Abstract

1

2 Uncovering the genes governing host-parasite coevolution is of importance for disease management
3 in agriculture and human medicine. The availability of increasing amounts of host and parasite
4 full genome-data in recent times allows to perform cross-species genome-wide association studies
5 based on sampling of genomic data of infected hosts and their associated parasites strains. We aim
6 to understand the statistical power of such approaches. We develop two indices, the cross species
7 association (CSA) and the cross species prevalence (CSP), the latter additionally incorporating
8 genomic data from uninfected hosts. For both indices, we derive genome-wide significance thresh-
9 olds by computing their expected distribution over unlinked neutral loci, *i.e.* those not involved
10 in determining the outcome of interaction. Using a population genetics and an epidemiological
11 coevolutionary model, we demonstrate that the statistical power of these indices to pinpoint the
12 interacting loci in full genome data varies over time. This is due to the underlying GxG interactions
13 and the coevolutionary dynamics. Under trench-warfare dynamics, CSA and CSP are very accurate
14 in finding out the loci under coevolution, while under arms-race dynamics the power is limited
15 especially under a gene-for-gene interaction. Furthermore, we reveal that the combination of both
16 indices across time samples can be used to estimate the asymmetry of the underlying infection ma-
17 trix. Our results provide novel insights into the power and biological interpretation of cross-species
18 association studies using samples from natural populations or controlled experiments.

21 evolution

22

1. Introduction

23 The increasing availability of host and parasite whole-genome data provides powerful means
24 to detect genes determining the outcome of host-parasite interactions. The simple underlying
25 idea is to perform all possible pairwise comparisons of Single Nucleotide Polymorphisms (SNPs)
26 between samples of hosts and parasites in order to draw correlations with the outcome of infection.
27 Recently, new Genome-Wide Association (GWA) methods to study host-parasite coevolutionary
28 interactions have been proposed and performed (termed co-GWAs, (Ebert 2018, MacPherson et al.

1 2018, Nuismer et al. 2017, Wang et al. 2018)). However, such analyses rely on performing large
2 scale controlled experiments with numerous host and parasites genotypes (thus can be termed as
3 controlled co-GWAs). A promising less-labour intensive alternative is to perform natural co-GWAs,
4 based on whole-genome data of infected hosts and their associated parasites sampled from natural
5 populations (Ansari et al. 2017, Bartha et al. 2013, Bartoli and Roux 2017). Such data sets inher-
6 ently contain phenotypic information (the infection outcome) for each sampled host-parasite pair,
7 namely the susceptibility/resistance of host genotypes and infectivity/non-infectivity of parasite
8 genotypes. Accordingly, the causal genetic variants for host susceptibility and parasite infectivity
9 are expected to show statistically significant associations (Host Genotype x Parasite Genotype). A
10 chief hypothesis is that such combination of host and parasite loci should explain a large variance
11 in the infection in contrast to the neutral SNPs in the genome, which by definition have no effect on
12 the interaction outcome. Natural co-GWAs have been applied, to our knowledge, twice to uncover
13 strong associations between human SNPs 1) of the major histocompatibility complex (MHC) and
14 known HIV epitopes (Bartha et al. 2013), and 2) of leukocyte antigen molecules and components
15 of the interferon lambda innate immune system and the hepatitis C virus NS5A protein (Ansari
16 et al. 2017). These studies conclude that the HIV and hepatitis C viruses do adapt to different
17 variants of the MHC or leukocyte/interferon lambda present in the human population (Ansari et al.
18 2017, Bartha et al. 2013).

19 In principle, natural co-GWAs can be readily extended to any coevolutionary system where it is
20 possible to call SNPs for a sample of infected hosts and the corresponding infecting parasites
21 (Bartoli and Roux 2017). For example, transcriptome data of infected hosts and the corresponding
22 infecting parasites (Dobon et al. 2016) or whole genome-data from controlled coevolutionary
23 experiments (Frickel et al. 2018) can be readily obtained. In these studies, a current restriction
24 (also a key requirement) to perform natural co-GWAs is to keep track of the co-occurrence of
25 host and parasite genotypes which can be technically challenging as often sequencing of pools of
26 infected hosts and parasites is performed.

27

28 One common underlying assumption of host-parasite co-GWAs is that the host genes deter-
29 mining the infection outcome, *i.e.* susceptibility/resistance, are coevolving with the corresponding
30 infectivity genes in the parasite. Coevolution is defined as reciprocal changes in allele frequencies
31 at the coevolving loci which result from selective pressures that two interacting species exert
32 on one another (Janzen 1980). This definition encompasses both, synergistic (symbiosis) and

1 antagonistic (host-parasite, prey-predator) interactions.
2 Allele frequency changes at the coevolutionary loci are commonly described by a continuum
3 between two extremes (Woolhouse et al. 2002), namely, the arms-race (Dawkins and Krebs
4 1979, Stahl and Bishop 2000, Woolhouse et al. 2002) and the trench-warfare (Stahl et al. 1999)
5 dynamics. Under arms-race dynamics, coevolution causes recurrent fixation of alleles at the
6 interacting loci, and accordingly, allelic polymorphism is only transient. In contrast, several alleles
7 are maintained for a long-period of time under trench-warfare dynamics, with frequencies either
8 persistently fluctuating over time or reaching a fixed stable polymorphic equilibrium. Note that
9 in both scenarios, allele frequencies fluctuate over time before reaching fixation or the stable
10 equilibrium.

11

12 The speed and type of frequency fluctuations depends on the host and parasite life-history traits
13 (review in Brown and Tellier (2011)), the strength of epidemiological dynamics (Ashby and Boots
14 2017) and the underlying GxG interactions. Given the assumption that few major genes determine
15 the interaction outcome, these GxG interactions can be captured in a so called infection matrix A .
16 Here, each entry α_{ij} stores the probability that a parasite genotype j can infect a host genotype
17 i (Tab. 1) or equivalently the degree of infection (disease severity). Two well known infection
18 matrices, are the matching-allele (MA) and the gene-for-gene (GFG) model. Both the MA and the
19 GFG models represent some point in a continuum of infection matrices (Agrawal and Lively 2002)
20 and are a subset of more complex matrices (with several alleles or loci, Gandon and Michalakis
21 (2002), Ashby and Boots (2017)). In MA interactions a given parasite genotype can only infect a
22 host when it matches the particular host allele (diagonal coefficients in Tab. 1b). For a 2x2 infection
23 matrix the probabilities to infect the "non-matching" host genotypes can be defined as $1 - c_1$ and
24 $1 - c_2$ (off diagonal coefficients in Tab. 1b). GFG interactions (Tab. 1c) are characterized by a
25 universally susceptible host genotype (here host $i = 1$) and an universally infective parasite (here
26 parasite $j = 2$). Here, the probability that host $i = 2$ is infected by parasite $j = 1$ is denoted by
27 $1 - c$.

28

29 In this study we address the following questions. 1) Which statistics can be used in co-GWAs
30 studies to pinpoint the loci under coevolution? 2) What is the power of these statistics to disen-
31 tangle the effect of neutral loci from that of coevolutionary loci? 3) What is the statistical power
32 of these statistics under various infection matrices and/or fluctuating allele frequencies? 4) Can

Table 1 Infection matrices for coevolutionary models

| a) general infection matrix | b) matching-allele | c) gene-for-gene |
|--|--|--|
| $\begin{pmatrix} \alpha_{11} & \alpha_{12} \\ \alpha_{21} & \alpha_{22} \end{pmatrix}$ | $\begin{pmatrix} 1 & 1 - c_1 \\ 1 - c_2 & 1 \end{pmatrix}$ | $\begin{pmatrix} 1 & 1 \\ 1 - c & 1 \end{pmatrix}$ |

The infection matrix \mathcal{A} determines the outcome of the interaction between host genotypes (rows) and parasite genotypes (columns). Each α_{ij} can be interpreted either as the probability for a given individual to be infected or as the degree of infection (disease severity or partial resistance).

1 these statistics be used to infer the underlying infection matrix based on collected samples without
2 further controlled infection experiments? We first develop two indices the cross-species association
3 (CSA) index (analogous to the measure used in Ansari et al. (2017), Bartoli and Roux (2017))
4 and the cross species prevalence (CSP) index to measure the association of alleles between the
5 coevolutionary loci in the host and the parasite. Second, we assess the statistical power of these
6 cross-species indices to pinpoint the coevolving loci among the genome-wide neutral SNPs. This
7 is realized by computing the expected distribution of these indices for all possible comparisons be-
8 tween host and parasite neutral loci. Note that we assume sampling from natural populations of
9 hosts and parasites which undergo recombination so that neutral SNPs are unlinked from the loci
10 under coevolution. As a result, we quantify the statistical power of these statistics to detect the loci
11 underlying coevolution over the course of coevolutionary cycles and for different underlying GxG
12 matrices. We demonstrate that performing co-GWAs with our indices across time samples allows
13 to infer the type of dynamics occurring (arms race versus trench warfare) as well as the under-
14 lying GxG interaction matrix. We then discuss the applicability of our co-GWAs indices to study
15 coevolution in natural or controlled systems.

16

2. Methods

17 2.1. The coevolutionary models

18 We assume that the outcome of an interaction between a host and a parasite, namely if the host
19 is infected or not, is determined by a single biallelic host and single biallelic parasite locus. These
20 two loci are defined as the coevolving loci. For simplicity, we consider a haploid model for hosts

1 and parasites. The outcome of the interaction between a particular host and parasite genotype is
 2 determined by the infection matrix $\mathcal{A} = (\alpha_{ij})$ with $1 \leq i, j \leq A$, where A is the total number of
 3 host (respectively parasite) genotypes (in this study $A = 2$, Table 1).

4 2.1.1. Model A: population genetics model

5 First, we use a simple population genetics model (henceforward termed model A) to study the allele
 6 frequency changes at the coevolving loci under the assumption of very large (infinite) haploid host
 7 and parasite population sizes. We assume that host and parasite generations are discrete and
 8 synchronized in terms of reproduction (Tellier and Brown 2007). The frequency of host genotype
 9 h_i and parasite genotype p_j in generation $g + 1$ is obtained as:

$$h_{i,g+1} = \frac{h_{i,g} w_{H,i}}{\bar{w}_{H,g}}, \text{ and } p_{j,g+1} = \frac{p_{j,g} w_{P,j}}{\bar{w}_{P,g}}$$

10 where $w_{H,i}$ ($w_{P,j}$) is the fitness of host genotype i (parasite genotype j). The average fitness of the
 11 host (parasite) population, $\bar{w}_{H,g}$ ($\bar{w}_{P,g}$), is obtained as $\sum_{i=1}^2 w_{H,i} \cdot h_{i,g}$ (respectively, $\sum_{j=1}^2 w_{P,j} \cdot p_{j,g}$).
 12 Every generation g a proportion ϕ_g (*i.e.* the disease prevalence) of the host population interacts
 13 with the parasite population in a frequency-dependent manner. Whether a particular interaction
 14 between host genotype i and parasite genotype j results in an infection or not depends on the
 15 matrix \mathcal{A} . An infection reduces the relative fitness of hosts by an amount s (cost of infection).
 16 Further, each host genotype i (parasite genotype j) can be associated with some fitness cost c_{H_i}
 17 (c_{P_j}), such as a cost of resistance (infectivity). Therefore, the frequencies of the different host and
 18 parasite genotypes can be modelled using the following recurrence equations:

$$h_{i,g+1} = \frac{h_{i,g} \cdot (1 - c_{H_i}) \cdot \left(1 - \phi_g \cdot s \cdot \sum_{j=1}^2 \alpha_{ij} p_{j,g} \right)}{\bar{w}_{H,g}} \quad (1a)$$

$$p_{j,g+1} = \frac{p_{j,g} \cdot (1 - c_{P_j}) \cdot \left(\sum_{i=1}^2 \alpha_{ij} h_{i,g} \right)}{\bar{w}_{P,g}} \quad (1b)$$

19 This dynamical system admits an equilibrium point when the conditions $h_{i,g+1} = h_{i,g} = \hat{h}_i$ and
 20 $p_{j,g+1} = p_{j,g} = \hat{p}_j$ hold for each host genotype i and each parasite genotype j . There are four so
 21 called trivial monomorphic equilibrium points at which one host and one parasite allele are fixed,

1 and one polymorphic equilibrium with frequencies:

$$\hat{h}_1 = \frac{\alpha_{22}(1 - c_{P_2}) - \alpha_{21}(1 - c_{P_1})}{(\alpha_{11} - \alpha_{21})(1 - c_{P_1}) + (\alpha_{22} - \alpha_{12})(1 - c_{P_2})} \quad (2a)$$

$$\hat{p}_1 = \frac{c_{H_1} - c_{H_2} + \phi s (\alpha_{12}(1 - c_{H_1}) - \alpha_{22}(1 - c_{H_2}))}{\phi s ((\alpha_{12} - \alpha_{11})(1 - c_{H_1}) + (\alpha_{21} - \alpha_{22})(1 - c_{H_2}))} \quad (2b)$$

2 In line with previous studies, for both the symmetric and asymmetric MA model we assume no
 3 costs $c_{H_1} = c_{H_2} = c_{P_1} = c_{P_2} = 0$ (Gandon and Nuismer 2009). For the GFG model we use the
 4 infection matrix shown in Tab. 1c) and assume that $0 < c_{H_2}, c_{P_2} < 1$ and $c_{H_1} = c_{P_1} = 0$ (Tellier and
 5 Brown 2007). Previous work have shown that Model A only produces arms-race dynamics. Indeed,
 6 the trace of the Jacobian evaluated at the equilibrium point is zero and the non-trivial equilibrium
 7 point (2a) is an unstable saddle point leading to host and parasite allele frequencies with increasing
 8 amplitude and period over time (Tellier and Brown 2007).

9 2.1.2. Model B: model with epidemiological dynamics and feedback

10 In model B we consider a continuous time coevolutionary model (Živković et al. 2019) based on a
 11 known Susceptible-Infected model (Ashby and Boots 2017, Boots et al. 2014, May and Anderson
 12 1983). This model allows for simultaneous changes in population sizes and allele frequencies.
 13 The total number of hosts of type i includes S_i susceptible and $\sum_j I_{ij}$ infected individuals. The
 14 change in number of susceptible hosts S_i is given by Eq. 3a and the change in number of infected
 15 individuals I_{ij} is given by Eq. 3b.

$$\frac{dS_i}{dt} = S_i \left[b(1 - c_{H_i}) - \gamma - \sum_{j=1}^2 \alpha_{ij}\beta(1 - c_{P_j}) \sum_{k=1}^2 I_{kj} \right] + b(1 - c_{H_i})(1 - s) \sum_{j=1}^2 I_{ij}, \quad (3a)$$

$$\frac{dI_{ij}}{dt} = -\gamma I_{ij} + S_i \left[\alpha_{ij}\beta(1 - c_{P_j}) \sum_{k=1}^2 I_{kj} \right]. \quad (3b)$$

16 The number of parasites of type j is obtained as $P_j = \sum_i I_{ij}$ and hence, the change in number of par-
 17 asites of type j is given by $\frac{dP_j}{dt} = \sum_i \frac{dI_{ij}}{dt}$. Hosts reproduce at natural birth rate b and die at natural
 18 death rate γ . The total host population size at generation t is $N(t) = \sum_{i,j} I_{ij}(t) + \sum_i S_i(t)$. We assume
 19 that there is no vertical disease transmission, and the infections are sustained in the populations
 20 through an overlap between generations. Uninfected hosts can get infected by horizontal disease

1 transmission with rate β . The costs c_{H_i} , c_{P_j} and s are defined as in model A. Previous analyses have
2 shown that depending on the parametrization (chosen infection matrix and parameter values) this
3 model results in a range of different dynamics (arms-race dynamics, trench-warfare dynamics with
4 stable limit cycles and trench-warfare dynamics with a stable attractor) (Ashby and Boots 2017,
5 Živković et al. 2019). We focus here chiefly on the trench warfare outcome, and especially when
6 the dynamics converges to the stable (attractor) polymorphic equilibrium point.
7 To simulate the dynamics, we discretise model B into small time steps of size δ_t . Hence, one discrete
8 generation t consists of $1/\delta_t$ time steps. The value of δ_t is chosen so that the discretised time dy-
9 namics matches with the continuous time expectation. The equilibrium points can be computed for
10 this system (Živković et al. 2019) but as the formulae are complex and not very intuitive we refrain
11 from using them here. The population size changes, allele frequencies changes and correspond-
12 ing association statistics values are computed over time and at the equilibrium point. The disease
13 prevalence is here an inherent property of the disease dynamics and allele frequencies as defined
14 under the eco-evolutionary feedbacks (Ashby et al. 2019, Boots et al. 2014), and thus varies over
15 time:

$$\phi(t) = \frac{\left(\sum_{j=1}^2 \beta (1 - c_{P_j}) \sum_{k=1}^2 I_{kj}(t)\right)}{N(t)}.$$

16 2.2. Definition of the association statistics

17 We assume that n_T host individuals have been sampled and genotyped at each biallelic single nu-
18 cleotide polymorphism (SNP) in the genome, so that two types of hosts are found ($i \in (1, 2)$). The
19 total host sample n_T consists of n_{Inf} infected hosts, the infected subsample, and n_H non-infected,
20 healthy, hosts, the non-infected subsample. A number of n_{Par} parasite samples is obtained from
21 the n_{Inf} infected hosts (one sample per host) and also genotyped at each biallelic SNP. Accordingly,
22 there are also two parasite types for each biallelic SNP ($j \in (1, 2)$). Note that the sites typically
23 considered here are SNPs as commonly used in GWAs and co-GWAs. Our definition also applies
24 to any type of mutation with two states such as insertion-deletion (of few to many base pairs) or
25 presence/absence polymorphism of larger genomic regions (e.g. coding genes).

Figure 1 Graphic illustration of the properties of our indices CSA and CSP. The host population consists of two host types H_1 (square) and H_2 (circle) and the parasite population consists of two types P_1 (black) and P_2 (grey). A proportion ϕ of the hosts is exposed to parasites. Hosts which are exposed to the parasite either become infected or they can resist infection. Infected hosts are coloured based on the identity of the infecting parasite genotype (grey or black). f_{ij} is the proportion of hosts with type i which are infected by parasites of type j in the proportion of all infected hosts. F_{ij} is the proportion of hosts of type i being infected by parasites of type j in the whole host population (sum of all hosts). F_{i0} is the proportion of non-infected hosts of type i in the whole host population. F_{i0} is composed of hosts of type i which either did not receive spores ($1 - \phi$) or which received spores but are resistant to the respective parasite.

1 2.2.1. The Cross-Species Association index (CSA)

2 We define the absolute Cross Species Association index (CSA) when sampling n_{Inf} hosts and $n_{\text{Par}} =$
3 n_{Inf} parasites as:

$$\text{CSA} = |f_{11}f_{22} - f_{21}f_{12}| \quad (4)$$

4 Here, f_{ij} is the number of hosts of type i being infected by a parasite of type j divided by the size of
5 the infected subsample (n_{Inf}), so that $\sum_{\forall i,j} f_{ij} = 1$. This statistic is an adaptation of the well-known
6 linkage disequilibrium (LD) measure in population genetics (Charlesworth and Charlesworth 2010,
7 Lewontin and Kojima 1960, p371-373) and related to the statistics performed in Bartha et al.
8 (2013) and Ansari et al. (2017).

9 Following population genetics theory (Charlesworth and Charlesworth 2010, p371-373), we nor-
10 malize CSA in two different ways such that the absolute values range from 0 to 1. First, we de-
11 fine CSA' which is obtained by normalizing each CSA value by the maximum CSA value possible,
12 $\text{CSA}^{\text{max}} = 0.25$. CSA reaches its maximum value when hosts of type 1 are solely infected by para-
13 sites of type 1 and hosts of type 2 are solely infected by parasites of type 2 and $f_{11} = f_{22} = 0.5$ (or
14 when hosts of type 1 are solely infected by parasites of type 2 and hosts of type 2 are solely infected
15 by parasites of type 1 and $f_{12} = f_{21} = 0.5$).

$$\text{CSA}' = \frac{\text{CSA}}{\text{CSA}^{\text{max}}} = \frac{|f_{11}f_{22} - f_{21}f_{12}|}{0.25} = 4 \cdot \text{CSA} \quad (5)$$

16 Our second normalization consists in dividing the CSA value by the square root of the product of
17 the frequencies of the different host and parasite alleles in the infected subsample.

$$\text{CSA}_r = \frac{f_{11}f_{22} - f_{21}f_{12}}{\sqrt{(f_{11} + f_{12})(f_{21} + f_{22})(f_{11} + f_{21})(f_{12} + f_{22})}} \quad (6)$$

18 We calculate the value of CSA at each generation g (eq. 4) based on our coevolutionary model A
19 (eq. 1a):

$$\text{CSA}_g = \left| \frac{\alpha_{11}h_{1,g}p_{1,g}\alpha_{22}h_{2,g}p_{2,g} - \alpha_{21}h_{2,g}p_{1,g}\alpha_{12}h_{1,g}p_{2,g}}{\Delta^2} \right| \quad (7)$$

20 where $\Delta = \alpha_{11}h_{1,g}p_{1,g} + \alpha_{22}h_{2,g}p_{2,g} + \alpha_{21}h_{2,g}p_{1,g} + \alpha_{12}h_{1,g}p_{2,g}$ (introduced to make sure in eq. 4
21 that $\sum_{\forall i,j} f_{ij} = 1$).

1 For Model B, the CSA at each time step t is obtained as:

$$\text{CSA}(t) = \left| \frac{I_{11}(t) \cdot I_{22}(t) - I_{12}(t) \cdot I_{21}(t)}{\left(\sum_i \sum_j I_{ij}(t)\right)^2} \right|. \quad (8)$$

2 Therefore, we can compute CSA' and CSA_r at each generation based on eq. 7 for Model A and
3 based on eq. 8 for Model B.

4 2.2.2. The Cross-Species Prevalence index (CSP)

5 We define the Cross Species Prevalence index (CSP) at any generation at which n_{Inf} infected, n_{H}
6 non-infected hosts and $n_{\text{Par}} = n_{\text{Inf}}$ pathogens are sampled.

$$\text{CSP} = \left| \frac{F_{11} + F_{12}}{F_{i0}} - \frac{F_{21} + F_{22}}{F_{20}} \right| \quad (9)$$

7 Here, F_{ij} is the proportion of host type i infected by parasite type j in the total host sample (n_{T}).
8 At the denominator, F_{i0} is the proportion of uninfected hosts of type i in the total sample. By
9 definition, $\frac{n_{\text{Inf}}}{n_{\text{T}}} = F_{11} + F_{12} + F_{21} + F_{22}$, $\frac{n_{\text{T}} - n_{\text{Inf}}}{n_{\text{T}}} = F_{10} + F_{20}$, and $F_{11} + F_{12} + F_{21} + F_{22} + F_{10} + F_{20} = 1$
10 (see Fig. 1). Note that F_{i0} is composed of individuals 1) which do not encounter any parasite due
11 to the incomplete disease prevalence in the population, and 2) which are exposed to parasites but
12 are resistant.

13 When eq. 9 is applied to our coevolutionary model A, CSP at each generation g is obtained as:

$$\text{CSP}_g = \left| \frac{\phi_g(\alpha_{11}h_{1,g}p_{1,g} + \alpha_{12}h_{1,g}p_{2,g})}{(1 - \phi_g)h_{1,g} + \phi_g((1 - \alpha_{11})h_{1,g}p_{1,g} + (1 - \alpha_{12})h_{1,g}p_{2,g})} - \frac{\phi_g(\alpha_{21}h_{2,g}p_{1,g} + \alpha_{22}h_{2,g}p_{2,g})}{(1 - \phi_g)h_{2,g} + \phi_g((1 - \alpha_{21})h_{2,g}p_{1,g} + (1 - \alpha_{22})h_{2,g}p_{2,g})} \right| \quad (10)$$

14 For Model B, the CSP at time t is given by:

$$\text{CSP}(t) = \left| \frac{I_{11}(t) + I_{12}(t)}{S_1(t)} - \frac{I_{21}(t) + I_{22}(t)}{S_2(t)} \right| \quad (11)$$

15 Irrespective of the model, CSP is only defined as long as there are some uninfected individuals of
16 both host types.

3. Results

1

2 3.1. Analytical results for model A

3 We first present some analytical results by computing CSA and CSP for the population genetics
 4 Model A with either a matching-allele (MA) or a gene-for-gene (GFG) interaction to provide some
 5 intuition on the behaviour of the presented indices. In the calculations, we only focus on CSA, as it
 6 is straightforward to obtain CSA' and CSA_r by applying the respective normalizations.

7 3.1.1. Under the Matching Allele infection matrix

8 For a matching-allele infection matrix and for $c_{H_1} = c_{H_2} = c_{P_1} = c_{P_2} = 0$ the equations for model
 9 A (eq. 1a) reduce to:

$$\begin{aligned} h_{1,g+1} &= \frac{h_{1,g}(1 - \phi_g s [p_{1,g} + (1 - c_1)p_{2,g}])}{\bar{w}_H}, \text{ and } h_{2,g+1} = \frac{h_{2,g}(1 - \phi_g s [p_{2,g} + (1 - c_2)p_{1,g}])}{\bar{w}_H}. \\ p_{1,g+1} &= \frac{p_{1,g}(h_{1,g} + h_{2,g}(1 - c_2))}{\bar{w}_P}, \text{ and } p_{2,g+1} = \frac{p_{2,g}(h_{2,g} + h_{1,g}(1 - c_1))}{\bar{w}_P}. \end{aligned} \quad (12)$$

10 By applying eq. 7 and eq. 9 to these MA-equations, we obtain $CSA_{g,MA}$ and $CSP_{g,MA}$ at any genera-
 11 tion g .

$$CSA_{g,MA} = \left| \frac{(c_1 + c_2 - c_1 c_2) h_{1,g} h_{2,g} p_{1,g} p_{2,g}}{(1 - c_2 h_{2,g} p_{1,g} - c_1 h_{1,g} p_{2,g})^2} \right|, \quad (13)$$

$$CSP_{g,MA} = \left| \frac{\phi_g (c_2 p_{1,g} - c_1 p_{2,g})}{(1 - \phi_g (1 - c_1 p_{2,g})) (1 - \phi_g (1 - c_2 p_{1,g}))} \right|. \quad (14)$$

12 It is evident that CSP, by contrast to the CSA, does not depend on the frequencies of the different
 13 host types but only on the parasite frequencies. Moreover, the CSP cannot be computed if the
 14 disease prevalence is at maximum ($\phi_g = 1$) and if neither of the host alleles provides any resistance
 15 to any parasite genotype ($c_1 = c_2 = 0$).

16 Further, the matching-allele model formulated in equation 12 has four monomorphic equilibria and
 17 one polymorphic equilibrium. The frequencies of the latter are given by:

$$\hat{p}_1 = \hat{h}_2 = \frac{c_1}{c_1 + c_2}, \text{ and } \hat{h}_1 = \hat{p}_2 = \frac{c_2}{c_2 + c_1}. \quad (15)$$

1 Inserting these equilibrium frequencies into eq. 13 and eq. 14 we can obtain the values of the
2 indices at the polymorphic equilibrium point.

$$\widehat{\text{CSA}}_{\text{MA}} = \frac{c_1^2 c_2^2}{(c_1 + c_2)^2 (c_1 + c_2 - c_2 c_1)}, \text{ and } \widehat{\text{CSP}}_{\text{MA}} = 0. \quad (16)$$

3 For a matching alleles interaction without any genotype costs, CSP is always zero at the equilibrium
4 point, irrespective of the values of c_1 and c_2 . The values of the CSA and CSP display a different
5 behaviour over time and at the equilibrium. Thus, comparing their values over time can yield
6 insights into the asymmetry of the infection matrix.

7 3.1.2. Under the Gene-For-Gene infection matrix

8 For a gene-for-gene infection matrix and for $0 < c_{H_2}, c_{P_2} < 1$ and $c_{H_1} = c_{P_1} = 0$, the equations for
9 the coevolutionary model A (eq. 1a) reduce to:

$$\begin{aligned} h_{1,g+1} &= \frac{h_{1,g}(1 - s\phi_g)}{\bar{w}_H}, \text{ and } h_{2,g+1} = \frac{h_{2,g}(1 - c_{H_2})(1 - \phi_g s [(1 - c)p_{1,g} + p_{2,g}])}{\bar{w}_H}, \\ p_{1,g+1} &= \frac{p_{1,g}(h_{1,g} + h_{2,g}(1 - c))}{\bar{w}_P}, \text{ and } p_{2,g+1} = \frac{p_{2,g}(1 - c_{P_2})}{\bar{w}_P}. \end{aligned} \quad (17)$$

10 Applying eq. 7 and eq. 9 to the GFG system of equation, yields the following values of $\text{CSA}_{g,\text{GFG}}$
11 and $\text{CSP}_{g,\text{GFG}}$ at some generation g .

$$\text{CSA}_{g,\text{GFG}} = \frac{ch_{1,g}h_{2,g}p_{1,g}p_{2,g}}{(1 - ch_{2,g}p_{1,g})^2}, \quad (18)$$

$$\text{CSP}_{g,\text{GFG}} = \frac{\phi_g c_{P_1,g}}{(1 - \phi_g)(1 - \phi_g(1 - c \cdot p_{1,g}))}. \quad (19)$$

12 As for the MA model, the CSP values, by contrast to the CSA, do not depend on the frequencies of
13 the different host types but only on the the parasite frequencies. The conditions for computing the
14 CSP are more restrictive than under the MA, as CSP is not defined as soon as the disease prevalence
15 is maximum ($\phi_g = 1$) and therefore, all hosts of type 1 are infected.

16 The polymorphic equilibrium frequencies of this model A with GFG are given by:

$$\begin{aligned} \hat{p}_1 &= \frac{c_{H_2}(1 - s\phi)}{c\phi s(1 - c_{H_2})}, \text{ and } \hat{h}_1 = \frac{c - c_{P_2}}{c}, \\ \hat{p}_2 &= 1 - \frac{c_{H_2}(1 - s\phi)}{c\phi s(1 - c_{H_2})}, \text{ and } \hat{h}_2 = \frac{c_{P_2}}{c}. \end{aligned} \quad (20)$$

1 Inserting these frequencies into eq. 18 and 19 we can obtain the values of the indices at the
2 polymorphic equilibrium point.

$$\widehat{CSA}_{\text{GFG}} = \frac{\frac{c_{P_2} c_{H_2} (c - c_{P_2}) (1 - s\phi)}{c^2 \phi s (1 - c_{H_2})} \left(1 - \frac{c_{H_2} (1 - s\phi)}{c \phi s (1 - c_{H_2})} \right)}{\left(1 - \frac{c_{P_2} c_{H_2} (1 - s\phi)}{c \phi s (1 - c_{H_2})} \right)^2}, \quad (21)$$

$$\widehat{CSP}_{\text{GFG}} = \frac{c_{H_2} (1 - \phi s)}{(1 - \phi) ((1 - \phi) s + c_{H_2} (1 - s))}. \quad (22)$$

3 To gain a deeper understanding of these results, we conduct numerical simulations for both types
4 of interactions over 500 generations and compare the values of the $CSA_r/CSA'/CSP$ over time to
5 the detection thresholds obtained for neutral loci.

6 **3.2. Detection thresholds for CSA and CSP**

7 In order to evaluate the power of CSA and CSP to pinpoint coevolutionary loci, it is necessary to
8 derive threshold (cut-off) values for these indices based on all possible comparisons of pairs of
9 loci from host and parasite genome data. Any pair of host and parasite SNPs exhibiting a value
10 above the cut-off is classically considered as a strong candidate pair governing the outcome of
11 infection and hence, to be under coevolution. It is common to obtain these cut-off values from the
12 distribution of all empirical values of a given data set (using ad hoc multiple testing correction,
13 see Bartha et al. (2013), Ansari et al. (2017)). By contrast, we assume here that sequences are
14 obtained from a random samples of infected and non-infected hosts from a panmictic, natural
15 or controlled, population with recombination. We thus can derive the expected distribution of
16 CSA (CSA' and CSA_r , correspondingly) and CSP for pairwise comparisons of many neutral host
17 and parasite SNPs based on population genetic assumptions, namely that allele frequencies are
18 distributed according to a neutral site-frequency spectrum (SFS).

19 By definition, neutral host and parasite loci are not determining the outcome of infection, and
20 therefore, each neutral host SNP-neutral parasite SNP-pair is characterized by an infection matrix
21 $A_{\text{neutral}} = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}$. Full genome data usually contain a large number of neutral SNPs which
22 are distributed across the whole genome. Given that the recombination rate is high enough, these
23 neutral SNPs are assumed to evolve independently from one another other and therefore, their
24 allele frequencies in the population and in the sample are mutually independent. In order to obtain

1 the expected neutral distribution of CSA and CSP we compute first all possible combinations of host
 2 and parasite alleles in the sample given a minor allele frequency count and the neutral infection
 3 matrix $\mathcal{A}_{\text{neutral}}$. Second, we compute the respective CSA/CSP value for each combination of host
 4 and parasite allele frequencies. Third, the expectations of CSA and CSP in a sample from a natural
 5 population at mutation-drift equilibrium is obtained by obtaining from the SFS the probability p
 6 that the host minor allele frequency count in the sample is v and the probability q that the parasite
 7 minor allele frequency count in the sample is w .

8

9 Our sample consists of n_{Inf} hosts and one representative parasite strain from each of these
 10 infected hosts (thus $n = n_{\text{Inf}} = n_{\text{par}}$). The expected CSA for neutral SNPs ($E(\text{CSA}_{vw})$) is measured
 11 for the association between a host SNP with minor allele frequency v and a parasite SNP with minor
 12 allele frequency w and is given by:

$$E(\text{CSA}_{vw}) = \Omega_{vw} \sum_{k=0}^l \frac{\binom{v}{k} \binom{n-v}{w-k}}{\binom{n_{\text{Inf}}}{w}} \left| \frac{kn_{\text{Inf}} - vw}{n_{\text{Inf}}^2} \right| \quad (23)$$

13 where $l = \min(v, w)$, and Ω_{vw} is the normalization for either obtaining CSA' (with $\Omega_{vw} = 4$, from
 14 eq. 5) or CSA_r (with $(\Omega_{vw} = \frac{1}{\sqrt{\frac{v}{n_{\text{Inf}}} \frac{n-v}{n_{\text{Inf}}} \frac{w}{n_{\text{Inf}}} \frac{n-w}{n_{\text{Inf}}}}})$, from eq. 6).

15 For the CSP, the computation is similar, though more complex, and the expectation is given by:

$$E(\text{CSP}_{vw}) = \sum_{z=\rho}^{m-1} \frac{\binom{n_{\text{Inf}}}{z} \binom{n_H}{v-z}}{\binom{n_T}{v} - \sum_{b=0}^{\rho-1} \binom{n_{\text{Inf}}}{b} \binom{n_H}{v-b} - \sum_{b=m}^v \binom{n_{\text{Inf}}}{b} \binom{n_H}{v-b}} \left| \frac{a}{\lambda n_H + (v-z)(-1)^\lambda} - \frac{n_{\text{Inf}} - a}{(1-\lambda)n_H - (v-z)(-1)^\lambda} \right| \quad (24)$$

16 with $\rho = \max(1, v - n_H + 1)$, $m = \min(n_{\text{Inf}}, v)$, $a = \min(z, n_{\text{Inf}} - z)$, and

$$\lambda = \begin{cases} 0 & \text{for } z \leq n_{\text{Inf}} - z \\ 1 & \text{for } z > n_{\text{Inf}} - z \end{cases}$$

17 Computational details are given in the Online Supplementary Material. The expectations of CSA
 18 and CSP over all pairwise comparisons of neutral host and parasite SNPs, are obtained by weighting
 19 each $E(\text{CSA}_{vw})$ and $E(\text{CSP}_{vw})$ value by the probability that a neutral host SNP has minor allele

1 frequency v (p_v) and a neutral parasite SNP has minor allele frequency w (q_w) in the sample:

$$\begin{aligned} E(CSA) &= \sum_{v=1}^{\lfloor n/2 \rfloor} \sum_{w=1}^{\lfloor n/2 \rfloor} p_v q_w E(CSA_{vw}), \\ E(CSP) &= \sum_{v=1}^{\lfloor n/2 \rfloor} \sum_{w=1}^{\lfloor n/2 \rfloor} p_v q_w E(CSP_{vw}). \end{aligned} \quad (25)$$

2 These probabilities are obtained from the relative folded site frequency spectrum of the sample
3 (eq. A2). We use the folded SFS, as we assume that there is no outgroup sequence available and
4 thus, the ancestral and derived state are indistinguishable at each SNP. For simplicity, we assume
5 that the allele frequency distribution of neutral SNPs in both, the host and the parasite, follows
6 the SFS under drift-mutation equilibrium for a Wright-Fisher model under constant population size
7 (Durrett (2010), p.50). These probabilities are found in the Appendix (eq. A2). We compute the
8 distributions (and extract the values of the 95 and 99 percentiles) for CSA and CSP for different
9 sample sizes and sampling schemes. In the following we show the results for $n_T = 200$ and
10 $n_{Inf} = n_H = 100$ (See the Online Supplementary Material for cut-off values under other sampling
11 schemes).

12 **3.3. Numerical simulations: Temporal changes of CSA/CSP and detection thresholds**

13 When simulating an asymmetric MA interaction ($c_1 = 0.9$, $c_2 = 0.7$, model A) over 500 generations
14 (Fig. 2) coevolution results in arms-race dynamics under Model A. We observe that CSA and CSP
15 fluctuate over time due to the coevolutionary cycles and the associated allele frequency changes.
16 Overall, the CSA values decrease over time and are constantly found below the detection threshold
17 after $g = 300$ generations. Therefore, under unstable coevolutionary dynamics with increasing
18 amplitude and period of the coevolutionary cycles (resulting ultimately in fixation of alleles), the
19 associations between hosts and parasites alleles in the infected sample become too weak to be
20 observable (Fig. 2c,d). Under an arms-race, one host allele occurs in very high frequency and the
21 parasite tracks this frequency down over time which generates the coevolutionary cycles. During
22 these cycles there is only a very limited amount of time at which both hosts and parasites alleles
23 are found in intermediate frequencies yielding high values of CSA index. On the other hand,
24 the CSP values under the MA model are consistently high and exhibit enough statistical power
25 to detect the loci under coevolution (Fig. 2d). This demonstrates the importance of obtaining

1 additional non-infected host samples. Under the same model A with symmetric MA, we find similar
2 outcome as in Fig. 2, albeit the oscillations of CSA and CSP values are perfectly matching the allele
3 frequency cycles and show a regular amplitude pattern (Fig. S8).

4 Under the GFG model with arms race, CSA values are consistently small with narrow peaks
5 (Fig. 3b,c) which are barely above the detection threshold. The CSP has several peaks above the
6 cut-off value, yet it maybe difficult to detect the coevolutionary locus even when time samples
7 are available if the more stringent 0.99-cut-off level is applied (Fig. 3d). The comparison of MA
8 and GFG arms race dynamics shows that the combination of CSA and CSP values over time gives
9 some indication about the symmetry of the infection matrix. Furthermore, the CSP exhibits the
10 highest power to disentangle loci under coevolution from the neutral background but also to infer
11 the asymmetry of the infection matrix. Generally, model A always results in arms-race dynamics,
12 however the amplitude and the time to fixation are affected by the underlying infection matrix and
13 the coevolutionary costs.

14 Under Model B trench-warfare dynamics can take place for MA-interactions and allele frequencies
15 can converge to a stable polymorphic equilibrium. Once the allele frequencies are at equilibrium,
16 CSA has a very strong power to distinguish the coevolving loci from the neutral background,
17 while the CSP decreases to zero (as shown above in eq. 16). In Model B, the disease prevalence
18 varies over time as a function of the changes in allele frequencies, so that it is expected that
19 CSP varies over time. However, once the allele frequencies reach a stable equilibrium also the
20 numbers in all host compartments eventually remain constant. When the ratio of infected to
21 non-infected individuals is the same for both host types then CSP drops to zero. The value of CSA
22 at equilibrium depends on the respective equilibrium frequencies and thus, is highest when alleles
23 are in frequency 0.5 (eq. 16). Even if coevolution results in stably sustained cycles, the CSA values
24 remain high as long as the amplitude of the cycles does not become too large and therefore allele
25 do not reach too high or too low frequencies (close to the boundaries). When allele frequency
26 fluctuations do not occur and the system is already at the polymorphic equilibrium, CSA is fixed
27 to a constant and high value (Fig. S9), while the CSP is fixed to zero (under a symmetric MA
28 infection matrix). Note that the epidemiological model B can also generate arms race dynamics
29 with a consequent fixation of one host and one parasite allele for some parameter combinations
30 under a GFG-interaction (Fig. S10). In such cases, the obtained results are similar to those of
31 Fig. 3 with both indices dropping to zero over time. Finally, we note that the two measures of CSA
32 we introduce, CSA' and CSA_r , show the same trend and similar power under an arms-race, while

1 the CSA_r is slightly more precise under trench warfare when allele frequencies reach very high or
 2 very low values (close to fixation or loss). Generally, the parasite population is dying out when the
 3 disease transmission rate (β) is either too high or too low, irrespective of the underlying infection
 4 matrix. For intermediate disease transmission rates under a MA-interaction, we either observe
 5 stable limit cycles for large values of s ($s \approx 1$) or convergence to a stable equilibrium for $s < 1$.
 6 These qualitative trends are similar when changing the infection matrix from MA to GFG, though
 7 the number of cycles to reach the stable equilibrium varies (Živković et al. 2019). Therefore, the
 8 highlighted results from Model B reflect the most commonly observed dynamics in this model.

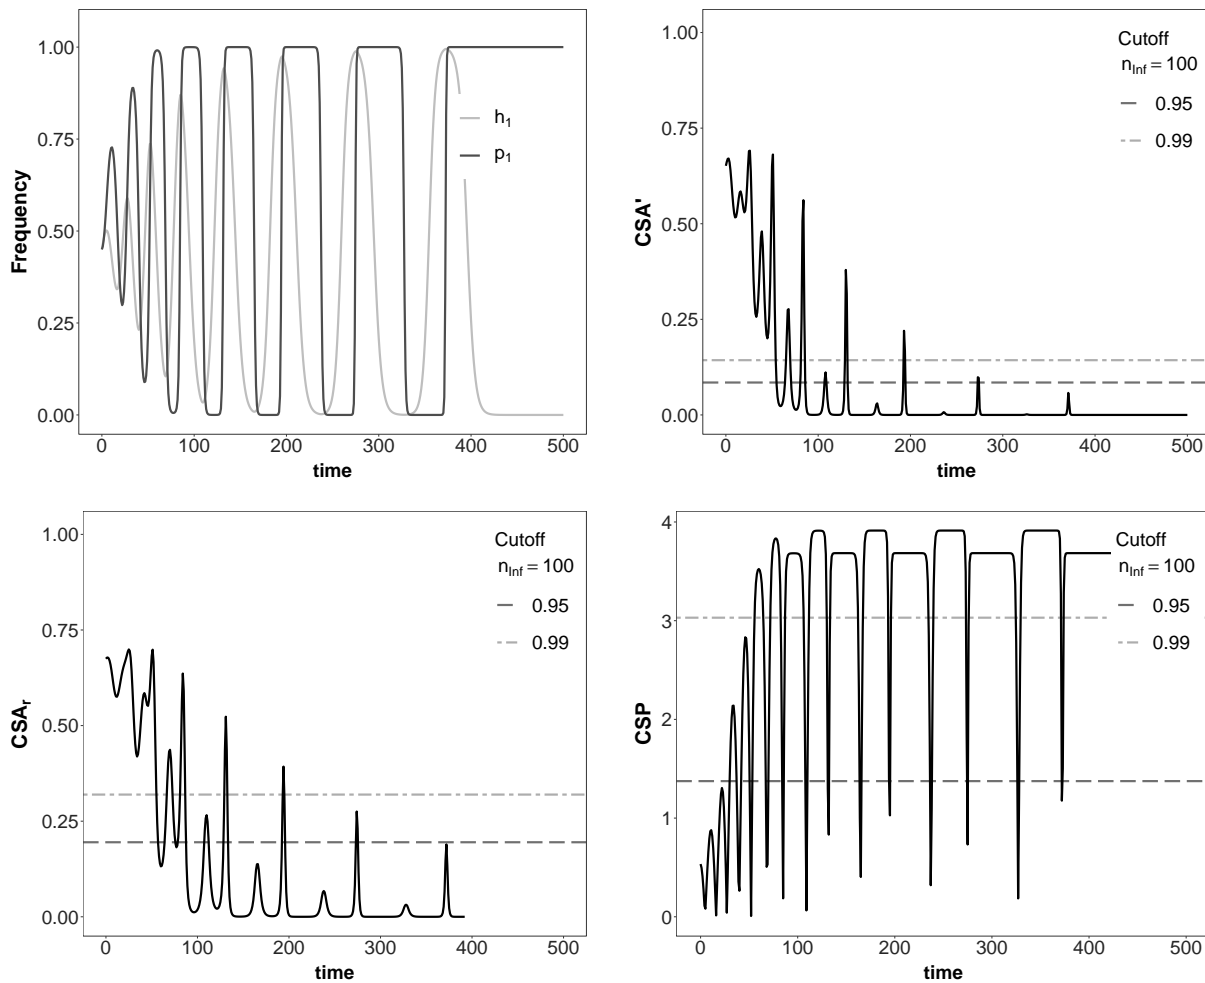

Figure 2 Temporal changes in allele frequencies, CSA' , CSA_r , and CSP in an unstable asymmetric MA-model (model A) with one parasite generation per host generation. For each index cut-off values are shown based on the expected neutral distributions for a total host sample size $n_T = 200$ and for $n_{inf} = n_H = 100$. The 0.95-cut-off value is shown as a dashed line and the 0.99-cut-off value as a dotted-dashed line. Top left: frequencies of h_1 (light grey) and p_1 (dark grey). Top right: CSA' . Bottom left: CSA_r . Bottom right: CSP. The model parameters are $c_1 = 0.9$, $c_2 = 0.7$, $\phi = 0.8$, $s = 0.35$, initial values $h_{1,g=0} = p_{1,g=0} = 0.45$.

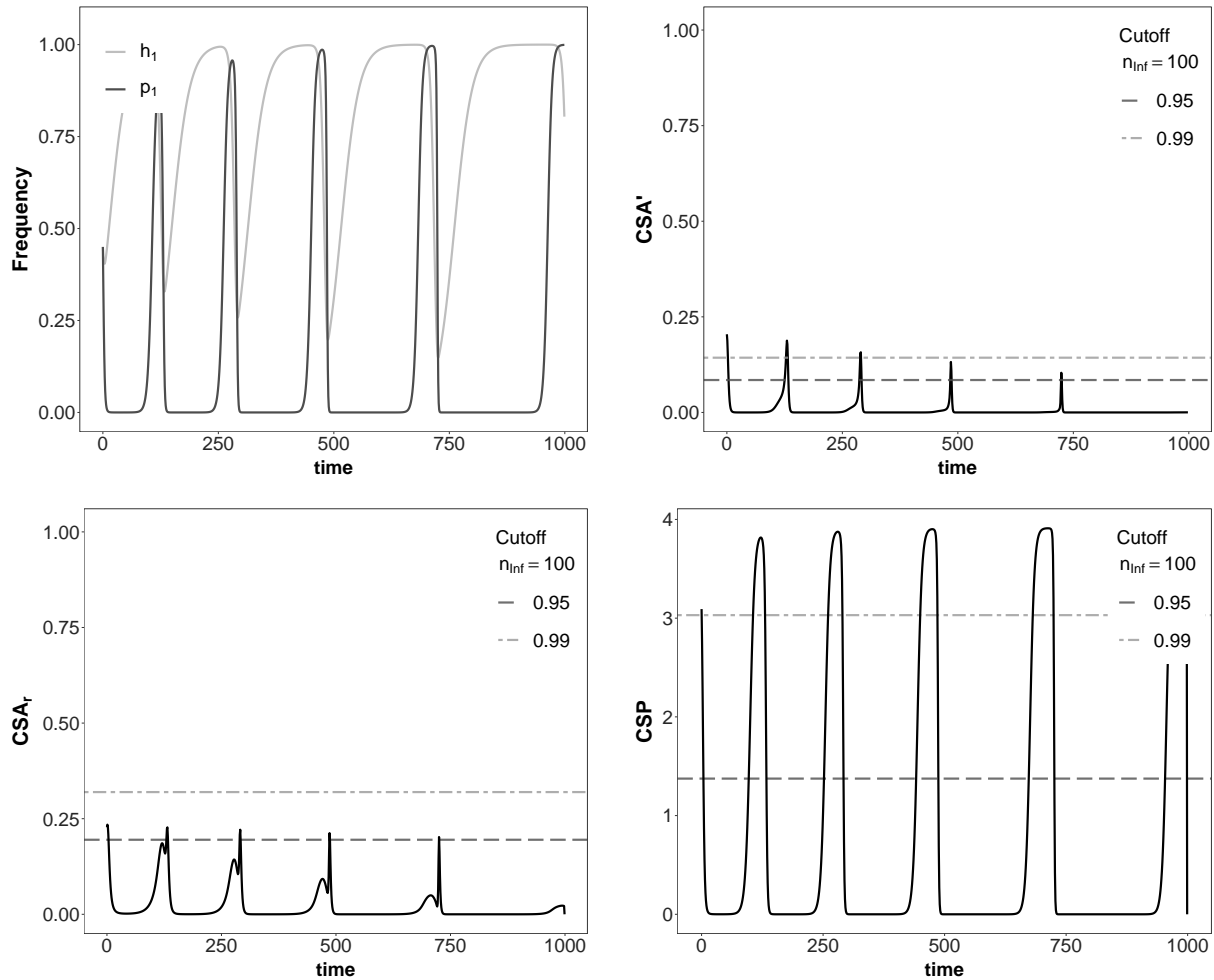

Figure 3 Temporal changes in allele frequencies, CSA' , CSA_r and CSP in an unstable GFG-model (model A) with one parasite generation per host generation. For each index cut-off values are shown based on the expected neutral distributions for a total host sample size $n_T = 200$ and for $n_{Inf} = n_H = 100$. The 0.95-cut-off value is shown as a dashed line and the 0.99-cut-off value as a dotted-dashed line. Top left: frequencies of h_1 (light grey) and p_1 (dark grey). Top right: CSA' . Bottom left: CSA_r . Bottom right: CSP . The model parameters are $c_{H_1} = c_{P_1} = 0$, $c_{H_2} = 0.05$, $c_{P_2} = 0.2$, $\phi = 0.8$, $s = 0.35$, $c = 0.9$, initial values $h_{1,g=0} = p_{1,g=0} = 0.45$.

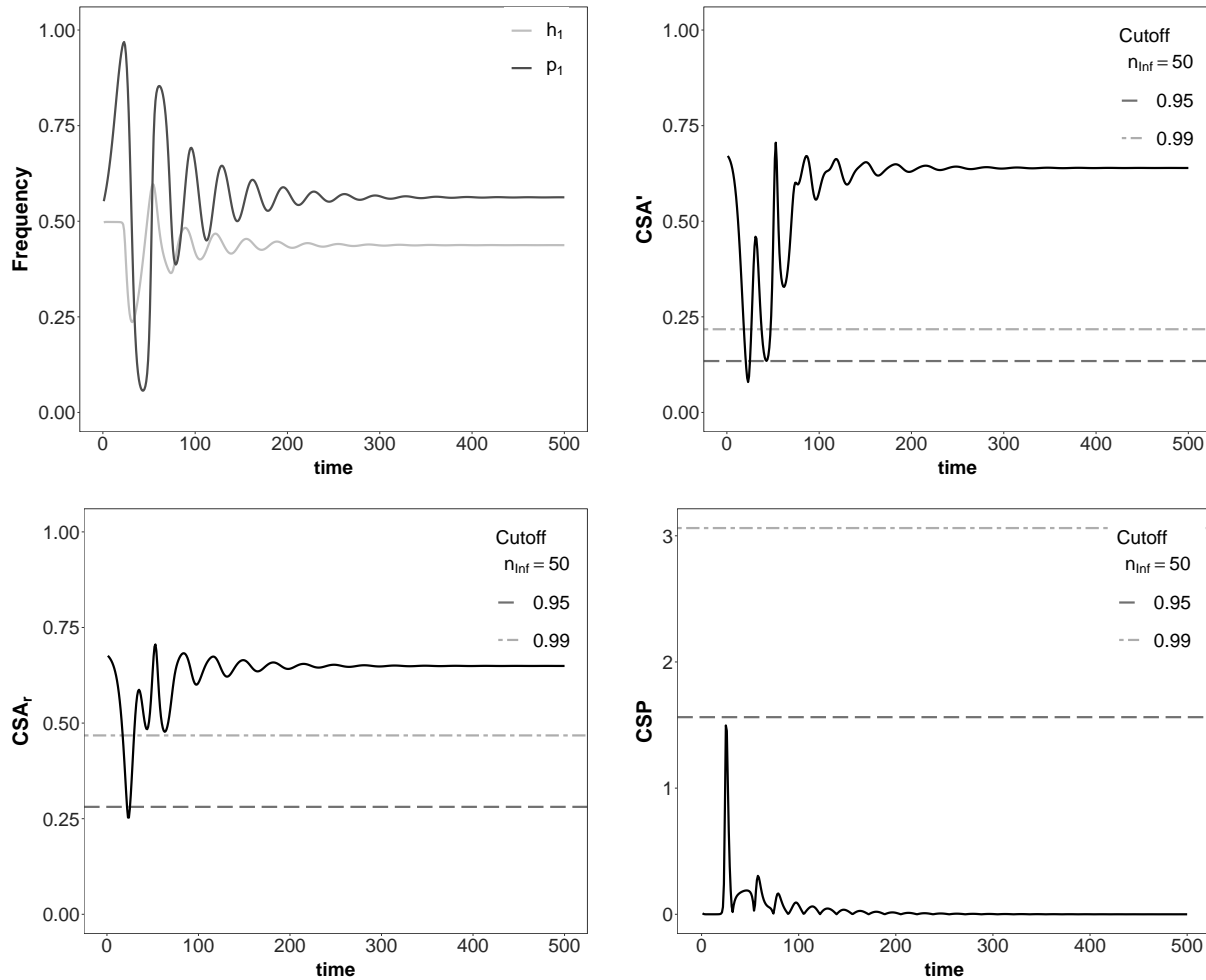

Figure 4 Temporal changes in allele frequencies, CSA' , CSA_r , and CSP in an epidemiological (model B) with an asymmetric MA-infection matrix. For each index cut-off values are shown based on the expected neutral distributions for a total host sample size $n_T = 200$ and for $n_{Inf} = n_H = 100$. The 0.95-cut-off value is shown as a dashed line and the 0.99-cut-off value as a dotted-dashed line. Top left: frequencies of h_1 (light grey) and p_1 (dark grey). Top right: CSA' . Bottom left: CSA_r . Bottom right: CSP. The model parameters are $\beta = 0.00005$, $s = 0.6$, $c_1 = 0.9$, $c_2 = 0.7$, $b = 1$, $\gamma = 0.9$, and $c_{H_1} = c_{P_1} = c_{H_2} = c_{P_2} = 0$. The initial values are $S_{1,t=0} = S_{2,t=0} = 4150$, $I_{11,t=0} = I_{12,t=0} = I_{21,t=0} = I_{22,t=0} = 415$. The time intervals for computations is $\delta_t = 0.001$.

4. Discussion

1
2 With the technological advances, it has become feasible to sequence full genomes of several
3 hosts from a given population as well as the parasite strains infecting them. Recent studies by
4 Ansari et al. (2017), Bartha et al. (2013) test for the degree of association between all the host
5 and parasite SNPs in a pairwise manner to obtain a genome wide natural co-GWAs. Here, we
6 show that the power of such studies can be improved by including additional sequence data from
7 non-infected individuals. Further, we derive cut-off values for significant associations based on
8 simple population genetics assumptions. Finally, we demonstrate that the power to identify the loci
9 underlying coevolution and thus, determining the infection outcome and the phenotype, varies in
10 time and depends on the asymmetry of the underlying infection matrix.

11
12 We expect *a priori* that the power to detect coevolutionary loci varies in time due to the coevo-
13 lutionary dynamics and the respective allele frequency changes at the involved loci. Our approach
14 is similar in spirit to studies measuring local adaptation by performing reciprocal transplant or
15 common garden experiments across several host-parasite populations being connected by migra-
16 tion (Gandon and Nuismer 2009, Nuismer et al. 2017). The CSA measure is closely related to the
17 covariance computed in Gandon and Nuismer (2009), Nuismer et al. (2017), which shows also
18 variable statistical power over time to detect coevolution. In contrast to reciprocal transplant or
19 common garden (Gandon and Nuismer 2009, Nuismer et al. 2017) experiments and host-parasite
20 controlled co-GWAs (MacPherson et al. 2018, Wang et al. 2018), the design of our natural co-GWA
21 (cross-species association) study already implicitly contains phenotypic information. The infection
22 experiment has been already "performed" by nature.

23 As indicated by analytical and simulation results, the two indices we introduce, CSA and CSP,
24 provide different information regarding 1) the symmetry of the infection matrix, 2) the type of
25 dynamics, and 3) whether the allele frequencies have reached a stable polymorphic equilibrium
26 point. We suggest to obtain samples from several time points rather than a single time point to
27 extract as much information as possible. First, in order to infer the infection matrix, we see that
28 two time samples for a MA or GFG interaction with an arms-race would likely both yield low
29 values of CSA, while the value of CSP would be comparatively high for a MA interaction and low
30 for a GFG interaction. Additional time samples would allow to capture the finer patterns of regular
31 peak behaviour. Second, two or few time samples are enough to allow for the inference of the type

1 of coevolutionary dynamics, namely arms-race or trench-warfare. A similar idea was proposed
2 in Gandon et al. (2008) for the study of local adaptation, when using phenotypic (infection)
3 data. In our case, increasing amplitudes of allele frequencies (arms race) leads to a decrease of
4 both CSA and CSP values over time, while decreasing amplitudes (trench-warfare dynamics) of
5 coevolutionary cycles generate increasing CSA values. Once these values remain constant across
6 time-samples a stable equilibrium point has been reached.

7

8 One crucial result of our study is the derivation of the neutral expectations for CSA and CSP
9 which allows us to compute detection thresholds for different sample sizes. A major difference
10 to the controlled co-GWAs studies (MacPherson et al. 2018, Wang et al. 2018) and our approach
11 is that the sequenced samples of infected and non-infected hosts are random samples from pan-
12 mictic reproducing host and parasite populations. This allows us to apply population genetics
13 theory to derive the expected power of our indices. To do so, we assume that host and parasite
14 populations are at drift-mutation equilibrium. Host and parasite population sizes (termed as the
15 demographic history in population genetics) are not necessarily constant over time either due to 1)
16 eco-evolutionary feedback arising from the epidemiological dynamics (as for example in model B),
17 and/or 2) due to abiotic environmental factors such as resource availability and habitat suitability.
18 Irrespective of the source causing the respective population size changes, it is possible to compute
19 the neutral SFS for both demographic scenarios based on previous work (Živković et al. 2019,
20 2015). This information could be used in eq. 25 to calculate the expectation of CSA and CSP for
21 neutral loci.

22 Note also that the influence of the available sample sizes on cut-off values can be large, as small
23 sample sizes ($n_T < 25$) decrease substantially the power to detect the coevolving loci (see Sup-
24 plementary Online Material). We suggest therefore as a strategy to collect at few time points and
25 obtain large sample sizes, rather than smaller sample sizes at many time points.

26

27 One simplifying assumption in our approach is the strict one to one relationship between the
28 host and the parasite, *i.e.* one parasite sample obtained per host. However, co-infections are
29 common for many diseases (Alizon et al. 2013, Tollenaere et al. 2016). A solution to deal with
30 such cases is to only use the major parasite strain found on the infected host (Bartha et al. 2013).
31 The presented results are further based on the assumption that only one major gene per species
32 is involved. However, our indices are applied independently to each pair of host and parasite

1 loci. Therefore, our approach is also suited to capture several major loci involved, as long as
2 they are freely recombining and as there are no epistatic or pleiotropic effects on the infection
3 outcome. In general, the approach presented here is also potentially applicable to detect the major
4 genes which are determining the compatibility between symbionts in mutualistic interactions. It
5 is straightforward to study the power of the presented indices for such types of interaction by
6 adjusting the equations governing the coevolutionary dynamics accordingly.

7
8 We conclude by presenting a set of recommendations for applying this method to different
9 host-parasite systems. It is advised to obtain infected and non-infected hosts and parasite ran-
10 dom samples at several time points from natural populations or from controlled coevolution
11 experiments. It has been shown that polycyclic parasites, that is parasites with several infection
12 cycles/generations per host generation, track down the host frequencies within a host generation
13 (Brown and Tellier 2011). Therefore, it is expected that the cross-species association method
14 has a high power when applied to parasite with strong life-cycle dependency on their hosts.
15 This effect should be strongly pronounced for parasites which have a much shorter generation
16 time than their hosts (viruses (Ansari et al. 2017, Bartha et al. 2013) or bacteria). For such
17 types of parasites taking serial samples within a single host generations should help to pinpoint
18 coevolutionary loci very accurately. Here, the coevolving loci are expected to show an increasing
19 association with the corresponding host loci over the course of a single host generation. How-
20 ever, the assumption of independence between neutral and coevolving loci can be violated when
21 studying viruses, bacteria or clonal fungi due to the absence of recombination. Our approach to
22 disentangle neutral loci from candidate loci based on threshold values for the indices relies on
23 recombination. In Bartha et al. (2013), the hurdle of linkage was overcome by first performing a
24 phylogeny of the virus samples, and a subsequent identification of clusters of polymorphic SNPs
25 across the phylogeny. Based on these clusters the association study was performed in a second step.

26
27 An implicit assumption in Bartha et al. (2013), Ansari et al. (2017), Bartoli and Roux (2017)
28 and our model is that disease transmission is random and panmictic so that potentially every host
29 can get in contact with the disease (no population sub-structuring affecting disease transmission).
30 Thus, it is crucial to assess the extent of population structure before performing a cross-species as-
31 sociation study as different populations can be at different stages of the coevolutionary cycle (e.g.
32 Sasaki (2000), Gavrillets and Michalakis (2008)). Neglecting population structure in such cases can

1 result in biased results.

2 Nevertheless, one could take advantage of the geographic mosaic of coevolution by obtaining se-
3 quence data from several populations when sequence data from several time points are not feasible.
4 However, note that the neutral SFS of pooled samples from a spatially structured population does
5 not follow the equations we used here. Hence, this has to be taken into account when obtaining
6 the threshold values for CSA and CSP. A description of the effect of spatial population structure on
7 allele frequency distributions can be for example found in Wakeley and Aliacar (2002) and Staedler
8 et al. (2009).

9 Host-parasite coevolution is a multifaceted process. We have shown the power of natural co-
10 GWAs to gain insights into this process, especially when time-samples are available, despite poten-
11 tial shortcomings due to model assumptions. A further worthwhile development will be the explicit
12 inclusion of spatial structure of host and parasite populations.

A1. Appendix: The neutral site frequency spectrum

We assume for simplicity that the allele frequency distribution of neutral SNPs in both, the host and the parasite, follows the site frequency spectrum (SFS) under drift-mutation equilibrium for a Wright-Fisher model under constant population size. Further, we assume that there is no outgroup sequence available, thus the ancestral and derived state are unknown for a given SNP. The expected folded SFS $\eta = \{\eta_1, \dots, \eta_{\lfloor n/2 \rfloor}\}$ under drift-mutation equilibrium for a sample of size n is given by:

$$\eta_k = \frac{\frac{\theta}{k} + \frac{\theta}{n-k}}{1 + \delta_{k,n-k}} \quad \text{for } 1 \leq k \leq \lfloor n/2 \rfloor \quad (\text{A1})$$

where θ is the population mutation rate, $\lfloor n/2 \rfloor$ denotes the largest integer being smaller or equal to $n/2$ and $\delta_{k,l}$ is Kronecker's delta with

$$\delta_{k,l} = \begin{cases} 0 & \text{for } k \neq l \\ 1 & \text{for } k = l \end{cases}$$

Thus, the probability (p_k) to choose a SNP with minor allele frequency k in a sample of size n , is given by:

$$p_k = \frac{\eta_k}{\sum_{i=1}^{\lfloor n/2 \rfloor} \eta_i} = \frac{\left(\frac{\frac{1}{k} + \frac{1}{n-k}}{1 + \delta_{k,n-k}} \right)}{\sum_{i=1}^{\lfloor n/2 \rfloor} \left(\frac{\frac{1}{i} + \frac{1}{n-i}}{1 + \delta_{i,n-i}} \right)} \quad (\text{A2})$$

These probabilities are independent of the population size and the mutation rate. However note that, changes in population size feed-back on the shape of the SFS and thus, the calculation of these probabilities.

Our computations include singletons, that is alleles with frequency $1/n$ in the sample. However, it is known that the sequencing and detection of singletons can be biased (*e.g.* with NGS technologies or pooling of samples). Therefore, singletons can be also removed from the CSA calculation and the CSP calculations should be adjusted accordingly by constraining the minor allele frequency in the infected subsample to be at least equal to two. Furthermore, if more complex demographic scenarios want to be included via their influence on the neutral host and/or parasite SFS, the probability A2 can be adjusted analytically or from results of coalescent simulations.

1 S1. Supplementary Online Information

2 In this supplement we add some details on the computations of the CSA and CSP values for neutral
3 loci as well as additional figures.

4 S1.1. Cross species association index (CSA)

5 Remember that we have obtained n_{Inf} host samples and one representative parasite strain from
6 each of these infected hosts. Thus, the host sample size (n_{Inf}) and the parasite sample size (n_{Par})
7 are the same ($n = n_{\text{Inf}} = n_{\text{Par}}$). In order to compute the expected CSA for neutral SNPs we first
8 have to derive an expression for the expected value of CSA ($E(\text{CSA}_{vw})$) measuring the association
9 between a host SNP with minor allele frequency v and a parasite SNP with minor allele frequency w .
10 Therefore, we first compute the number of all such possible combinations. For each combination,
11 the value CSA is $\text{CSA}_{vw,k}$ and the probability of that particular combination is $\binom{v}{k} \binom{n_{\text{Inf}}-v}{w-k}$. The
12 expectation $E(\text{CSA}_{vw})$ is then:

$$E(\text{CSA}_{vw}) = \Omega_{vw} \sum_{k=0}^l \frac{\binom{v}{k} \binom{n_{\text{Inf}}-v}{w-k}}{\binom{n_{\text{Inf}}}{w}} \text{CSA}_{vw,k} \quad (\text{S1})$$

$$= \Omega_{vw} \sum_{k=0}^l \frac{\binom{v}{k} \binom{n_{\text{Inf}}-v}{w-k}}{\binom{n_{\text{Inf}}}{w}} \left(\left| \frac{k}{n_{\text{Inf}}} \cdot \frac{n_{\text{Inf}}-v-(w-k)}{n_{\text{Inf}}} - \frac{v-k}{n_{\text{Inf}}} \cdot \frac{w-k}{n_{\text{Inf}}} \right| \right) \quad (\text{S2})$$

$$= \Omega_{vw} \sum_{k=0}^l \frac{\binom{v}{k} \binom{n_{\text{Inf}}-v}{w-k}}{\binom{n_{\text{Inf}}}{w}} \left| \frac{kn_{\text{Inf}}-vw}{n_{\text{Inf}}^2} \right| \quad (\text{S3})$$

13 where $l = \min(v, w)$.

14 Here the index k can be interpreted as the number of hosts with the minor allele which are infected
15 by a parasite with the minor allele, or put in a different way, $w-k$ out of the $n_{\text{Inf}}-v$ hosts with the
16 major allele are infected by a parasite with the minor allele. Accordingly, $v-k$ hosts with the minor
17 allele are infected by a parasite which has the major allele, and $n_{\text{Inf}}-v-(w-k)$ hosts with the major
18 allele are infected by parasites with the major allele. We define Ω_{vw} as the normalization for ei-
19 ther obtaining CSA' (with $\Omega_{vw} = 4$, as in eq. 5) or CSA_r (with $(\Omega_{vw} = \frac{1}{\sqrt{\frac{v}{n_{\text{Inf}}} \frac{n_{\text{Inf}}-v}{n_{\text{Inf}}} \frac{w}{n_{\text{Inf}}} \frac{n_{\text{Inf}}-w}{n_{\text{Inf}}}}})$, from eq. 6).

20

1 S1.2. Distribution of CSA for different sample sizes

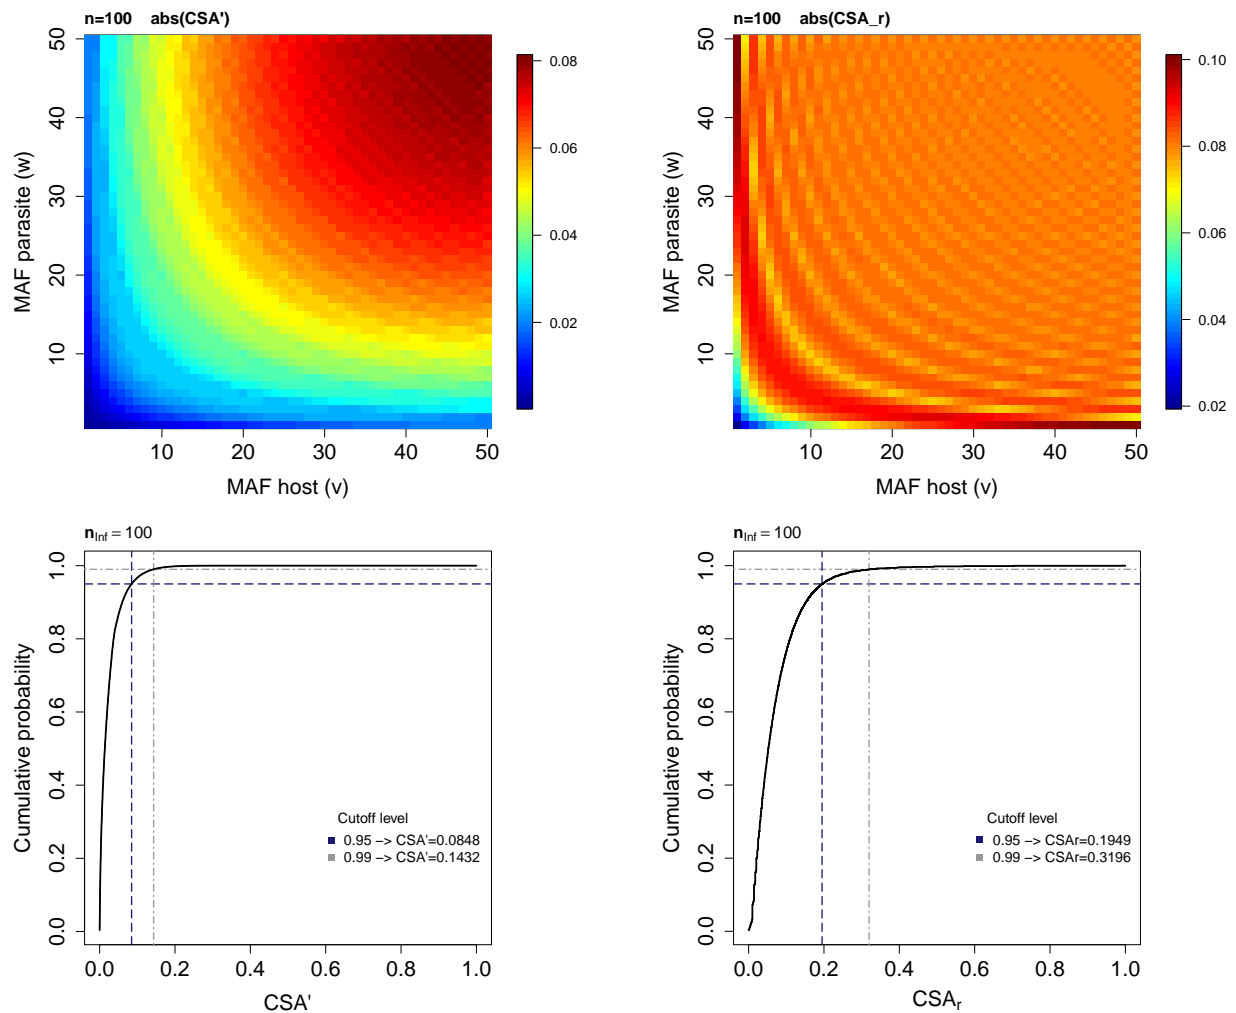

Figure S1 Expected values of CSA' (top left) and CSA_r (top right) when comparing all neutral host SNPs with minor allele frequency v ($v \in \{1, \dots, \lfloor n_{\text{Inf}}/2 \rfloor\}$) to all neutral parasite SNPs with minor allele frequency w ($w \in \{1, \dots, \lfloor n_{\text{Par}}/2 \rfloor\}$) and the resulting expected cumulative distribution function of $E(CSA')$ (bottom left) and $E(CSA_r)$ (bottom right) for a sample size of $n_{\text{Inf}} = n_{\text{Par}} = 100$.

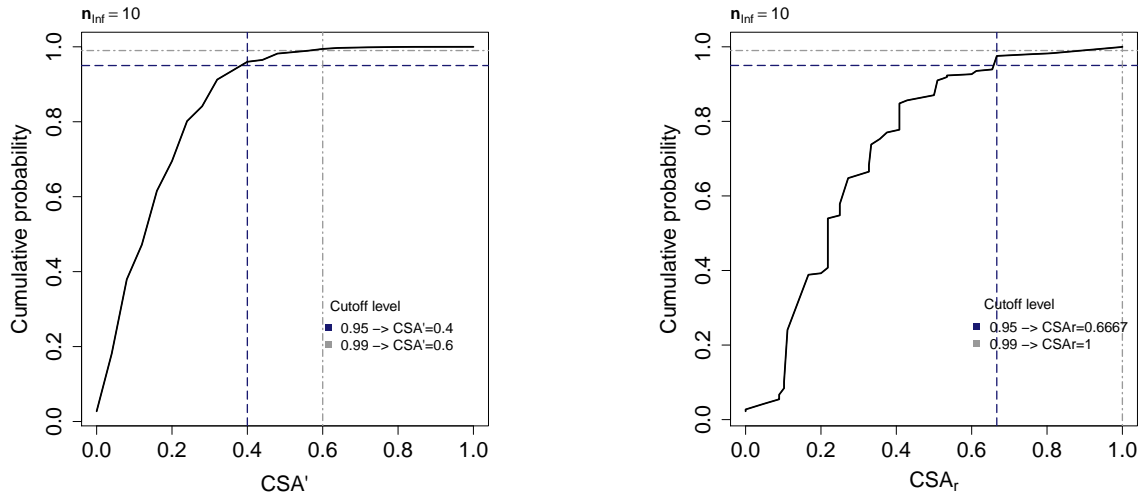

Figure S2 Expected cumulative distribution function of CSA' (left) and CSA_r (right) when comparing all neutral host SNPs with minor allele frequency v ($v \in \{1, \dots, \lfloor n/2 \rfloor\}$) to all neutral parasite SNPs with minor allele frequency w ($w \in \{1, \dots, \lfloor n/2 \rfloor\}$) for a sample size of $n_{Inf} = n_{Par} = 10$.

Figure S3 Expected cumulative distribution function of CSA' (left) and CSA_r (right) when comparing all neutral host SNPs with minor allele frequency v ($v \in \{1, \dots, \lfloor n/2 \rfloor\}$) to all neutral parasite SNPs with minor allele frequency w ($w \in \{1, \dots, \lfloor n/2 \rfloor\}$) for a sample size of $n_{Inf} = n_{Par} = 25$.

Figure S4 Expected cumulative distribution function of CSA' (left) and CSA_r (right) when comparing all neutral host SNPs with minor allele frequency v ($v \in \{1, \dots, \lfloor n/2 \rfloor\}$) to all neutral parasite SNPs with minor allele frequency w ($w \in \{1, \dots, \lfloor n/2 \rfloor\}$) for a sample size of $n_{Inf} = n_{Par} = 50$.

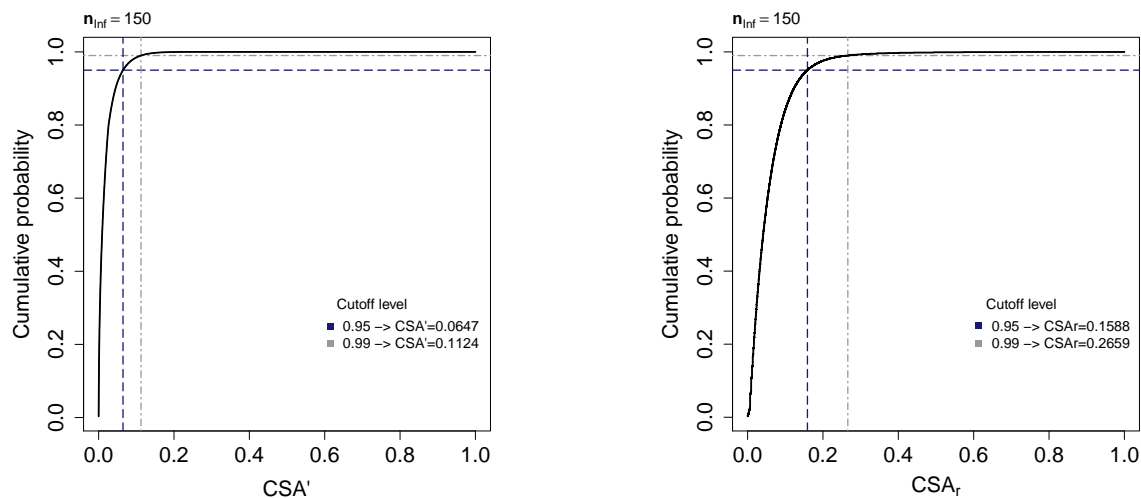

Figure S5 Expected cumulative distribution function of CSA' (left) and CSA_r (right) when comparing all neutral host SNPs with minor allele frequency v ($v \in \{1, \dots, \lfloor n/2 \rfloor\}$) to all neutral parasite SNPs with minor allele frequency w ($w \in \{1, \dots, \lfloor n/2 \rfloor\}$) for a sample size of $n_{Inf} = n_{Par} = 150$.

1 S1.3. Cross species prevalence index (CSP)

2 We label the host allele with minor frequency in the **infected subsample** as $i = 1$ and the host
3 allele with major frequency in the infected subsample as $i = 2$. Note that the allele with minor
4 allele frequency in the infected subsample is not necessarily the minor allele in the whole sample
5 (see Fig. S6). In cases where both alleles have equal frequencies in the infected subsample, the al-
6 lele with minor allele frequency in the whole sample will be labelled as 1 and the allele with major

Figure S6 Two possible host configurations when sampling a total number $n_T = 12$ host individuals among which $n_{\text{Inf}} = 6$ individuals are infected (grey box) and $n_{\text{H}} = 6$ individuals are healthy (light blue box) and the minor host allele frequency is $v = 5$. Host individuals which have the minor allele (based on the whole sample) are shown in light blue, host individuals with the major allele (based on the whole sample) are shown in dark blue. Labelling of the alleles for the calculation of CSP is based on the minor allele frequency in the infected subsample. On the left, the minor allele is labelled by 1 as it is also the minor allele in the infected subsample. On the right, the major allele of the total sample is labelled by 1 as it represents the allele with minor allele frequency in the infected subsample.

1 allele frequency in the whole sample will be labelled as 2. Therefore, F_{11} (F_{12}) is the proportion of
 2 hosts with label 1 which are infected by a parasite with the minor (major) allele. F_{21} (F_{22}) is the
 3 proportion of hosts with label 2 which are infected by a parasite with the minor (major) allele. Fur-
 4 ther, F_{10} (respectively F_{20}) is the proportion of non-infected hosts carrying allele 1 (respectively 2).
 5 If for a neutral locus there are v minor alleles in the total host sample n_T , these minor alleles can be
 6 found with equal probability on each of the n_T individuals (irrespective of the infection status) as a
 7 neutral SNP does not have an effect on the infection outcome. Similarly, all of the w parasite minor
 8 alleles can be randomly assigned to any of the n_{par} parasite individuals which are infecting the n_{Inf}
 9 host individuals. Further, note that CSP is only informative when the minor and major allele can
 10 be found in both, the infected and the non-infected subsample. Therefore, we exclude SNPs which
 11 are singletons in the total host sample (n_T). We proceed as follows to obtain the expected CSP for
 12 a neutral host SNP with minor allele frequency v and neutral parasite SNP with minor allele
 13 frequency w .
 14 First, we have to find all host combinations (and their probability) for which the minor and ma-
 15 jor host alleles are found in both the infected and non-infected subsamples. We define z as the
 16 number of minor host alleles which are found in the infected subsample for a given combination.
 17 Accordingly, the number of major host alleles in the infected subsample is $n_{\text{Inf}} - z$, the number of

1 minor host alleles in the non-infected subsample is $v - z$ and the number of major host alleles in
2 the non-infected subsample is $n_T - n_{\text{Inf}} - (v - z)$. Based on the resulting composition of the infected
3 subsample the alleles are labelled. The indicator variable λ is used to keep track of whether the
4 minor allele in the total sample is the minor ($\lambda = 0$) or the major ($\lambda = 1$) allele in the infected
5 subsample.
6 Second, the n_{par} parasites among which w individuals have the minor parasite allele are assigned
7 within the n_{Inf} sample. Hereby, k denotes the number of hosts with label 1 which are infected by
8 a parasite with the minor allele (see CSA). Thus, the expected value of CSP for a SNP with minor
9 allele frequency v in the host and minor allele frequency w in the parasite is given by:

$$E(CSP_{vw}) = \sum_{z=\rho}^{m-1} \frac{\binom{n_{\text{inf}}}{z} \binom{n_H}{v-z}}{\binom{n_T}{v} - \sum_{b=0}^{\rho-1} \binom{n_{\text{inf}}}{b} \binom{n_H}{v-b} - \sum_{b=m}^v \binom{n_{\text{inf}}}{b} \binom{n_H}{v-b}} \left| \frac{\binom{a}{k} \binom{n_{\text{inf}}-a}{w-k}}{\binom{n_{\text{inf}}}{w}} - \frac{\frac{k}{n_T} + \frac{a-k}{n_T} \frac{w-k}{(1-\lambda)n_H - (v-z)(-1)^\lambda}}{\lambda n_H + (v-z)(-1)^\lambda} \right| \quad (\text{S4})$$

$$E(CSP_{vw}) = \sum_{z=\rho}^{m-1} \frac{\binom{n_{\text{inf}}}{z} \binom{n_H}{v-z}}{\binom{n_T}{v} - \sum_{b=0}^{\rho-1} \binom{n_{\text{inf}}}{b} \binom{n_H}{v-b} - \sum_{b=m}^v \binom{n_{\text{inf}}}{b} \binom{n_H}{v-b}} \left| \frac{a}{\lambda n_H + (v-z)(-1)^\lambda} - \frac{n_{\text{inf}} - a}{(1-\lambda)n_H - (v-z)(-1)^\lambda} \right|$$

$$E(CSP_{vw}) = \sum_{z=\rho}^{m-1} \frac{\binom{n_{\text{inf}}}{z} \binom{n_H}{v-z}}{\binom{n_T}{v} - \sum_{b=0}^{\rho-1} \binom{n_{\text{inf}}}{b} \binom{n_H}{v-b} - \sum_{b=m}^v \binom{n_{\text{inf}}}{b} \binom{n_H}{v-b}} \left| \frac{a}{\lambda n_H + (v-z)(-1)^\lambda} - \frac{n_{\text{inf}} - a}{(1-\lambda)n_H - (v-z)(-1)^\lambda} \right| \quad (\text{S5})$$

$$1. \quad \rho = \min(1, v - n_H + 1), m = \min(n_{\text{inf}}, v), a = \min(z, n_{\text{inf}} - z)$$

S7

$$\lambda = \begin{cases} 0 & \text{for } z \leq n_{\text{inf}} - z \\ 1 & \text{for } z > n_{\text{inf}} - z \end{cases} \quad (\text{S6})$$

Figure S7 Cumulative distribution function of the expected value of CSP when taking a host sample of total size $n_T = 200$ which includes $n_{Inf} = 100$ infected hosts and $n_H = 100$ healthy hosts.

1 The condition that z starts from $\rho = \max(1, v - (n_T - n_{Inf}) + 1)$ is necessary to avoid combina-
2 tions where 1) no minor allele is found in the infected subsample, and 2) the healthy sample only
3 consists of hosts with the minor allele. The condition that z has values up to $m - 1$ is necessary to
4 avoid two configurations where 1) none of the minor alleles is found in the non-infected subsam-
5 ple, and 2) all individuals in the infected subsample have the minor allele. For a given host allele
6 combination, we perform the labelling step mentioned above by defining $a = \min(z, n_{Inf} - z)$.
7 Then, we assign the n_{Par} parasites, w of them having the minor allele, to the n_{Inf} host. Here, k is
8 the number of hosts with label 1 which are infected by a parasite with the minor allele ($F_{11} \cdot n_T$).
9 Accordingly, $a - k$ is the number of hosts with label 1 which are infected by a parasite with major
10 allele ($F_{12} \cdot n_T$), $w - k$ is the number of hosts with label 2 which are infected by a parasite with
11 minor allele ($F_{21} \cdot n_T$) and $n_{Inf} - a - (w - k)$ with label 2 which are infected by a parasite with the
12 major allele.

S2. Supplementary figures

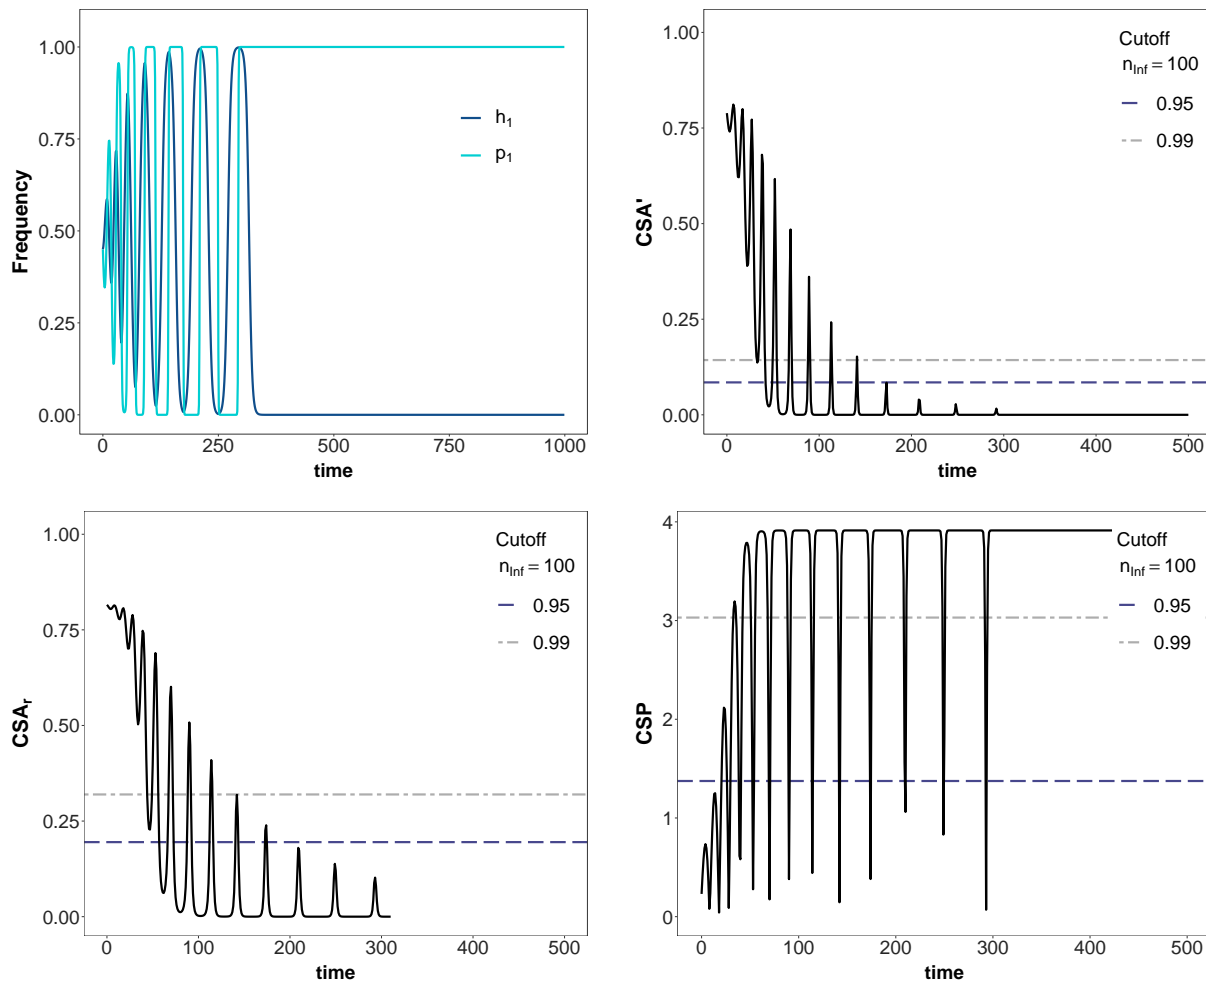

Figure S8 Temporal changes in allele frequencies, CSA' , CSA_r , and CSP in an unstable MA-model (model A) with one parasite generation per host generation. For each index cut-off values are shown based on the expected neutral distributions for a total host sample size $n_T = 200$ and for $n_{inf} = n_H = 100$. The 0.95-cut-off value is shown in blue (dashed line) and the 0.99-cut-off value is shown in grey (dotted-dashed line). Top left: frequencies of h_1 (dark blue) and p_1 (light blue). Top right: CSA' . Bottom left: CSA_r . Bottom right: CSP. The parameters values of the model are: $c_1 = c_2 = 0.9$, $c_{H_1} = c_{P_1} = c_{H_2} = c_{P_2} = 0$, $\phi = 0.8$, $s = 0.35$, $h_{1,init} = p_{1,init} = 0.45$

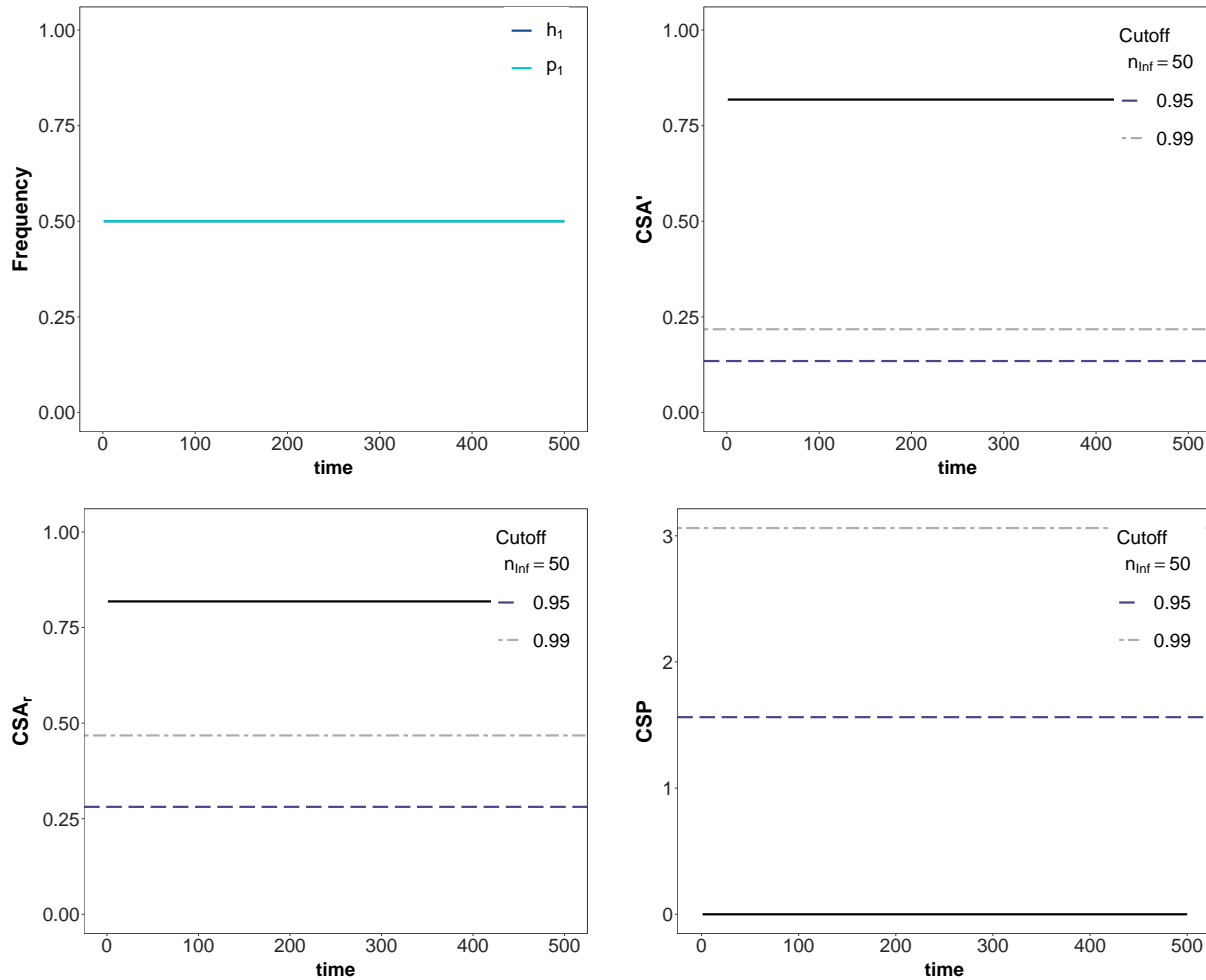

Figure S9 Temporal changes in allele frequencies, CSA' , CSA_r and CSP in an epidemiological model (model B) with a symmetric MA-infection matrix. For each index cut-off values are shown based on the expected neutral distributions for a total host sample size $n_T = 200$ and for $n_{inf} = n_H = 100$. The 0.95-cut-off value is shown in blue (dashed line) and the 0.99-cut-off value is shown in grey (dotted-dashed line). Top left: frequencies of h_1 (dark blue) and p_1 (light blue). Top right: CSA' . Bottom left: CSA_r . Bottom right: CSP. The parameters values of the model are: $c_{H_1} = c_{P_1} = c_{H_2} = c_{P_2} = 0$, $\beta = 0.00005$, $s = 0.6$, $c_1 = c_2 = 0.9$, $S_{1,init} = S_{2,init} = 4150$, $I_{11} = I_{12} = I_{21} = I_{22} = 415$, $\delta_t = 0.001$, $b = 1$, $\gamma = 0.9$

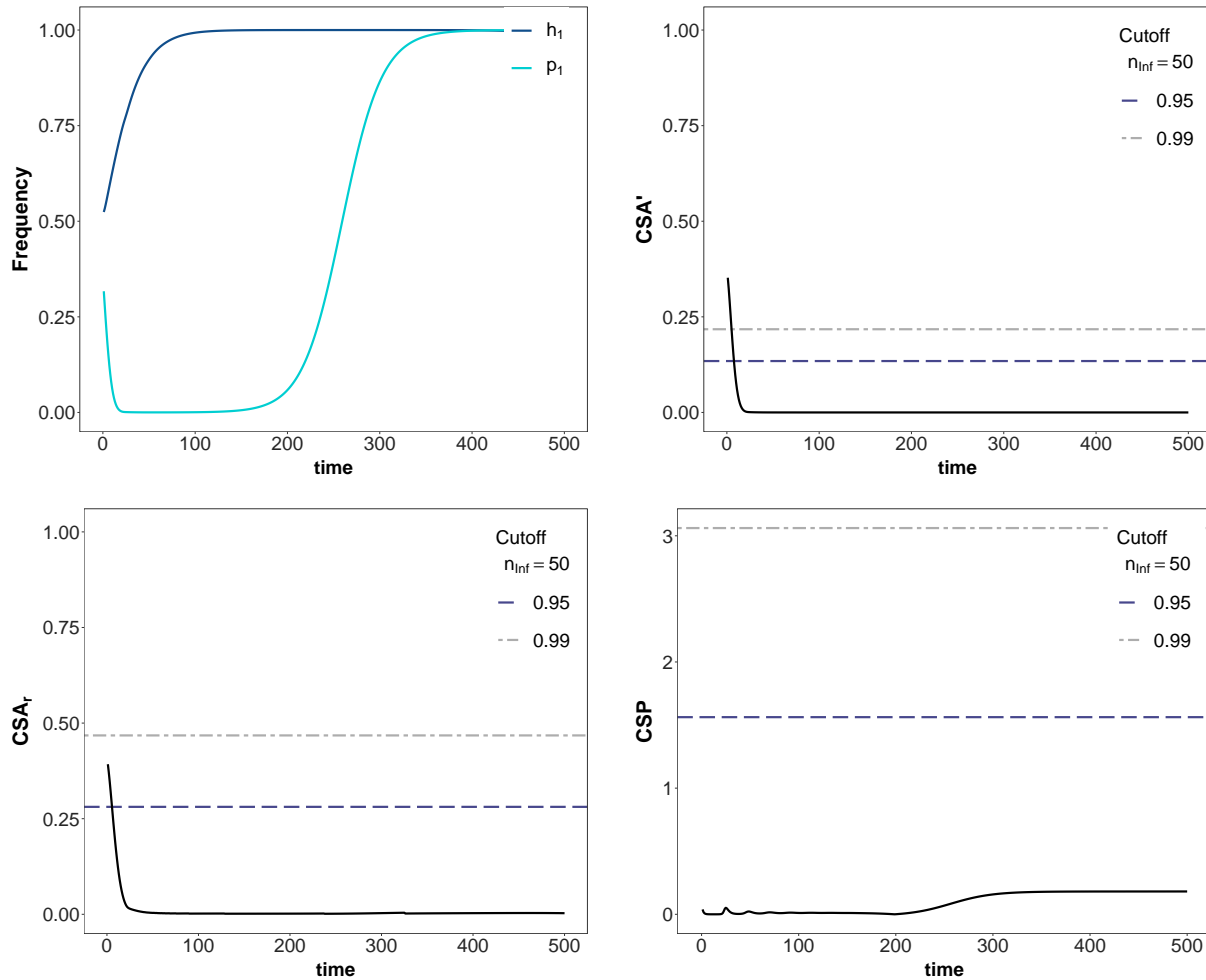

Figure S10 Temporal changes in allele frequencies, CSA' , CSA_r , and CSP an epidemiological (model B) with a GFG-infection matrix. For each index cut-off values are shown based on the expected neutral distributions for a total host sample size $n_T = 200$ and for $n_{inf} = n_H = 100$. The 0.95-cut-off value is shown in blue (dashed line) and the 0.99-cut-off value is shown in grey (dotted-dashed line). Top left: frequencies of h_1 (dark blue) and p_1 (light blue). Top right: CSA' . Bottom left: CSA_r . Bottom right: CSP . The parameters values of the model are: $c_{H_1} = c_{P_1} = 0$, $c_{H_2} = c_{P_2} = 0.05$, $\beta = 0.00005$, $s = 0.6$, $c = 0.9$, $S_{1,init} = S_{2,init} = 4150$, $I_{11} = I_{12} = I_{21} = I_{22} = 415$, $\delta_t = 0.001$, $b = 1$, $\gamma = 0.9$
