Abstract

Background: Neuroimaging studies provide evidence for disrupted resting-state functional brain network activity in bipolar disorder (BD). Electroencephalographic (EEG) studies found altered temporal characteristics of functional EEG microstates during depressive episode within different affective disorders. Here we investigated whether euthymic patients with BD show deviant resting-state large-scale brain network dynamics as reflected by altered temporal characteristics of EEG microstates.
Methods: We used high-density EEG to explore between-group differences in duration, coverage and occurrence of EEG microstates in 17 euthymic adults with BD and 17 age- and gender-matched healthy controls.
Results: Microstate analysis revealed five microstates (A-E) in global clustering across all subjects. In patients compared to controls, we found increased occurrence and coverage of microstate A that did not significantly correlate with anxiety scores.
Conclusion: Our results provide neurophysiological evidence for altered large-scale brain network dynamics in BD patients and suggest the increased presence of A microstate to be an electrophysiological trait characteristic of BD.

1 Introduction

Bipolar disorder (BD) is a common and severe psychiatric disorder, with an important personal and societal burden (Cloutier et al., 2018; Eaton et al., 2012). The prevalence of bipolar disorder worldwide is considered to range between 1% and 3% (Merikangas et al., 2007). BD patients are frequently misdiagnosed and often identified at late stages of disease progression, which can lead to inadequate treatment (Hirschfeld, 2007) and worse functional prognosis (Vieta et al., 2018). A better

understanding of the underlying pathophysiology is needed to identify objective biomarkers of BD that would improve diagnostic and/or treatment stratification of patients.

Potential candidates for neurobiological biomarkers could arise from functional brain network abnormalities in BD patients. Evidence from brain imaging studies consistently points to abnormalities in circuits implicated in emotion regulation and reactivity. Particularly, attenuated frontal and enhanced limbic activations are reported in BD patients (Chen et al., 2011; Houenou et al., 2011; Kupferschmidt and Zakzanis, 2011). Interestingly, regions implicated in the pathophysiology of the disease, such as the inferior frontal gyrus, the medial prefrontal cortex (mPFC), the amygdala present altered activation patterns even in unaffected first-degree relatives of BD patients (Piguet et al., 2015), pointing toward brain alterations that could underlie disease vulnerability. Moreover, evidence from functional magnetic resonance imaging (fMRI) studies showed aberant resting-state functional connectivity between frontal and meso-limbic areas in BD when compared to healthy controls (Vargas et al., 2013). A recently developed functional neuroanatomic model of BD suggests, more specifically, decreased connectivity between ventral prefrontal networks and limbic brain regions including the amygdala (Strakowski et al., 2012; Chase and Philips, 2016). The functional connectivity abnormalities in BD in brain areas associated with emotion processing were shown to vary with mood state. A resting-state functional connectivity study of emotion regulation networks demonstrated that subgenual anterior cingulate cortex (sgACC)-amygdala coupling is critically affected during mood episodes, and that functional connectivity of sgACC plays a pivotal role in mood normalization through its interactions with the ventrolateral PFC and posterior cingulate cortex (Rey et al., 2016). Nevertheless, although different fMRI metrics allowed to report deviant patterns of large-scale networks and altered resting-state functional connectivity (Rey et al., 2016; Wang et al., 2016) in BD, the precise temporal dynamics of the functional brain networks at rest remain to be determined.

Large-scale neural networks dynamically and rapidly re-organize themselves to enable efficient functioning (de Pasquale et al., 2018; Bressler and Menon, 2010). Fast dynamics of the resting-state large-scale neural networks can be studied on sub-second temporal scales with EEG microstate analysis (Pascual-Marqui et al., 1995; Van de Ville et al., 2010; Michel and Koenig, 2018). EEG microstates are defined as short periods (60-120 ms) of quasi-stable electric potential scalp topography (Lehmann et al., 1987; Koenig et al., 2002). Therefore, microstate analysis can cluster the scalp's topographies of the resting-state EEG activity into the set of a few microstate classes including the four canonical classes A-D (Michel and Koenig, 2018) and more recent additional ones (Custo et al., 2017; Bréchet et al., 2019). Since each microstate class topography reflects a coherent neuronal activity (Khanna et al., 2015; Michel and Koenig, 2018), the temporal characteristics, such as duration, occurrence and coverage, may be linked to the expression of spontaneous mental states and be representative of the contents of consciousness (Changeux and Michel, 2004; Lehmann et al., 1990). Numerous studies reported abnormalities in temporal properties of resting-state EEG microstates in neuropsychiatric disorders (for review see Khanna et al., 2015; Michel and Koenig, 2018). Evidence from microstate studies suggests that altered resting-state brain network dynamics may represent a marker of risk to develop neuropsychiatric disorders (Tomescu et al., 2014, 2015; Andreou et al., 2014), may predict clinical variables of an illness (Gschwind et al., 2016), or help to assess the efficacy of a treatment (Atluri et al., 2018; Sverak et al., 2018). Only two studies investigated resting-state EEG in BD patients (Strik et al., 1995; Damborská et al., 2019). These studies examined patients during a depressive episode within different affective disorders. Adaptive segmentation of resting-state EEG showed abnormal microstate topographies and reduced overall average microstate duration in patients that met criteria for unipolar or bipolar mood disorders or for dysthymia (Strik et al., 1995). Using a *k*-means cluster analysis, an increased occurrence of

microstate A with depression as an effect related to the symptom severity was observed during a period of depression in unipolar and bipolar patients (Damborská et al., 2019).

Trait markers of BD based on neurobiological findings can be considered as biomarkers of illness (Piguet et al., 2016). These trait markers of BD can be studied during the periods of remission, or euthymia. No microstate study, however, has been performed on euthymic BD patients to the best of our knowledge. Thus, the main goal of the current study was to explore group differences between euthymic patients with BD and healthy controls in terms of resting-state EEG microstate dynamics. We hypothesized that BD patients during remission will show altered temporal characteristics of EEG microstates such as duration, coverage, and occurrence.

2 Materials and Methods

2.1 Subjects

Data were collected from 17 euthymic adult patients with BD and 17 healthy control (HC) subjects. The patients were recruited from the Mood Disorders Unit at the Geneva University Hospital. A snowball convenience sampling was used for the selection of the BD patients. Control subjects were recruited by general advertisement. All subjects were clinically evaluated using clinical structured interview (DIGS: Diagnostic for Genetic Studies, (Nurnberger et al., 1994). Bipolar disorder was confirmed in the experimental group by the usual assessment of the specialized program, an interview with a psychiatrist, and a semi-structured interview and relevant questionnaires with a psychologist. Exclusion criteria for all participants were a history of head injury, current alcohol or drug abuse. Additionally, a history of psychiatric or neurological illness and of any neurological comorbidity were exclusion criteria for controls and bipolar patients, respectively. Symptoms of mania and depression were evaluated using the Young Mania Rating Scale (YMRS) (Young et al., 1978) and the Montgomery-Åsberg Depression Rating Scale (MADRS) (Williams and Kobak, 2008), respectively. Participants were considered euthymic if they scored < 6 on YMRS and < 12 on MADRS at the time of the experiment, and were stable for at least 4 weeks before. All patients were medicated, receiving pharmacological therapy including antipsychotics, antidepressants and mood stabilizers, and had to be under stable medication for at least 4 weeks. The experimental group included both BD I (n = 10) and BD II (n = 7) types. Results of an event-related EEG study that was conducted on a sample partially overlapping with the current dataset showed that these patients present a dysfunctional gaze processing, results that were reported elsewhere (Berchio et al., 2017).
To check for possible demographic or clinical differences between groups, subject characteristics such as age, education or level of depression were compared between groups using independent t-tests. Anxiety is highly associated with bipolar disorder (Simon et al., 2004; 2007) and is a potential confounding variable when investigating microstate dynamics at rest. For example, decreased duration of EEG microstates at rest in patients with panic disorder has been reported (Wiedemann et al., 1998). To check for possible differences in anxiety symptoms, all subjects were assessed with the State-trait Anxiety Inventory (STAI) (Spielberger et al., 1970) and the scores were compared between patients and controls using independent t-tests.
This study was carried out in accordance with the recommendations of the Ethics Committee for Human Research of the Geneva University Hospital, with written informed consent from all subjects. All subjects gave written informed consent in accordance with the Declaration of Helsinki. The protocol was approved by the Ethics Committee for Human Research of the Geneva University Hospital, Switzerland.

2.2 EEG recording and pre-processing

The EEG was recorded with a high density 256-channel system (EGI System 200; Electrical Geodesic Inc., OR, USA), sampling rate of 1kHz, and Cz as acquisition reference. Subjects were sitting in a comfortable upright position and were instructed to stay as calm as possible, to keep their eyes closed and to relax for 5 minutes. They were asked to stay awake.
To remove muscular artifacts originating in the neck and face the data were reduced to 204 channels. Two to four minutes of EEG data were selected based on visual assessment of the artifacts and band-pass filtered between 1 and 40 Hz. Subsequently, in order to remove ballistocardiogram and oculo-motor artifacts, infomax-based Independent Component Analysis (Jung et al., 2000) was applied on all but one or two channels rejected due to abundant artifacts. Only components related to physiological noise, such as ballistocardiogram, saccadic eye movements, and eye blinking, were removed based on the waveform, topography and time course of the component. The cleaned EEG recordings were down-sampled to 125 Hz and the previously identified noisy channels were interpolated using a three-dimensional spherical spline (Perrin et al., 1989), and re-referenced to the average reference. All the preprocessing steps were done using MATLAB and the freely available Cartool Software 3.70 (https://sites.google.com/site/cartoolcommunity/home), programmed by Denis Brunet.

2.3 EEG data analysis

To estimate the optimal set of topographies explaining the EEG signal, a standard microstate analysis was performed using *k*-means clustering (see Supplementary Fig. 1). The polarity of the maps was ignored in this procedure (Brunet et al., 2011; Murray et al, 2008; Pascual-Marqui et al., 1995). To determine the optimal number of clusters, we applied a meta-criterion that is a combination of seven independent optimization criteria (for details see Bréchet et al., 2019). In order to improve the signal-to-noise ratio, only the data at the time points of the local maximum of the Global Field Power (GFP) were clustered (Pascual-Marqui et al., 1995; Koenig et al., 2002; Britz et al, 2010, Tomescu et al., 2014). The GFP is a scalar measure of the strength of the scalp potential field and is calculated as the standard deviation of all electrodes at a given time point (Michel et al., 1993; Brunet et al., 2011; Murray et al., 2008). The cluster analysis was first computed at the individual level and then at global level across all participants (patients and controls), clustering each participant's representative maps.

In order to retrieve the temporal characteristics of the microstates, spatial correlation was calculated between every map identified at the global level and the individual subject's topographical map in every instant of the pre-processed EEG recording. Each continuous time point of the subject's EEG (not only the GFP peaks) was then assigned to the microstate class of the highest correlation, again ignoring polarity (Brunet et al., 2011; Bréchet et al., 2019; Michel and Koenig, 2018; Santarnecchi et al., 2017). Temporal smoothing parameters (window half size = 3, strength (Besag Factor) = 10) ensured that the noise during low GFP did not artificially interrupt the temporal segments of stable topography (Brunet et al., 2011; Pascual-Marqui et al., 1995). For each subject, three temporal parameters were then calculated for each of the previously identified microstates: (i) occurrence, (ii) coverage, and (iii) duration. Occurrence indicates how many times a microstate class recurs in one second. The coverage in percent represents the summed amount of time spent in a given microstate class as a portion of the whole analyzed period. The duration in milliseconds for a given microstate class indicates the amount of time that a given microstate class is continuously present. In order to assess the extent to which the representative microstate topographies explain the original EEG data, the global explained variance (GEV) was calculated as the sum of the explained variances of each microstate weighted by the GFP. Microstate analysis was performed using the freely available Cartool Software 3.70, (https://sites.google.com/site/cartoolcommunity/home), programmed by Denis Brunet. Mann-Whitney U test was used to investigate group differences for temporal parameters of each microstate. Multiple comparisons were corrected using the false discovery rate (FDR) method (Benjamini, 2010).

Spearman's rank correlations were calculated between the MADRS, YMRS, STAI-state, and STAI-trait scores and significant microstate parameters to check for possible relationships between symptoms and microstate dynamics. Statistical evaluation was performed by the routines included in the program package Statistica'13 (1984-2018, TIBCO, Software Inc, Version 13.4.0.14).

3 Results

There were no significant differences in age and level of education between the patient and the control groups. In both groups, very low mean scores on depression and mania symptoms were observed, which did not significantly differ between the two groups. BD patients showed higher scores on state and trait scales of the STAI. For all subject characteristics, see Table 1.

The meta-criterion used to determine the most dominant topographies revealed five resting-state microstate maps explaining 82.2 % of the global variance (Fig. 1). The topographies resembled those previously reported as A, B, C, and D maps (Khanna et al., 2015; Michel and Koenig, 2018; Koenig et al., 2002; Britz et al., 2010) and one of the three recently identified additional maps (Custo et al., 2017). We labeled these scalp maps A – E in accordance with the previous literature on microstates. The scalp topographies showed left posterior-right anterior orientation (map A), a right posterior-left anterior orientation (map B), an anterior-posterior orientation (map C), a fronto-central maximum (map D), and a parieto-occipital maximum (map E).

Since some microstate parameters showed a non-homogeneity of variances in the two groups (Levene's tests for coverage of the C microstate and duration of the A and C microstates; $p<0.01$), we decided to calculate Mann-Whitney U test to investigate group differences for temporal parameters of each microstate.

We found significant between-group differences for microstate parameters of the A and B microstates. Both microstates showed increased presence in patients in terms of occurrence and coverage. The two groups did not differ in any temporal parameter of microstates C, D, or E. The results of the temporal characteristics of each microstate are summarized in Table 2 and Figure 2.

The results of Spearman's rank correlation revealed a significant positive association between the coverage of the microstate B and the STAI-state ($r = 0.40$) and STAI-trait ($r = 0.54$) scores. The results of Spearman's rank correlation revealed a significant positive association between the occurrence of the microstate B and the STAI-trait ($r = 0.47$) scores. The results of Spearman's rank correlation revealed no significant associations between the STAI-state or STAI-trait scores and the occurrence or coverage of the microstate A (all absolute r-values < 0.35).

The results of Spearman's rank correlation revealed no significant associations between the MADRS and YMRS scores and the occurrence or coverage of the microstate A and B (all absolute r-values $<$ 0.30).

4 Discussion

Our study presents the first evidence for altered resting-state EEG microstate dynamics in euthymic patients with bipolar disorder. Patients were stable and did not significantly differ in their depressive or manic symptomatology from healthy controls at the time of experiment. Despite this fact, they showed abnormally increased presence of microstates A and B, the latter correlating with anxiety level. The key discovery in the current study is the increased occurrence and coverage of microstate A in euthymic bipolar patients compared to healthy controls. In an earlier combined fMRI-EEG study the microstate A was associated with the auditory network (Britz et al., 2010). Moreover, generators of the functional EEG microstates were estimated in recent studies, where sources of the microstate A showed left-lateralized activity in the temporal lobe, insula, mPFC, and occipital gyri (Custo et al., 2017; Bréchet et al., 2019).

In the fMRI literature as well, resting-state functional connectivity alterations of the insula (Yin et al., 2018), the auditory network (Reinke et al., 2013), and the mPFC (Gong et al., 2019) were reported in BD patients. Verbal episodic memory deficits and language-related symptoms in BD patients were suggested to be associated with a diminished functional connectivity within the auditory/temporal gyrus and to be compensated by increased fronto-temporal functional connectivity (Reinke et al., 2013). The mPFC was also identified as a major locus of shared abnormality in BD and schizophrenia (Öngür et al., 2010), showing reduced default mode network connectivity from the mPFC to the hippocampus and fusiform gyrus, as well as increased connectivity between the mPFC and primary visual cortex in BD. Hypoconnectivity of the default mode network from the left posterior cingulate cortex to the bilateral mPFC and bilateral precuneus, and reduced salience connectivity of the left sgACC to the right inferior temporal gyrus in BD patients (Gong et al., 2019) was observed in unmedicated BD patients. In euthymic BD subjects compared to healthy controls, resting-state functional connectivity of the insula (Minuzzi et al., 2018) and amygdala (Li et al., 2018) to other brain regions was reported to be increased and decreased, respectively. In summary, the evidence from fMRI studies shows both hypoconnectivity (Gong et al., 2019; Öngür et al., 2010) and hyperconnectivity (Minuzzi et al., 2018; Reinke et al., 2013; Öngür et al., 2010) pointing to complex alterations of functional resting-state networks. Our findings of increased presence of the microstate A in euthymic BD patients might be related to the hyperconnectivity of the underlying networks that involve the temporal lobe, insula, mPFC, and occipital gyri.

Anxiety symptoms were previously associated with greater severity and impairment in bipolar disorder (Simon et al., 2004) and euthymic bipolar patients tend to present high residual level of anxiety (Albert et al., 2008), as it was the case here. No significant correlation was found between the increased anxiety scores and the increased occurrence or coverage of the microstate A. Our results therefore indicate that this alteration of microstate dynamics might represent a characteristic feature of BD that is not affected by anxiety.

The demonstrated alterations in microstate A dynamics during clinical remission might reflect (i) an impaired resting-state large-scale brain network dynamics as a trait characteristic of the disorder and/or (ii) a compensatory mechanism needed for clinical stabilization of the disorder.

Our study is the first to examine EEG microstate dynamics in BD patients during remission. Interestingly, in our recent study we showed positive associations of depressive symptoms with the occurrence of microstate A in a heterogenous group of patients with affective disorders (Damborská et al., 2019). The increased microstate A occurrence with depression as an effect related to the symptom severity (Damborská et al., 2019) and as a here demonstrated group difference of BD patients vs. controls, is not congruent with the previously reported reduced duration of the EEG microstates during a depressive episode (Strik et al., 1995). The experimental group in that study was not restricted to bipolar patients, however, and included also patients who met the criteria for unipolar depression or dysthymia. Moreover, authors examined the overall microstate duration and did not examine distinct microstates separately. These and other aspects, such as different clustering methods used, make it difficult to compare our findings with that early evidence of dirupted microstate dynamics in depression.

The microstate B was previously associated with the visual network (Britz et al., 2010; Custo et al., 2014, 2017; Bréchet et al., 2019). In our group of BD patients, we found an abnormally increased occurrence and coverage of microstate B that was associated with higher anxiety. Previous studies also suggest that anxiety may influence visual processing (Phelps et al., 2006; Laretzaki et al., 2010) and that connections between amygdala and visual cortex might underlie enhanced visual processing of emotionally salient stimuli in patients with social fobia (Goldin et al., 2009). Our finding of increased presence of microstate B positively associated with anxiety level in euthymic BD patients is consistent with these observations. To the best of our knowledge, there are no other studies that would aim to

examine in detail the relationship between anxiety and resting-state EEG microstate dynamics. An early microstate study reported decreased overall resting-state microstate duration in panic disorder (Wiedemann et al., 1998). This study, however, did not assess temporal characteristics of different microstates separately and it is therefore difficult to compare those findings with our observations. Further evidence is needed to determine, whether the increased presence of microsate B in our experimental group is a characteristic feature of BD or anxiety, or whether it is related to both conditions.

Changes in microstate A and B have been reported in several psychiatric conditions such as dementia, narcolepsy, multiple sclerosis, panic disorder, etc. (for review see Michel and Koenig, 2018). Increases in duration and occurrence of microstate A and B were observed in patients with multiple sclerosis (Gschwind, et al., 2016). Moreover, the changes in dynamic patterns of these two microstates, predicted depression scores and other clinical variables. It was suggested that multiple sclerosis affects the "sensory" (visual, auditory) rather than the higher-order (salience, central executive) functional networks (Michel and Koenig, 2018). Our findings of impaired dynamics in microstates A and B suggest a similar interpretation for the BD. Evidence from fMRI studies points to topographical dysbalances between the default mode and sensorimotor networks in BD patients with opposing patterns in depression and mania (Martino et al., 2016). Cyclothymic and depressive temperaments were associated with opposite changes in the sensorimotor network variability in the resting state signal measured by fractional standard deviation of Blood-Oxygen-Level Dependent signal (Conio et al., 2019). Our findings of altered microstates A and B dynamics is consistent with this fMRI evidence of impaired sensorimotor network in affective disorders, and moreover suggests that neural correlates of these deficits are prominent even during the euthymic state in BD patients.
In summary, results of the current study seem to indicate that dysfunctional activity of resting-state brain networks underlying A microstate is a detectable impairment in BD during an euthymic state. The presence of microstate A represents a measure that might be implicated in clinical practice. Importantly, this parameter, whose changes were observed during remission, could be potentially useful for early identification of bipolar disorder that could help better management of the disease. If future studies confirm the same pattern in prodromal or vulnerable subjects, it could also help detection of at-risk subjects and therefore the possiblility for early intervention. The present study has, however, some limitations. Our low sample size made it impossible to examine any potential influence of medication on the microstate parameters by comparing patients receiving a specific drug with those not receiving it. Possible effects of medication on our results should be therefore taken into account. Due to the same reason, it was not possible to examine any potential influence of subtypes of bipolar disorder on microstate results.

5 Conclusions

Our study described altered EEG resting-state microstate temporal parameters in euthymic bipolar patients. These findings provide an insight into the resting-state global brain network dynamics in bipolar disorder. The increased presence of the A microstate might be considered as a candidate electrophysiological non-specific trait marker of BD. Nevertheless, studies examining possible interactions between microstate dynamics and BD symptoms are needed to better understand the dysfunction of large-scale brain network resting-state dynamics in this affective disorder.

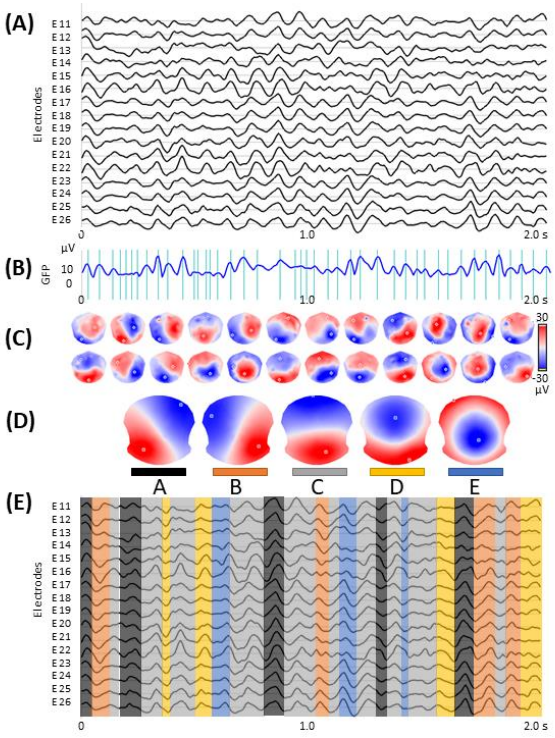
8 Figures



Supplementary Figure 1. Microstate analysis: **(A)** resting-state EEG from subsample of 16 out of 204 electrodes; **(B)** global field power (GFP) curve with the GFP peaks (vertical lines) in the same EEG period as shown in (A); **(C)** potential maps at successive GFP peaks, indicated in (B), from the first 1 s period of the recording; **(D)** set of five cluster maps best explaining the data as revealed by K-means clustering of the maps at the GFP peaks; **(E)** the original EEG recording shown in (A) with superimposed color-coded microstate segments. Note that each time point of the EEG recording was labelled with the cluster map, shown in (D), with which the instant map correlated best. The duration of segments, occurrence, and coverage for all microstates were computed on thus labeled EEG recording.

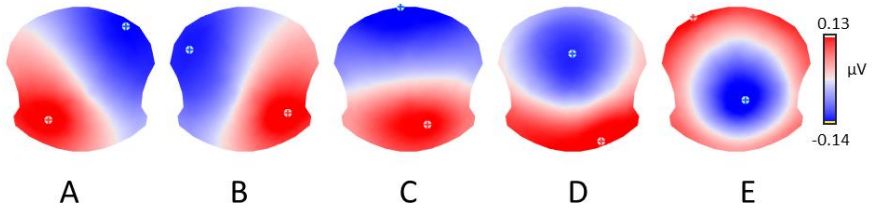


Figure 1. The five microstate topographies identified in the global clustering across all subjects.

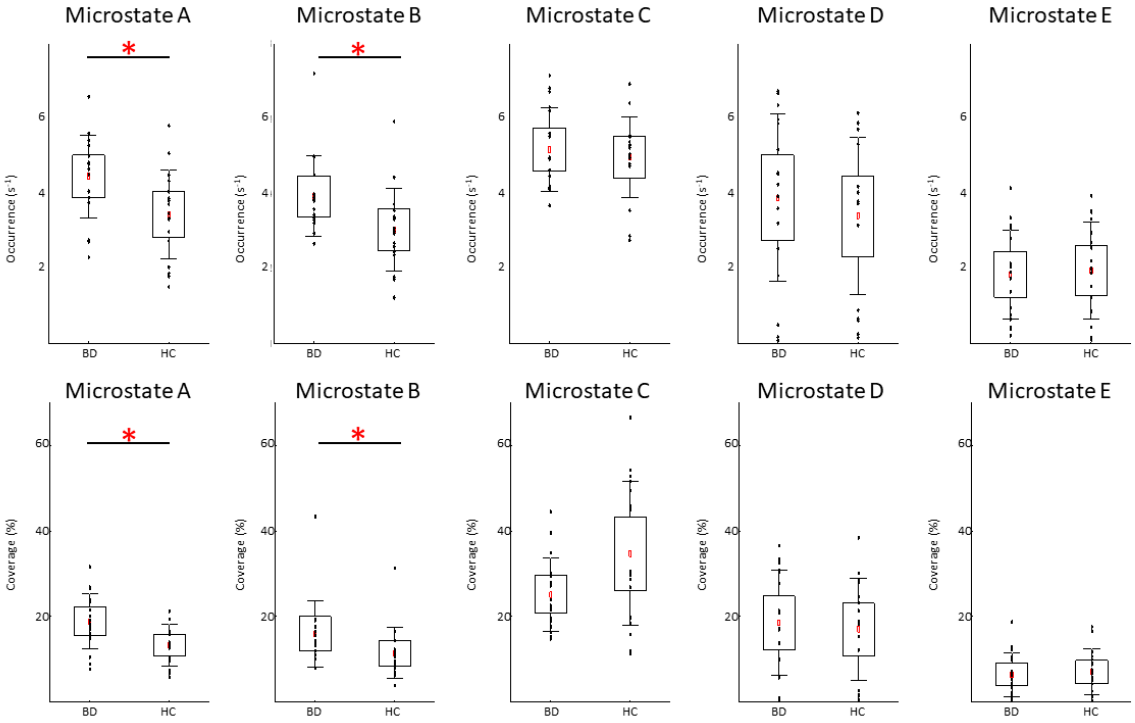

Figure 2. Temporal dynamics of EEG microstates in patients with bipolar disorder (BD) and in healthy controls (HC). In each subplot, the raw data is plotted on top of a boxplot showing the mean (□), 95% confidence interval (box plot area), 1 standard deviation (whiskers), and significant differences (*). In all plots, x-axes represent the subject group; y-axes represent the occurrence (upper plots) or coverage (lower plots). Note significantly increased occurrence and coverage of the microstate A and B in the BD compared to HC group (FDR corrected $p < 0.05$).

9 Conflict of Interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

10 Author Contributions

AD – designed the study, performed the analysis, and wrote the initial draft; JMA, AGD and CP – were responsible for clinical assessment; CMM – served as an advisor; CB – collected the HD-EEG data and was responsible for the overall oversight of the study. All authors revised the manuscript.

11 Funding

This project received funding from the European Union Horizon 2020 research and innovation program under the Marie Skłodowska-Curie grant agreement No. 739939. The funding source had no role in the design, collection, analysis, or interpretation of the study.

12 Acknowledgments

The authors wish to thank Anne Meredith Johnson for providing language help. Special thanks go to Anne-Lise Kung, psychologist, for her involvement in clinical data collection.
