree for the TIR1 and AFB1 clades with the parsimoniously inferred relative dates for the appearance of the three substitutions in the first helix of the F-Box that were shown to interfere with SCF assembly. The *Salvadora AFB1* transcript assembly lacked the sequence encoding this helix so that ancestor's sequence could not be predicted.

Figure 1—figure supplement 2. Alternate *tir1/afb* alleles. **A**, Diagram of exon/intron structure showing the locations of each mutation used in this study. T-DNA insertions are shown as triangles with the arrowheads indicating the locations of left-border sequences. The box in the third exons indicates the regions targeted by miR393. **B**, Root elongation inhibition assay of seedlings homozygous or heterozygous (F$_1$ progeny of Col-0 crosses) for three *tir1* alleles. Sample sizes were 20-31 per treatment. Two-tailed *t*-test *p* values: *, ≤0.05 and **, ≤0.005 compared to Col-0; °, ≤0.05 and °°, ≤0.005 compared to *tir1-10*; and †, ≤0.05; ††, ≤0.005 compared to *tir1-10/+*. The *tir1-9* allele (Ws-2 background) was backcrossed twice to Col-0 and an additional time for *tir1-9/+*. **C**, 32-day old Col-0, *afb2-3 afb1345*, and *afb2-1 afb1345* plants. **D**, 42-day old Col-0, *tir1-1 afb1345*, and *tir1-10 afb1345* plants.

Summary of phenotypes for mutant combinations. For the quantitative traits (Figure 1—figure supplement 4), the ranges for each of the phenotypes were divided into five bins, from "–" to "++++" in increasing severity. NA, Not applicable (embryo or seedling lethal); ND, not determined. The "% Rootless Embryo" column reflects the percent of rootless and inviable seedlings from plants grown at 20°C except where noted. The % Siliques Missing Valves column reflects those missing more than one-third of a valve (*n* = 53 to 81).

Figure 1—figure supplement 4. Shoot and root phenotypes of *tir1/afb* mutants. The seedlings/plants were grown in three batches (separated by dashed lines). Average inflorescence height (**A**) and rosette diameter (**B**) of 42-day-old plants of the given genotypes. (**C**) Average numbers of inflorescence branches (≥ 1 cm) with the shades of gray distinguishing branches from primary, secondary, and tertiary inflorescences. In panels **A–C**, *n*=5 plants each except for for *afb2*, *tir1afb2*45, and Col-0 (batch C) for which *n*=4. (**D**) Average numbers of emerged lateral roots after five days on media lacking IAA then four days on media containing 100 nM IAA (*n*=12 seedlings). (**E**) Inhibition of root elongation assays. Seedlings were grown for five days on media lacking IAA then transferred to media containing 20 nM, 100 nM, 500 nM IAA, or DMSO-only control and grown for three days. Growth during the three days on media containing IAA is expressed as a percentage of the growth of the same genotype on control plates (*n*=12 seedlings for each treatment). The lines with an asterisk included a cross to an *afb4-2* containing line in their pedigrees, and alternate lines never exposed to the TILLING background were included in the third batch for five of the six such lines. The *afb123* line included in the first batch—and none of the others—exhibited a long-hypocotyl phenotype presumably acquired from the *afb4-2* line so it was excluded. The error bars indicate standard error of the mean (**A–D**) or the relative standard error of the ratio (**E**).

Figure 1—figure supplement 5. Embryonic root formation in *tir1/afb* mutants. **A**, representative seedlings of *tir1afb23* mutants with and without roots. **B**, four *tir1afb1245* seedlings with (left) and without roots (three on right), **C**, four rootless *tir1afb234* mutants. **D**, graph showing the percent of seedlings of different genotypes lacking roots (dark gray) or not germinating (light gray). The temperatures indicate the conditions in which the parents were grown, Percival growth chambers set to 17°C or 20°C or an environmental room with temperatures between 22°C and 23°C. For *tir1afb234* and *tir1afb1234*, adventitious roots needed to be induced with a 3-day treatment on 10 µM NAA before transplanting to soil and growing for seed collection in a different Percival chamber set to 22°C. Error bars indicate standard error of the mean for progeny of four different parents of the given genotype/temperature combination. For the Fisher's exact tests, all four families' tallies were combined, from 142–255 seeds per genotype/condition were tested. *, Different from 20°C for the same genotype using Fisher's exact test, $p < 0.001$. †, Different from *tir1afb23* using Fisher's exact test, $p < 0.01$.

Figure 3—figure supplement 1. Transgene complementing the *tir1afb12345* sextuple mutant. **A**, diagram of the Transfer-DNA region of pMP1855 containing genomic regions of *TIR1*, *AFB5*, and *AFB2* fused to *mOrange2*, *mCherry*, and *mCitrine*, respectively. BAR, Basta- (phosphinothricin-) resistance gene flanked by the *Agrobacterium nopaline synthase* promoter and terminator. **B**–**D**, confocal images of a globular-stage embryo from a *TIR1/AFB5/AFB2 #d2/d2* plant detecting mOrange2 (**B**), mCherry, (**C**), and mCitrine (**D**). **E**–**F**, phenotypes of a 32-day-old WT Col-0 plant and a *tir1afb12345* plant hemizygous for the *TIR1/AFB5/AFB2 #d2* transgene of the same age.

Figure 3—figure supplement 2. Appearance of autofluorescence in sextuple mutant embryos. Torpedo-stage transgene-complemented sextuple mutant (**A**) and sextuple mutants equivalent to between early torpedo to bent-cotyledon stages (**B**–**D**) were imaged using similar microscope settings for SR2200 stain (blue), mCitrine (yellow), mOrange2 (orange), and mCherry (red). In the mutants, autofluorescence appears in all three fluorescent protein channels in the same patterns albeit much less intensely in the YFP channel. The settings for YFP were much less sensitive than the others because AFB2-mCitrine was much brighter than TIR1-mOrange2 and AFB5-mCherry (likely due to dimmer fluorescent proteins with much slower maturation rates as well as lower expression levels). Scale bars are 10 µm.

Figure 3—figure supplement 3. Gamete transmission through the megagametophyte and pollen

	Parent	Genotype of gamete				n	χ^2	p
		Complemented	(%)	sextuple	(%)			
TIR1/AFB5/AFB2-d2/+ *tir1-1 afb2-3 afb1345*	♂	107	56%	84	44%	191	2.77	0.1
	♀	54	56%	43	44%	97	1.25	0.26
TIR1/AFB5/AFB2-d2/+ *tir1-10 afb2-1 afb1345*	♂	118	46%	136	54%	254	1.28	0.26
	♀	133	51%	129	49%	262	0.06	0.8
Combined	♂	225	51%	220	49.4%	445	0.06	0.81
	♀	187	52%	172	47.9%	359	0.63	0.43

Plants of the given genotype were used in crosses to wild type (Col-0) as either the pollen donor (♂) or the recipient (♀). The progeny were sprayed with herbicide to identify F1 progeny inheriting the transgene. The Chi-squared tests compared the observed numbers of sextuple and complemented-sextuple gametophytes to the expected 1:1 ratio.

Figure 5—figure supplement 1. (**A**) Comparison of 42-day old Col-0, *tir1afb2*3, *afb2*3, and *tir1afb23 TIR1-mCitrine#2* plants. (**B**) Comparison of 42-day old Col-0, *tir1afb1245*, *tir1afb14*5, and *tir1afb1245 AFB2-mCitrine#5* plant phenotypes. (**C**) Comparison of 42-day old Col-0, *tir1afb2*3, *tir1afb2*, and *tir1afb23 AFB3-mCitrine#1* plant phenotypes. Each of the transgenes complements the silique and inflorescence height phenotypes. D Sensitivities of *AFB*4-expressing transgenic lines to picloram. Root elongation was measured for seedlings grown on media containing 20 μM picloram, expressed as a percentage of elongation on media lacking picloram. Lines *AFB4-mCitrine#3* and *AFB4-tdTomato#16* are more sensitive to picloram than WT indicating that the transgene is likely expressed at higher levels than the endogenous *AFB4* locus. Sample sizes were 15-16 per line per treatment. Error bars show the SE of the ratio. Letters at top distinguish lines with different responses to picloram *(t*-test, *p* < 0.05).

Figure 5—figure supplement 2. Comparison of *TIR1/AFB-mCitrine* lines. Roots of 5-day-old seedlings for two different lines are shown with a merged image of propidium iodide (magenta) and the fluorescent signal of mCitrine (yellow) or mEGFP (green) on the left and fluorescent signal alone on the right. **A**, *TIR1-mCitrine#2*; **B**, *TIR1-mCitrine#4*; **C**, *AFB1-mCitrine#7*; **D**, *AFB1-mCitrine #5*; **E**, *AFB2-mCitrine#5*; **F**, *AFB2-mCitrine#3*; **G**, *AFB3-mCitrine#1*; **H**, *AFB3-mEGFP#2*; **I**, *AFB4-mCitrine#1*; **J**, *AFB4-mCitrine#3*; **K**, *AFB5-mCitrine#23*; and **L**, *AFB5-mCitrine#9*. The first line for each gene is the same as shown in Figure 5 panels G–L. The numbers in the lower left corner indicate similar microscope settings from 1 (least sensitive) to 4 (most sensitive). Scale bars equal 25 µm.

Figure 5—figure supplement 3. AFB1-mCitrine expression is unchanged in F_1 hybrids used for signal quantification. Images of root epidermal cells in the elongation zone from 7-day-old seedlings are shown for the fluorescent signal of AFB1-mCitrine (yellow), propidium iodide (magenta) and mTurquoise2 (cyan), and a merged image. In panel **C**, the mTurquoise2 signal is included in cyan. **A**, *afb1-3 AFB1-mCitrine#7 × UBQ10:H2B-2×mTurquoise2* F_1 and **B**, *afb1-3 AFB1-mCitrine#7*. Scale bars equal 10 µm.

Figure 6—figure supplement 1. Time courses of root elongation. Graph of the root length in μm versus time in seconds with DMSO and 10 nM IAA treatments (blue and orange lines, respectively) in wild type (a), *afb1* (b), *tir1afb1* (c), *tir1afb12* (d), *tir1afb13* (e), *tir1afb135* (f), *tir1afb134* (g), *tir1afb1245* (h), *tir1afb1345* (i), *afb1 AFB1-mCitrine*#7 (j), *tir1* (k), *afb23* (l), *afb45* (m), *tir1afb2* (n), *tir1afb3* (o), *tir1afb23* (p), *tir1afb345* (q). Bars indicate standard deviation of the mean (SEM). Blue region indicates no differences between the length of treated and non-treated conditions while pale orange indicates significant difference according to two ways *t*-test (*p* = 0.05). n indicates the number of roots imaged in three independent experiments.

Figure 6—figure supplement 2. Movie of wild type root tip with mock (DMSO, left panel) and 10 nM IAA (right panel) treatments. Images were acquired every 25 seconds for 20 minutes. Scale bar 100 μm.

Figure 6—figure supplement 3. Movie of *afb1-3* root tip with mock (DMSO, left panel) and 10 nM IAA (right panel) treatments. Images were acquired every 25 seconds for 20 minutes. Scale bar 100 μm.

Figure 6—figure supplement 4. Graphs showing changes in length of hypocotyl segments treated with 5 µM NAA or 0.025% ethanol (Controls) for three hours. The genotypes shown on the right correspond to the nearest curve with NAA treatment at the 180 minute timepoint. The curves for the control treatment are not labeled. Error bars show standard error of the mean. For pairwise *t*-test *p* values for each treated genotype at each time point, see Supplemental File 5. The experiments shown in panels **A** and **B** were done on different days.

Figure 7—figure supplement 1. Gravitropic response of *tir1/afb* lines, repeat experiment. Seedlings for each line were imaged every 30 minutes after rotating the plates 90° and the mean difference in the root-tip angle from the original angle ± SEM are plotted versus time. Col-0 and *afb1-3* are included in all panels for comparison. Time points at which lines differed from Col-0 are indicated by degree symbols (°) and differences between lines with and without the *afb1* mutation or an *AFB1-mCitrine* transgene are indicated by asterisks (*) of the colors shown in the legend (*t*-test, $p < 0.05$). Colors (sample size): black, Col-0 (33); red, *afb1-3* (24); blue, *tir1afb345* (42); purple, *tir1afb1345* (41); cyan, *tir1-1* (39); lavender, *tir1-1 afb1-3* (40); light green, *afb1-3 AFB1-mCitrine#5* (39); and dark green, *afb1-3 AFB1-mCitrine#7* (41).
