6 RUNNING TITLE

7

8 Impact of drought across development is related in bean

9

10 HIGHLIGHT

11

12 In common bean, higher biomass accumulation under drought alone does not guarantee higher  
13 yield, as maintenance of higher growth rates and partitioning processes act as an additional  
14 requirement.

15

16 ABSTRACT

17

18 While drought limits yield largely by its impact on photosynthesis and therefore biomass  
19 accumulation, biomass is not the strongest predictor of yield under drought. Instead, resource  
20 partitioning efficiency, measured by how much total pod weight is contained in seeds at maturity  
21 (Pod Harvest Index), is the stronger correlate in *Phaseolus vulgaris*. Using 20 field-grown  
22 genotypes, we expanded on this finding by pairing yield and resource partitioning data with  
23 growth rates of leaflets and pods. We hypothesized that genotypes which decreased partitioning  
24 and yield most under drought would also have strongest decreases in growth rates. We found that  
25 while neither leaflet nor pod growth rates correlated with seed yield or partitioning, impacts to  
26 leaflet growth rates under drought correlate with impacts to yield and partitioning. As expected,  
27 biomass production correlated with yield, yet correlations between the decreases to these two  
28 traits under drought were even stronger. This suggests that while biomass contributes to yield,  
29 biomass sensitivity to drought is a stronger predictor. Lastly, under drought, genotypes may  
30 achieve similar canopy biomass yet different yields, which can be explained by higher or lower

1 partitioning efficiencies. Our findings suggest that inherent sensitivity to drought may be used as  
2 a predictor of yield.

#### 14 INTRODUCTION

15

16 Among abiotic stresses, drought has the most detrimental impact on seed yield in the common

17 bean (*Phaseolus vulgaris* L.) (Thung and Rao, 1999). While drought limits yield largely by its

18 impact on photosynthesis and therefore canopy biomass accumulation, findings show that

19 increasing canopy biomass alone does not necessarily lead to an increase in seed yield (Shibles

20 and Weber, 1996). Instead, the ability to partition resources efficiently towards reproductive

21 structures appears to provide the stronger increase to seed yield under drought (Omae *et al.*,

22 2012; Polania *et al.*, 2016). In particular, one important correlate is Pod Harvest Index (PHI), a

23 measure of photosynthate mobilization from pods (fruits) into seeds (Assefa *et al.*, 2013). Plants

24 with higher PHI values partition greater amounts of pod biomass into seeds, increasing seed

25 yield and resource use efficiency. This means that while some plants can amass a large amount

26 of canopy biomass under drought, only the ones most efficient at moving, or allocating, those

27 resources into their seeds obtain high yield. This raises the simple yet unanswered question: what

28 makes genotypes differ in their ability to allocate resources toward seed production under

29 drought?

30

1 Organs that accumulate resources from the rest of the plant (sinks) must obtain resources from  
2 other organs that produce or store those resources (sources). Since drought strongly hinders  
3 photosynthesis, this is likely to impair source availability. If a plant is source-limited, typically  
4 due to photosynthetic limitations, there may be too few resources available to allocate to sinks.  
5 However, studies show that seed filling in *Phaseolus vulgaris* is at most only partially coupled  
6 with photosynthesis (Smith, 2017). When source resources are not limiting, the rate at which  
7 they flow between sources and sinks is largely determined by active allocation processes, such as  
8 phloem loading, sugar metabolism, and the sink's ability to take up and utilize these resources  
9 (Farooq *et al.*, 2009). These processes are controlled by signaling as opposed to substrate  
10 availability, although sucrose itself acts as a signal regulating many of these processes (Liu,  
11 Offler, and Ruan 2013). Different sink organs, or the same organ within different genotypes, can  
12 vary widely in the rate at which they metabolize and take up resources, impacting that organ's  
13 ability to attract photosynthate to be delivered to it. For example, *Phaseolus vulgaris* seeds  
14 among different genotypes have been shown to take up sucrose at differing rates, even when  
15 there were no differences in available sucrose in the sap surrounding the seed (Tegeder *et al.*,  
16 2000) and their growth rates have been shown to correlate with activity of enzymes involved in  
17 carbohydrate metabolism, such as invertase and sucrose synthase (Wardlaw, 1990). Since seed  
18 production in *Phaseolus vulgaris* is hindered by drought, even in genotypes with high canopy  
19 biomass, we predicted that susceptible genotypes may be impacted by a weakening of their  
20 ability to take up resources – quantified as sink strength. If true, perhaps whatever signal/s limit  
21 allocation, uptake, or use of resources in seeds may also affect these same processes in growing  
22 leaves or pods.

23

24 A greenhouse experiment showed good correlation between leaf growth rate and seed yield in  
25 *Phaseolus vulgaris* lines (Banan and Van Volkenburgh, 2012). While growth rates are not  
26 necessarily a measure of resource acquisition, especially under water deficit (Muller *et al.*,  
27 2011), we hypothesized that they may act as an approximation for sink strength and drought  
28 sensitivity, such that genotypes whose leaves or pods maintain high growth rates under drought  
29 may also achieve higher seed yields and PHI values. In this study, our objective was to test this  
30 hypothesis by comparing leaflet growth rates (LGR), pod growth rates (PGR), seed yield, and  
31 resource partitioning efficiency (via PHI) to one another and determine drought's impacts on

1 these processes. In this study, the ‘impact’ on a trait specifically refers to the percent decrease in  
2 value between well-watered and droughted plants, where genotypes with larger decreases are  
3 considered more impacted. While many studies have previously compared various lines’  
4 agronomy and phenology in the field (e.g., Beebe et al. 2013; Polania et al. 2016; I. M. Rao et al.  
5 2017; Smith 2017), data on growth rates of pods and leaves collected alongside these  
6 measurements, with quantifications of the impacts to these traits under drought, are lacking. This  
7 study aimed to fill that gap to: 1) understand whether impacts on growth rates and partitioning  
8 efficiency under drought relate to drought resistance (high seed yield) and 2) look at impacts on  
9 growth under drought in different tissue types to better understand systemic drought responses.

10

## 11 MATERIALS & METHODS

12

### 13 *Plant material*

14 We conducted a field study using 19 lines of common bean (*P. vulgaris* L.) and one line of  
15 tepary bean (*P. acutifolius*). These 20 genotypes were chosen to represent a wide range of  
16 observed PHI values in field grown plants (Table 1), providing variability for probing  
17 physiological responses. Sixteen of these genotypes were made up of two RIL (recombinant  
18 inbred lines) populations, including the four parents and 6 RILs from each cross. These RIL  
19 populations were created using parents (MD23-24 x SEA5 – MR RIL) and (BAT881 x G21212 –  
20 BH RIL) which differed in their response to abiotic stress, such that their offspring would mostly  
21 fall between them in traits related to stress resistance, including PHI (Polania *et al.*, 2017; Diaz *et*  
22 *al.*, 2018). The remaining lines, SEN56, INB841, and DOR390, were chosen as routine checks;  
23 DOR390 for drought-sensitivity, INB841 for drought resistance, and SEN56 for high pod  
24 partitioning efficiency. *P. acutifolius* (G40001) was included since it is highly drought tolerant  
25 and has very high PHI.

26

### 27 *Growth environment*

28 Field experiments were carried out at the International Center for Tropical Agriculture (CIAT) in  
29 Palmira, Colombia located at 3° 29” N latitude, 76° 21”W longitude at an altitude of 965m from  
30 July – September of 2018. Characteristics of the field and rain-out shelter trial as well as soil  
31 characteristics were described previously (Polania et al., 2016). Climate data, including

1 minimum and maximum temperature, rainfall, and pan evaporation during the field trails were  
2 collected at 15 min intervals. During the experiment, temperatures ranged between 14.1-37.2 °C,  
3 with a daytime average of 25 °C, average air relative humidity was 78%, average solar radiation  
4 was 500 watt/m<sup>2</sup> and average daylight PAR of 970 μmol m<sup>-2</sup> s<sup>-1</sup>). Total rainfall during the  
5 active crop growth period was 190 mm with potential pan evaporation 469 mm. Irrigation was  
6 maintained in the field for the control treatment, and two drought-stress treatment levels (see  
7 below) were managed under rain-out shelter conditions. The irrigated control treatment received  
8 6 furrow irrigations (each 30 mm of water) together with two rains (55 and 30 mm) to ensure  
9 adequate soil moisture during the season. For replication, all the treatments were split into 3  
10 separate randomized blocks each containing 4 internal columns. Each of these columns was  
11 made up of 20 plots, one for each genotype, which contained 8 individual plants. Each column  
12 had a different, random order of the plots. In total, 12 replicate plots existed per treatment. A  
13 border *Phaseolus vulgaris* genotype ‘Amadeus’ was used at each exterior edge as well as  
14 between columns. The soil is a Mollisol (fine-silty mixed, isohyperthermic Aquic Hapludoll) as  
15 described by the USDA classification system, with no major fertility problems (pH = 7.7). For a  
16 more detailed description, see Beebe et al. 2008 and Rao et al. 2017. All other information  
17 concerning this field experiment was similar to Polania et al., 2016.

18

### 19 *Drought treatment*

20 Two different drought treatments were used to determine the independent effects of water stress  
21 on two different growth processes, leaflet growth rates and pod growth rates. For determining  
22 impacts to leaflet growth rates, water was withheld 10 days before leaflet growth measurements  
23 began at BBCH stage 15-17 (5-7 true leaves unfolded; 27 days after sowing) (Feller *et al.*, 1995).  
24 After 5 consecutive days of leaflet measurements, this early droughted treatment (ED) was re-  
25 watered to 80% of field capacity using 30 mm of water by sprinklers. After this re-watering,  
26 water was again withheld for the remainder of the experiment until the final harvest (69-77 days  
27 after sowing). For determining impacts to pod growth rates, a separate part of the rain-out shelter  
28 remained well-watered throughout canopy development, similarly to the control field, and only  
29 had water withheld 5 days before pod measurements began at BBCH stage 69 (end of flowering,  
30 first pods visible) (Feller *et al.*, 1995) referred to as the late drought treatment (LD). LD plants  
31 continued to have water withheld after pod measurements for the remainder of the experiment

1 until the final harvest (69-77 days after sowing). To prevent any rainfall that might occur from  
2 disrupting either drought condition, ED and LD fields were grown under a rain-out shelter – a  
3 transparent, rolling-roof structure that was positioned over the fields whenever rain threatened  
4 (Fig. 1), otherwise remained open. Each drought treatment (ED and LD) was applied just before  
5 the specific developmental process being measured began (leaf elongation and pod elongation,  
6 respectively) in order to probe that specific process' response to water stress while limiting  
7 impacts to other processes, such as canopy development. A third field was maintained as the  
8 well-watered (WW) treatment, adjacent to the rain-out shelter but not under it. This field was  
9 watered to field capacity every 2-3 days to maintain relatively constant volumetric water content  
10 (Fig. 2). Although the ED plants were only intended for leaflet growth rate measurements  
11 initially, surprisingly high survival allowed for pod growth measurements to be taken on these  
12 plants, as well as yield, PHI, and biomass dry weight. These data are included in some analyses.

13

#### 14 *Growth rates*

15 During canopy development, when the plants were 3.5 weeks old, leaflet growth rates were  
16 measured from 3 replicate plots per treatment in both WW and ED conditions. Within each of  
17 these plots, 3 individual plants were selected, for a total of 9 replicates per treatment. For each  
18 replicate, a terminal leaflet between the length of 40-70 mm, around 30-50% fully expanded  
19 (corresponding to the start of linear elongation phase, data not shown), was tagged and blade  
20 length from base to tip was measured using a ruler and recorded. Length measurements of the  
21 same leaflet continued for a total of 5 consecutive days, each measurement taken 24 hours apart.

22

23 For pod growth rates in all three conditions, 3 individual plants were also chosen per each of  
24 three plots, and the very first and second pods which developed on each individual plant were  
25 marked. Pod lengths from base to tip were measured with a ruler daily. Measurements began  
26 when pod lengths were between 10-20 mm and continued for 3-6 consecutive days, each  
27 measurement taken 24 hours apart.

28

#### 29 *Water potential*

30 During the week of leaflet length measurements, water potential only for plants in ED and WW  
31 conditions was measured (since the LD condition had not yet entered its drought condition,

1 therefore was identical to the WW treatment, data not shown). During the week of pod  
2 elongation measurements, water potential for ED, LD and WW were all measured. An individual  
3 leaf per plot was measured for each genotype, and this was repeated across two blocks. This  
4 resulted in 2 measurements per genotype per treatment. These replicates came from different  
5 plants than those marked for growth rate measurements. Near fully-expanded terminal leaflets  
6 near the top of the canopy were selected and cut at the furthest end of their petiolule from the  
7 leaflet blade using a razor blade. The leaflet was quickly put into a humid plastic bag and stored  
8 in the dark on ice until the measurement was determined, no longer than 10 minutes after cutting.  
9 Leaf water potential was taken using established protocols for a Scholander pressure chamber  
10 with a compression gasket system (model 615, PMS Instrument Co., USA). For midday  
11 measurements, leaves were collected between 1400-1600. Pre-dawn measurements were made  
12 with the same procedure between 0530-0800.

13

#### 14 *Solute potential*

15 After each leaflet's water potential was measured, it was individually placed into a 2 ml  
16 Eppendorf tube and stored on ice until placed into a -20C freezer. Later, solute potential was  
17 determined using established protocols with a vapor pressure osmometer (model 5100B, Wescor  
18 Inc., USA). Samples were thawed for 20 minutes, exposed to remove condensation, and slightly  
19 pressed between two microscope glass slides to release sap which was then measured. Three  
20 measurements were taken per sample and averaged.

21

#### 22 *Yield, PHI, Biomass*

23 Upon physiological maturity, 3 consecutive plants were destructively harvested from each of 6-  
24 13 replicate plots. All dry seeds from these 3 plants were weighed together then divided by 3 to  
25 give dry seed yield per plant. Whole pod dry weight (including seeds) was also determined for  
26 the same 3 plants together in each plot and PHI was calculated per each replicate plot using  
27 equation 1.

28

29 *Equation 1. Pod Harvest Index* = 
$$\frac{\text{seed biomass dry weight at harvest}}{\text{whole pod biomass dry weight at harvest}} \times 100$$

30

1 Whole canopy (above-ground) dry biomass was averaged for the same 3 plants weighed together  
2 from each plot.

3

#### 4 *Statistical analysis*

5 Linear regression correlations were made between traits which were then tested for statistical  
6 significance via the student's t-test using Microsoft Excel (one-tailed, unpaired) alpha = 0.05  
7 level of significance. Graphs represent mean values  $\pm$  standard deviation.

8

9 When describing results, absolute values and impacts are reported, where absolute values refer to  
10 actual recorded values, whereas impacts refers to a calculated percent decrease between the  
11 droughted and WW values for a trait (equation 2). The genotypes that decreased by a larger  
12 percentage were considered to be more impacted and drought sensitive.

13

14 *Equation 2. Percent decrease in growth rate* =  $\frac{\text{WW growth rate} - \text{WS growth rate}}{\text{WW growth rate}} \times 100$

15

## 16 RESULTS

17

### 18 *Leaf water potential and solute potential*

19 To quantify internal water status within the plants, leaf water potential was measured predawn  
20 and midday. Measurements were taken over multiple days and values from 2 or 3 days of  
21 measurements were averaged by condition and graphed by week (Fig. 3A). As intended, when  
22 all genotypes were averaged together, water potential values were significantly lower in water-  
23 stressed conditions compared with WW, showing the drought condition resulted in water deficit  
24 compared to WW. This was true for all pre-dawn and midday WW to water-stressed  
25 comparisons.

26

27 When each genotype was looked at individually, grouped by treatment and time point, difference  
28 among genotypes within a condition/timepoint ranged from -0.31 MPa (for WW/week of leaflet  
29 elongation, which had the most similar values between genotypes) to -0.54 MPa (for LD/week of  
30 pod elongation, which had the most different values between genotypes). Even though variation  
31 existed in leaf water potential between genotypes, leaf water potential value by genotype did not

1 correlate with the other physiological or agronomic traits measured for that genotype, such as  
2 leaflet and pod growth rates, biomass and PHI (PHI shown). This suggests that maintaining  
3 higher (closer to zero) leaf water potential values did not result in faster growing leaflets or pods,  
4 nor with higher seed yield, PHI or canopy biomass. Among the individual genotypes, there was  
5 also a range in how impacted they were by drought. When values were compared between ED  
6 and WW during the week of leaflet elongation, some genotypes had little to no decrease in water  
7 potential, while others decreased by close to 50% of the WW values. However, as with the  
8 absolute water potential values, genotypes whose water potential was most impacted by drought  
9 were not the same genotypes whose growth rates, PHI, yield, or biomass were most impacted  
10 (data not shown).

11  
12 Solute potential trends were similar to water potential, with values typically decreasing between  
13 droughted and WW (ED for leaflet measurement week, LD for pod measurement week) (Fig.  
14 3B). One notable difference is that solute potential of LD vs WW during the week of pod  
15 measurements were not different from each other. Lastly, as with water potential values, solute  
16 potential values and impacts to solute potential values did not correlate with growth or other  
17 agronomic traits nor the impacts to growth or agronomic traits, respectively.

### 18 19 *Leaflet and pod growth rates*

20 As expected, most leaflet growth rates (measured in the ED condition) were significantly  
21 impacted by drought, however, fewer pod growth rates (measured in the LD condition) were  
22 significantly impacted. Leaflet growth rates always decreased between ED and WW, but the  
23 amount of decrease varied widely by genotype, ranging from 3% to 46% (Fig. 4A). All decreases  
24 of 20% or more were significant, which was the case for 16 of the 20 genotypes. Pod growth  
25 rates also typically decreased between LD and WW treatments, by around 2% to 45%, although  
26 for three genotypes (MR116, INB841, and BH50), pod growth rates increased under LD (Fig  
27 4B). Of those three, only increases in BH50 were significant. Impacts to pod growth rates were  
28 only significant for 7 of the 20 genotypes. Yet, since both leaflet and pod growth rates decreased  
29 by similar extents, we hypothesized that genotypes whose leaflet growth rates were most  
30 impacted would also have the most impacted pod growth rates. This would have suggested that  
31 drought impacts growth processes in different tissues in a common or conserved way. However,

1 the degree to which these different tissue types were impacted was not consistent across  
2 genotypes; genotypes whose leaflet growth rates decreased the most under drought did not have  
3 pods whose growth rates decreased most. Instead, these two growth rates seemed to be  
4 independently impacted by drought stress within a genotype (Fig. 4 inset).

#### 6 *Growth rates and seed yield*

7 Leaflet growth rates had a weak but significant correlation with yield under WW. However,  
8 neither leaflet growth rate nor pod growth rates were correlated with yield under WS conditions,  
9 nor was there correlation between pod growth rates and yield under WW conditions (Fig. 5A and  
10 B). ). Instead, the impact of drought on leaflet growth rate was better correlated with the impact  
11 of drought on yield. Specifically, we found that the genotypes whose leaflet growth rates were  
12 most impacted by drought (compared between ED:WW) also tended to have seed yield highly  
13 impacted (compared between LD:WW). This was true among the 19 *P. vulgaris* genotypes (Fig.  
14 5C). Interesting, while *P. acutifolius* had very low impact on yield under WS as expected, leaf  
15 growth rate was highly impacted, showing that leaf growth and yield impacts in this species are  
16 more decoupled. Unlike leaflet growth rates, pod growth rate sensitivity to drought did not  
17 correlate with yield decreases under drought stress (Fig. 5D).

18  
19  
20 Furthermore, genotypes with the highest leaflet growth rates under WW conditions (BH50, BH9,  
21 and BAT881) were the most impacted under ED (Fig. 6). This result, in combination with the  
22 fact that these genotypes also experienced strong decreases in yield under LD (95%, 88% and  
23 93%, respectively), suggests that genotypes with the fastest LGR under WW conditions are at  
24 high risk of negative impact to leaflet growth rates and seed yield under drought. However,  
25 genotypes with the fastest growing pods under WW conditions did not have pod growth rates  
26 that were most impacted under LD (data not shown –  $R^2=0.08$ ).

#### 28 *PHI*

29 Under WW, average PHI values ranged from 0.74 to 0.83, with few significant differences  
30 among genotypes. However, under LD, average PHI values ranged from 0.47 to 0.78 and under  
31 ED even wider, from 0.24 to 0.77 (Fig. 7). While differences amongst WW genotypes were

1 small and rarely significant, larger differences existed amongst both the ED and the LD  
2 genotypes individually, as well as differences between each drought condition and WW for most  
3 genotypes. Although significant decreases between WW to ED and LD existed for most  
4 genotypes, the amount of difference between droughted and WW values varied widely by  
5 genotype from 0.02 to 0.31 under ED and 0.03 to 0.54 under LD. The genotype with not only  
6 one of the highest PHI values under WW but also the least impacts to PHI under either drought  
7 condition was G40001, *P. acutifolius*, which was included because it was known to maintain  
8 high PHI under drought.

9  
10 When PHI values were compared against LGR and PGR, no significant correlations were found  
11 in either WW or WS conditions, nor impacts to these values between well-watered to water  
12 stressed (data not shown).

13

#### 14 *PHI and yield*

15 Studies from CIAT consistently show PHI correlates more strongly with seed yield under  
16 drought and well-watered conditions than biomass, with these correlations typically strongest in  
17 droughted plants over those growing in WW conditions (Rao *et al.*, 2017). In our study, PHI did  
18 not correlate with yield under WW conditions, however, under water deficit the relationship  
19 between PHI and yield was high, as expected, with significant positive correlation under LD  
20 conditions (Fig. 8A). Likewise, decreased in PHI and yield under LD have significant positive  
21 correlation (Fig. 8B).

22

#### 23 *Canopy biomass and seed yield*

24 While canopy biomass was correlated with seed yield under LD conditions (data not shown –  $R^2$   
25 = 0.59), the correlations between the impacts on these two traits were even higher. Specifically,  
26 impact on canopy biomass under LD correlated more strongly with seed yield than any other trait  
27 (Fig. 9); those plants with the largest decreases in canopy biomass also had the largest decreases  
28 in seed yield. This suggests that while biomass itself is a large contributor to seed yield potential,  
29 the relative sensitivity of a plant's biomass accumulation to drought was a better predictor of  
30 yield over absolute values of biomass itself.

31

## 1 DISCUSSION

2

3 As intended, both ED and LD water-stress conditions resulted in water deficits within the plants  
4 when compared to WW. Surprisingly, leaf water status did not seem to play a direct role in  
5 limiting growth and yield, since neither leaf water potential nor solute potential values correlated  
6 with growth rates, canopy biomass, PHI or yield. Nor were genotypes whose water or solute  
7 potentials were the most impacted by drought the same genotypes whose growth rates, canopy  
8 biomass or PHI were the most impacted. This suggests that leaflet and pod elongation, biomass  
9 accumulation, and resource partitioning are not limited directly by low leaf water potential, since  
10 genotypes with the lowest leaf water potential did not have lowest values in the above-mentioned  
11 traits.

12

13 Impacts of drought on leaflet and pod growth rates within each genotype were uncoupled,  
14 meaning genotypes whose leaflet growth rates decreased the most (under ED – Fig. 4A) were not  
15 the same as those whose pod growth rates decreased most (under LD – Fig. 4B). Although we  
16 had predicted drought responses across tissue types would be similar, due to conserved drought-  
17 sensitivity mechanisms, we found leaflet growth rate impacts could not be used as an indicator of  
18 how pod growth rates would be impacted (Fig. 4 inset). This could be due to the fact that under  
19 drought, tissues types become water stressed at different rates, with pods and seeds being the last  
20 impacted (Westgate and Grant, 1989). Pods may be buffered from this stress because of the  
21 critical role they play in survival which may allow growth processes to be less affected in pods.  
22 Meanwhile in leaves, which are experiencing stronger water deficit, drought signals such as  
23 abscisic acid (ABA) may be hindering growth. And while ABA can limit photosynthesis,  
24 through causing stomata to close, ABA accumulation also signals inhibition of wall loosening  
25 and cell growth in growing leaves, which could separate this phenomenon from substrate  
26 limitation (Davies and Van Volkenburgh, 1983). Drought signals may still affect leaflet and pod  
27 tissues similarly, but pods in our study may not have experienced the same level of stress as  
28 leaves. Future work could dissect this with measurements of water potential in these different  
29 tissues as well as through quantification of stress indicators within them, including ABA levels  
30 or dehydrin accumulation etc.

31

1 We predicted that leaflet and pod growth rates would correlate with seed yield and partitioning  
2 efficiency (PHI). We found that while leaflet and pod growth rates themselves did not correlate  
3 with partitioning or yield under water deficit, the sensitivity of leaflet growth rate to drought did  
4 predict the sensitivity of yield to drought. In other words, genotypes whose leaflet growth rates  
5 were most impacted by drought in comparison to control had yields most impacted as well. We  
6 had predicted that genotypes which were able to maintain higher LGR under drought may do so  
7 via maintenance of high sink strength in leaves. This in turn could allow them to maintain higher  
8 pod growth rates and seed filling, which would ultimately lead to higher yield. This hypothesis  
9 was based on published results where terminal drought tolerance was explained by higher  
10 efficiency of carbon mobilization from leaves to pods and seeds (Cuellar-Ortiz *et al.*, 2008;  
11 Rosales *et al.*, 2012). This does not appear to be true when looking at absolute values of growth  
12 rates and yield, as some high yielders had lower leaflet and pod growth rates (Fig. 5A & 5B). Yet  
13 it does appear true in terms of sink strength sensitivity, where impacts to leaflet growth and yield  
14 seem to be linked by a conserved mechanism affecting processes related to sink strength (Fig.  
15 5C). These data suggest that relative LGR sensitivity to drought may act as a good predictor of  
16 overall drought resistance.

17  
18 Unsurprisingly, given that LGR and PGR within a genotype were not similarly impacted by  
19 drought, PGR impacts under LD were not a good predictor of yield (Fig. 5D), which is the  
20 opposite of the result under LGR. This could again be because the pod is buffered from water  
21 stress, separating its response from other sink tissues. However, for the ED treatment, absolute  
22 PGR and yield did have a significantly positive correlation. Since we only saw this to be true  
23 under ED, we believe this could mean that more severe stress (especially when it leads to large  
24 impacts to biomass, as it did in the ED treatment) impacts PGR due to lack of resources, whereas  
25 under the LD treatment, genotypes that slowed most did so due to a stronger response to drought  
26 signaling or status, rather than a lack of substrate.

27  
28 Unlike leaflet and pod growth rates, canopy biomass values did correlate strongly with seed yield  
29 under both WW and LD conditions. Yet, stronger still were correlations between impacts to  
30 biomass and impacts to yield under LD (Fig. 9). This again supports the above-mentioned  
31 hypothesis that genotype sensitivity to drought may be its strongest predictor of yield under

1 drought. Yet, particularly under LD conditions, genotypes in this study which achieved a similar  
2 biomass displayed a range of yields, with some genotypes differing even up to 80%. Therefore,  
3 while the correlations show that higher biomass is necessary to achieving higher seed yield under  
4 drought stress, as has been shown previously, (Polania et al. 2017; I. M. Rao et al. 2017),  
5 reductions in canopy biomass alone does not fully answer the question as to what results in  
6 reduction of yield under drought.

7  
8 Therefore, based on previous findings that PHI is the best predictor of yield, we assessed  
9 whether PHI values help to account for differences in yield when biomass could not. First, we  
10 tested correlations between PHI and yield under the three conditions. We found that PHI did not  
11 correlate with yield under WW conditions. However, we did find correlations under ED  
12 conditions and even higher under LD conditions (Fig. 8A). We also found that impacts to yield  
13 and PHI between LD and WW correlated significantly (Fig. 8B) Beyond testing how PHI alone  
14 related to yield, we wanted to know whether differences in PHI could be used to better  
15 understand how genotypes can acquire the same canopy biomass yet achieve different yields.  
16 Indeed, we found they could. For example, under LD, average canopy biomass ranged from 20-  
17 55g per plant, depending on genotype. As mentioned above, within that range, genotypes whose  
18 canopy biomass were the same could vary by 80% in their yield. Specifically, genotypes MR81  
19 and BH45 had very similar high average canopy biomass under LD – around 43g. Yet while  
20 MR81 yielded second highest of all the genotypes under LD, with 6.72g dry seed weight, BH45  
21 was on the lower end of the yield spectrum with only 1.25g. If 6.72g is considered 100% of the  
22 potential yield possible for this canopy biomass, a yield of 1.25g is only 19% of that potential.  
23 When we paired this finding with PHI values for these genotypes, the differences in yield  
24 between the two could be explained by differences in their partitioning efficiency, with MR81  
25 maintaining a high PHI of 0.76 while BH45 had a much-reduced value of 0.58 (Fig. 7).

26  
27 Our results help to tease apart systemic and tissue-specific responses to drought and to  
28 understand how impacts to different growth or partitioning processes under drought relate to  
29 yield. While our results did not support the prediction that leaflet and pod growth rates predict  
30 seed yield, our findings together suggest that inherent differences in partitioning efficiencies and  
31 drought sensitivity may underlie a mechanism for drought resistance shared across stages of

1 plant development. Future work will explore physiological mechanisms regulating leaflet growth  
2 and PHI, and how they are impacted under drought, to better understand this mechanism. While  
3 this study does not indicate clear physiological mechanisms to answer the question of what  
4 allows for filling of seeds in tolerant lines under drought, there are valuable agricultural insights.  
5 Plants with fastest leaflet growth had highest negative impacts on their leaflet growth under ED.  
6 Those genotypes whose leaflet growth rates were most impacted also had yields most impacted.  
7 Gaining a deeper understanding of how drought sensitivity impacts a plant's whole life cycle  
8 (from canopy development, to flowering and pod production, to seed filling and maturation) may  
9 allow for larger gains in efficiency in yield.

10

11 Many crops whose yield has improved during the green revolution did so not by increasing their  
12 total production, but instead by partitioning a greater amount of resources to yield (Wardlaw,  
13 1990). For example, rice and wheat yield went from having 30% of total biomass in yield at  
14 maturity to 50% in the 1960s (Khush, 1999). *Phaseolus vulgaris* yield partitioning efficiency on  
15 the other hand, has yet to see similar improvements as common bean maintains the ancestral trait  
16 of delayed seed production under drought (Beebe *et al.*, 2008, 2013). The observation that  
17 partitioning appears to limit yield under drought might fuel work to attain further improvements  
18 to partitioning in *Phaseolus vulgaris*. Gaining a deeper understanding of how partitioning is  
19 impacted by drought may allow for larger genetic gains in efficiency in this trait.

20

21 This research has the potential to increase basic understanding of plant physiology and to  
22 improve crop yields. Climate change (particularly change in precipitation distribution) is  
23 affecting soil fertility and soil water availability. In Colombia, 80% of *Phaseolus vulgaris*  
24 smallholders' production is intended for national consumption. However, with much of the  
25 production under rainfed conditions on smallholder farms, yields are increasingly threatened.  
26 Over the past decades, the *Phaseolus vulgaris* breeding program in CIAT succeeded in  
27 identifying genotypes with increased resistance to drought, yet the mechanisms which contribute  
28 to this resistance aren't fully understood. By identifying physiological traits to assist in  
29 developing improved *Phaseolus vulgaris* cultivars, this work attempts to contribute to more  
30 stable yields and food security. Discoveries on sink strength in common bean may also help to  
31 uncover common mechanisms shared by other crops, increasing the impact of our findings.

## ACKNOWLEDGMENTS

We thank Dr. Idupulapati Rao, Dr. Steve Beebe, and Dr. Maria Reguera for invaluable discussions and input leading to this project. Our thanks also to Jose Polania and to the field team at CIAT for their work and dedication. We wish to recognize the USAID project “Bean Improvement for Tropical Producers and Consumers: Tomorrow and Beyond” and the TL-3 Project “Improving Livelihoods for Smallholder Farmers: Enhanced Grain Legume Productivity and Production in Sub-Saharan Africa and South Asia” for funding, as well as the Department of Biology at the University of Washington for travel funds making this research possible.

## LEGENDS

Table 1. Growth type (2A = indeterminate bush habit, erect stems without guide; 2B = indeterminate bush habit, erect stems with guide, tendency to climb; 3B = indeterminate bush habit with weak mainstem and with prostrate branches, short guide, not tendency to climb). Seed color (1 = white; 2 = cream-beige; 3 = yellow; 4 = brown-maroon; 5 = pink; 6 = red; 7 = purple; 8 = black). Seed size, based on the weight of 100 seeds (1 = small, < 25 g; 2 = middle, 25-40 g; 3 = big, > 40 g)

Fig. 1. Photograph of the field and rain-out shelter, closed

Fig. 2. Average soil water content at different depths across the three conditions; Early Drought, Late Drought and Well-watered. Water content in depths from 0-100 cm were monitored three times daily across the three conditions, averaged, and plotted over the course of the experiment.

Fig. 3. Average leaf water potential (A) and solute potential (B) at predawn or midday during the two weeks of growth measurements. ‘Leaf week’ refers to when leaflet growth rate measurements were taken, ‘Pod week’ when pod growth rates were taken. All bars represent the average across all 20 genotypes, using 2 or 3 measurements per genotype. Error bars show standard error.

Fig. 4. Impacts of drought on leaflet growth rates (A) and pod growth rates (B) by genotype. Impact is shown as percentage decrease in rate between Well-watered (WW) and droughted; early drought (ED) for leaflet growth rate impacts and late drought (LD) for pod growth rate impacts. A negative percent decrease, as occurred for four genotypes in B, indicates an increase in rate under LD compared to WW. Inset shows correlation between impact of drought on leaflet and pod growth rates.

Fig. 5. Correlations between yield and growth rates. In A, correlations were tested between average WW leaflet growth rate and WW yield (blue) and ED average leaflet growth rates and LD yield (orange). B shows the same but for pod growth rates and yield under LD (yellow). In A

and B, circles denote WW and squares represent water stressed. C and D tested correlations between impacts to yield (percent decreases between LD and WW) and (C) impacts to leaflet growth rates (percent decrease between ED and WW) or (D) impacts to pod growth rates (between LD and WW). Note that in A and C, ED leaflet growth was compared to LD yield, whereas in B and D, LD pod growth was compared to LD yield.

Fig. 6. Correlation between WW leaflet growth rates and impacts to leaflet growth rates

Fig. 7. PHI values for all 20 genotypes under WW (blue), ED (orange), and LD (yellow) conditions. Genotypes have been ordered in ascending order based on LD PHI values. Error bars show standard error.

Fig. 8. Correlations between yield and PHI. In A, correlations were tested between absolute yield and PHI under WW (blue) and LD (yellow) for the 20 genotypes. B shows correlations between impacts to these two traits comparing between LD to WW.

Fig. 9. Correlation between impacts to yield and biomass between LD and WW conditions.
