# **Abstract**

Reactivation of earlier perceptual activity is thought to underlie long-term memory recall. Despite evidence for 9 this view, it is unknown whether mnemonic activity exhibits the same tuning properties as feedforward perceptual 10 activity. Here, we leveraged population receptive field models to parameterize fMRI activity in human visual cortex 11 during spatial memory retrieval. Though retinotopic organization was present during both perception and memory, 12 large systematic differences in tuning were also evident. Notably, whereas there was a three-fold decline in spatial 13 precision from early to late visual areas during perception, this property was entirely abolished during memory 14 retrieval. This difference could not be explained by reduced signal-to-noise or poor performance on memory 15 trials. Instead, by simulating top-down activity in a network model of cortex, we demonstrate that this property is 16 well-explained by the hierarchical structure of the visual system. Our results provide insight into the computational 17 constraints governing memory reactivation in sensory cortex. 18

*Keywords*: episodic memory, spatial memory, reinstatement, reactivation, visual cortex, population receptive field, hierarchical model

# 22 Introduction

Episodic memory retrieval allows humans to bring to mind the details of a previous experience. This process is 23 hypothesized to involve reactivating sensory activity that was evoked during the initial event (James, 1890; Hebb, 24 1968; Damasio, 1989; McClelland et al., 1995). For example, remembering a friend's face is thought to involve 25 reactivating neural activity that was present when seeing that face. There is considerable evidence from human 26 neuroimaging demonstrating that the same visual cortical areas active during perception are also active during 27 imagery and long-term memory retrieval (Kosslyn et al., 1995; O'Craven & Kanwisher, 2000; Wheeler et al., 2000; 28 Slotnick et al., 2005; Polyn et al., 2005; Kuhl et al., 2011; Bosch et al., 2014; Waldhauser et al., 2016; Lee et al., 29 2018; Bone et al., 2018). These studies have found that mnemonic activity in early visual areas like V1 reflects 30 the low-level visual features of remembered stimuli, such as spatial location and orientation (Kosslyn et al., 1995; 31 Thirion et al., 2006; Bosch et al., 2014; Naselaris et al., 2015; Sutterer et al., 2019). Likewise, category-selective 32 activity in high-level visual areas like FFA and PPA is observed when subjects remember or imagine faces and 33 houses (O'Craven & Kanwisher, 2000; Polyn et al., 2005). The strength and pattern of visual cortex activity has 34 been associated with retrieval success in memory tasks (Kuhl et al., 2011, 2013; Gordon et al., 2014), suggesting 35 that cortical reactivation is relevant for behavior. 36

These studies, and many others, have established similarities between the neural substrates of visual perception and visual memory. However, relatively less attention has been paid to identifying and explaining *differences* between activity patterns evoked during perception and memory. In the present work, we asked the following question: which properties of stimulus-driven activity are reproduced in visual cortex during memory retrieval and which are not? The extreme possibility—that all neurons in the visual system produce identical responses when perceiving vs remembering a given stimulus—can likely be rejected. Early studies demonstrated that sensory

responses were reduced during memory retrieval relative to perception (Wheeler et al., 2000), and perception and 43 memory give rise to distinct subjective experiences. A more plausible proposal is that visual memory functions as a 44 "weak" version of feedforward perception (Pearson et al., 2015; Pearson, 2019), with memory activity organized in 45 the same fundamental way as perceptual activity, but with reduced signal-to-noise. This hypothesis is consistent 46 with informal comparisons between perception and memory BOLD amplitudes and data suggesting that visual 47 imagery produces similar behavioral effects to weak physical stimuli in many tasks (Ishai & Sagi, 1995; Pearson 48 et al., 2008; Tartaglia et al., 2009; Winawer et al., 2010). A third possibility is that memory reactivation differs from 49 stimulus-driven activation in predictable and systematic ways beyond signal-to-noise. Such differences could arise 50 due to a change in the neural populations recruited, a change in those populations' response properties, or a 51 systematic loss of information during sensory encoding or post-sensory processing. 52 One way to adjudicate between these possibilities is to make use of models from visual neuroscience that 53 quantitatively parameterize the relationship between stimulus properties and the BOLD response. In the spatial 54 domain, population receptive field models (pRF) define a 2D receptive field that transforms stimulus position on the 55 retina to a voxel's BOLD response (Dumoulin & Wandell, 2008; Wandell & Winawer, 2015). These models are based 56 on well-understood physiological properties of the primate visual system and account for a large amount of variance 57

in the BOLD signal observed in human visual cortex during perception (Kay et al., 2013b). Using these models to
 quantify memory-evoked activity in the visual system offers the opportunity to precisely model the properties of
 memory reactivation in visual cortex and their relationship to visual activation. In particular, the fact that pRF models
 describe neural activity in terms of stimulus properties may aid in interpreting differences between perception and
 memory activity patterns by projecting these differences onto a small number of interpretable physical dimensions.

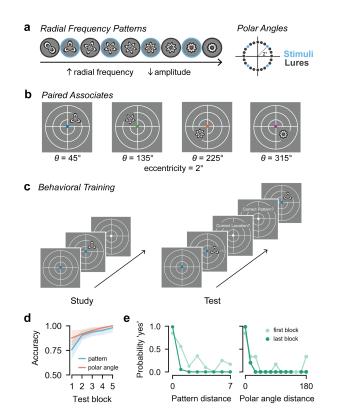

Here, we used pRF models to characterize the spatial tuning properties of mnemonic activity in human visual 63 cortex. We first trained human subjects to associate spatially localized stimuli with colored fixation cues. We then 64 measured stimulus-evoked and memory-evoked activity in visual cortex using fMRI. Separately, we fit pRF models 65 to independent fMRI data, which allowed us to estimate receptive field location and size within multiple visual field 66 maps for each subject. Using pRF-based analyses, we quantified the location, amplitude, and precision of neural 67 activity within these visual field maps during perception and memory retrieval. Finally, we explored the cortical 68 computations that could account for our observations by simulating neural responses using a stimulus-referred pRF 69 model and a hierarchical model of neocortex. 70

# 71 Results

# 72 Behavior

Prior to being scanned, subjects participated in a behavioral training session. During this session, subjects 73 learned to associate four colored fixation dot cues with four stimuli. The four stimuli were unique radial frequency 74 patterns presented at 45, 135, 225, or 315 degrees of polar angle and 2 degrees of eccentricity (Fig. 1a,b). 75 Subjects alternated between study and test blocks (Fig. 1c). During study blocks, subjects were presented with the 76 associations. During test blocks, subjects were presented with the cues and had to detect the associated stimulus 77 pattern and polar angle location among similar lures (Fig. 1a,c; see Methods). All subjects completed a minimum of 78 4 test blocks (mean = 4.33, range = 4-5), and continued the task until they reached 95% accuracy. Subjects' overall 79 performance improved over the course of training session (Fig. 1d). In particular, subjects showed improvements in 80 the ability to reject similar lures from the first to the last test block (Fig. 1e). 81

After subjects completed the behavioral training session, we collected fMRI data while subjects viewed and 82 recalled the stimuli (Fig. 2a). During fMRI perception runs, subjects fixated on the central fixation dot cues and 83 viewed the four stimuli in their learned spatial locations. Subjects performed a one-back task to encourage covert 84 attention to the stimuli. Subjects were highly accurate at detecting repeated stimuli (mean = 86.9%, range = 85 79.4%-93.2%). During fMRI memory runs, subjects fixated on the central fixation dot cues and recalled the 86 associated stimuli in their spatial locations. On each trial, subjects made a judgment about the subjective vividness 87 of their memory. Subjects reported that they experienced vivid memory on an average of 89.8% of trials (range: 88 72.4%-99.5%), weak memory on 8.9% of trials (0.5%-25.0%), and no memory on 1.2% of trials (0.5%-2.6%). 89

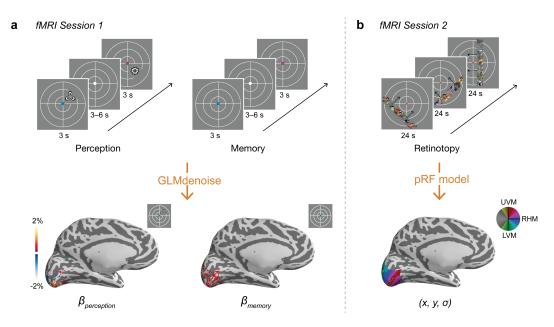

**Figure 1. Stimuli and behavioral training. (a)** The four radial frequency patterns and polar angle locations used in the fMRI experiment are outlined in blue. The intervening patterns and locations were used as lures during the behavioral training session. (b) Immediately prior to the scan, subjects learned that each of four colored fixation dot cues was associated with a unique radial frequency pattern that appeared at a unique location in the visual field. (c) During training, subjects alternated between study and test blocks. During study blocks, subjects were presented with the associations while maintaining central fixation. During test blocks, subjects were presented with the cues followed by test probes while maintaining central fixation. Subjects gave yes/no responses to whether the test probe was presented at the target polar angle and whether it was the target pattern. (d) Accuracy of pattern and polar angle responses improved over the course of the training session. Lines indicate average accuracy across subjects. Shaded region indicates 95% confidence interval. (e) Memory performance became more precise from the first to the last test block. During the first block, false alarms were high for stimuli similar to the target. These instances decreased by the last test block. Dots indicates probability of a 'yes' response for all trials and subjects in either the first or last block. The x axis is organized such that zero corresponds to the target and increasing values correspond to lures more dissimilar to the target.

### <sup>90</sup> Memory reactivation is spatially organized

We used a GLM to estimate the BOLD response evoked by seeing and remembering each of the four spatially 91 localized stimuli (Fig. 2a; see Methods). Separately, each subject participated in a retinotopic mapping session. 92 We fit pRF models to these data to estimate pRF locations (x, y) and sizes  $(\sigma)$  in multiple visual areas (Fig 2b). To 93 more easily compare perception- and memory-evoked activity across visual areas, we transformed these responses 94 from cortical surface coordinates into visual field coordinates using the pRF parameters. For each subject, ROI, 95 and stimulus, we plotted the amplitude of the evoked response at the visual field position (x, y) estimated by the 96 pRF model (Fig. 3a). We then interpolated these values over 2D space, z-scored the values, rotated all stimulus 97 responses to the same polar angle, and averaged across stimuli and subjects (see Methods). These plots are useful 98 for comparison across regions because they show the organization of the BOLD response in a common space that 99 is undistorted by the size and magnification differences present in cortex. 100 We generated these visual field plots for V1, V2, and V3 as an initial way to visualize the evoked responses

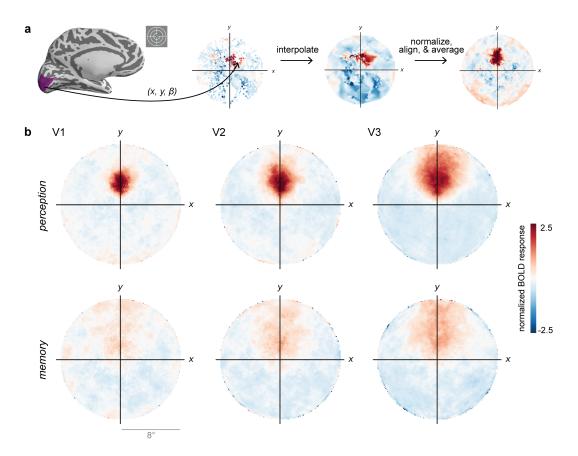

We generated these visual field plots for V1, V2, and V3 as an initial way to visualize the evoked responses during perception and memory. Readily apparent is the fact that stimulus-evoked responses during perception were robust and spatially-specific (Fig. 3b, top). The spatial spread of perceptual responses increased from V1 to V3, consistent with estimates of increasing receptive field size in these regions (Wandell & Winawer, 2015; Kay et al., 2013b). While the memory responses were weaker and more diffuse, they were also spatially organized, with peak activity in the same location as the perception responses (Fig. 3b, bottom).

**Figure 2. fMRI task design and measurements. (a)** Following training, subjects participated in two tasks while being scanned. During perception runs, subjects viewed the colored fixation dot cues and associated stimuli while maintaining central fixation. Subjects performed a one-back task on the stimuli to encourage covert attention to each stimulus. During memory runs, subjects viewed only the cues and recalled the associated stimuli while maintaining central fixation. Subjects made a judgment about the vividness of their memory (vivid, weak, no memory) on each trial. We used the perception and memory fMRI time series to perform a GLM analysis that estimated the response evoked by perceiving and remembering each stimulus for each vertex on the cortical surface. Responses in visual cortex for an example subject and stimulus are shown at bottom. **(b)** In a separate fMRI session on a different day, subjects participated in a retinotopic mapping session. During retinotopy runs, subjects viewed bar apertures embedded with faces, scenes, and objects drifting across the visual field while they maintained central fixation. Subjects performed a color change detection task on the fixation dot. We used the retinotopy fMRI time series to solve a pRF model that estimated the receptive field parameters for each vertex on the cortical surface. A polar angle map is plotted for an example subject at bottom.

We quantified these initial observations. Because our stimulus locations were isoeccentric, we reduced our 107 responses to variance along one spatial dimension: polar angle. To do this, we restricted our ROIs to surface 108 vertices with pRF locations near the stimulus eccentricity, rotated stimuli to a common polar angle, normalized the 109 responses, and averaged across stimuli and subjects (see Methods). We then plotted the group average BOLD 110 response in bins of polar angle distance from the stimulus (Fig. 4a). We generated these polar angle response 111 functions for V1–V3 and for three mid-level visual areas: hV4, LO, and V3ab (Fig. 4b). To capture the pattern of 112 positive and negative BOLD responses we observed, we fit the average data in each ROI with a difference of two 113 von Mises distributions, where both the positive and the negative von Mises were centered at the same location. 114 Visualizing the data and the von Mises fits (Fig. 4b), it's clear that both perception and memory fits show a peak at 115  $0^{\circ}$ , or the true location of the stimulus, in every region. 116

To formally test this, we calculated bootstrapped confidence intervals for the location parameter of the von Mises 117 distributions by resampling subjects with replacement (see Methods). We then compared the accuracy and reliability 118 of location parameters between perception and memory (Fig. 4c, left). As expected, location parameters derived 119 from perception data were highly accurate. 95% confidence intervals for perception location parameters overlapped 120  $0^{\circ}$  of polar angle, or the true stimulus location, in all ROIs. These confidence intervals spanned only 7.0° on average 121 (range: 3.9°-9.5°), demonstrating that there was low variability in location accuracy across subjects in every ROI. 122 Critically, memory parameters were also highly accurate, with confidence intervals overlapping 0° in every ROI (Fig. 123 4c, left). Thus, in every visual area measured, the spatial locations of the remembered stimuli could be accurately 124 estimated from mnemonic activity. Memory confidence intervals spanned 17.6° on average (range =  $11.0^{\circ}-21.3^{\circ}$ ), 125 indicating that location estimates were somewhat less reliable during memory during perception. However, even 126 the widest memory confidence interval spanned only 21.3°. This is far less than the 90° separating each stimulus 127 location, suggesting that there was no confusability between stimuli present in distributed memory activity. Because 128 both perception and memory location parameters were highly accurate, and because differences in reliability were 129 relatively small, there was no overall difference between perception and memory in the estimated location of peak 130

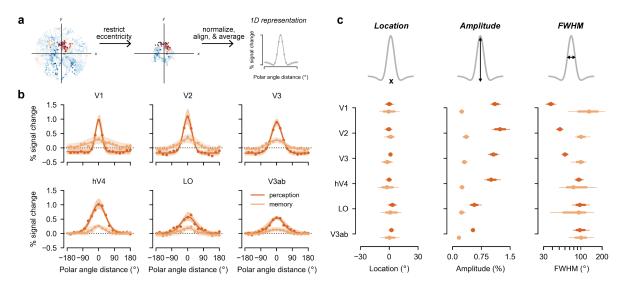

**Figure 3.** Perception and memory activity in visual field coordinates. (a) For a given subject, ROI, and stimulus, we plotted the perceptionor memory-evoked response ( $\beta$ ) in the visual field position estimated by the pRF model (x,y). We then interpolated over 2D space and *z*-scored the responses. We rotated these representations by the polar angle location of the stimulus so that they aligned on the upper vertical meridian, and then averaged over stimuli. This procedure produces an average activation map in visual field coordinates for each ROI and subject. This map is plotted for V1 in an example subject, at right. (b) Plots of perception-evoked and memory-evoked activity, averaged across all subjects, from V1, V2, and V3. These plots reproduce known features of spatial processing during perception, such as increasing receptive field size from V1–V3. They also qualitatively demonstrate that perceptual activity is not perfectly reproduced during memory retrieval but that some retinotopic organization is preserved.

activity (main effect of perception/memory:  $\beta = 0.14$ , 95% CI = [-6.72, 6.14], p = 0.94; Fig. 4c, left). These results provide strong evidence that memory-triggered activity in human visual cortex is spatially organized within known visual field maps, as it is during visual perception. These findings support prior reports of retinotopic activity during memory and imagery (Kosslyn et al., 1995; Slotnick et al., 2005; Thirion et al., 2006), but provide more quantitative estimates of this effect.

### Amplitude and precision differ between perceptual and mnemonic activity

Aspects of perception and memory responses other than the peak location differed considerably. First, memory 137 responses were lower in amplitude than perception responses (Fig. 4b). To quantify this observation, we derived a 138 measure of amplitude from the difference of von Mises functions fit to our data (see Methods). We also computed 139 bootstrapped confidence intervals for this amplitude metric, following the prior analysis. We then compared these 140 estimates between perception and memory. First, response amplitudes for perception data were higher than 141 for the memory data (main effect of perception/memory:  $\beta = 0.95$ , 95% CI = [0.80, 1.13], p = 0.013; Fig. 4c, 142 middle). The average amplitude during perception was 0.92% signal change, and the average amplitude during 143 memory was 0.26% signal change. Amplitude confidence intervals for perception and memory did not overlap in 144 any ROI, indicating that these differences were highly significant in each region. Critically, the fact the perception 145 amplitudes were larger than memory amplitudes does not imply that memory responses were at baseline. In 146 fact, 95% confidence intervals for memory amplitudes did not overlap with zero in any region (Fig. 4c, middle), 147

**Figure 4. Perception and memory have shared and distinct activation features. (a)** We created 1D polar angle response functions by restricting data to eccentricities near the stimulus, aligning stimuli to a common polar angle, and averaging responses into polar angle distance bins. A difference of two von Mises distributions was fit to the group average response. Responses in cortical areas that have pRFs near the stimulus position are plotted at x = 0. (b) Polar angle response functions, averaged across all subjects and stimuli, are plotted separately for perception and memory. Dots represent average data across all stimuli and subjects. Lines represent the fit of the difference of two von Mises distributions to the average data, and shading represents the 95% confidence interval around this fit. While the peak location of the response is shared across perception and memory, there are clear differences in the amplitude and width of the responses. (c) Bootstrapped 68% (thick lines) and 95% confidence intervals (thin lines) for the location, amplitude and FWHM of the difference of von Mises fits are plotted to quantify the responses. In all ROIs, the peak location of the response is equivalent during perception and memory (at 0°, the stimulus location), while the amplitude of the response is reliably lower during memory than during perception. The FWHM of the response increases across ROIs during perception but not during memory, resulting in highly divergent FWHM for perception and memory in early visual areas.

demonstrating that responses were significantly above baseline in all areas measured. These results demonstrate that the amplitude of spatially-organized activity in visual cortex is attenuated (but present) during memory retrieval.

Second, memory responses were wider than perception responses (Fig. 4b). We operationalized the precision 150 of perception and memory responses by computing the full width at half maximum (FWHM) of the difference of von 151 Mises fit to our data and by generating confidence intervals for this measure. Note that FWHM is not sensitive to the 152 overall scale of the response function: a perception response function rescaled to have the same amplitude as the 153 memory response function will have an unchanged FWHM. On average, FWHM during perception was significantly 154 smaller than during memory (main effect of perception/memory:  $\beta$  = -75.2, 95% CI = [-138.5, -33.1], p = 0.0002; Fig. 155 4c, right). However, these differences were not equivalent across ROIs (perception/memory x ROI interaction:  $\beta =$ 156 18.8, 95% CI = [5.78, 35.5], p = 0.021). Specifically, perception FHWM increased moving up the visual hierarchy 157 (main effect of ROI:  $\beta = 13.3$ , 95% CI = [10.3, 20.6], p = 0.0056), indicating increased width or decreased precision 158 in later visual areas compared to early visual areas (Fig. 4c, right). For example, V1 had the narrowest (most 159 precise) response during perception, with an average FWHM of 38.0°(95% CI: [32.0°, 45.0°]), while V3ab had the 160 widest responses during perception, with a FWHM of 97.0°(95% CI: [78.0°, 132.5°]). This increasing pattern follows 161 previously described increases in population receptive field size in these regions (Wandell & Winawer, 2015; Kay 162 et al., 2013b). Note that a separate question, not addressed here, is the precision with which the stimulus can be 163 decoded from a representation, which is not necessarily related to receptive field size. 164

Strikingly, this pattern of increasing FWHM from early to late visual areas was abolished during memory (main effect of ROI:  $\beta$  = -5.49, 95% CI = [-18.7, 8.41], *p* = 0.20; Fig. 4c, right). For areas V1–hV4, the regions we can sort hierarchically with the most confidence, the pattern across ROIs trended toward being reversed, with the widest responses observed in the *earliest* areas (main effect of ROI:  $\beta$  = -15.7, 95% CI = [-39.8, 12.4], *p* = 0.083). These data demonstrate that fundamental aspects of spatial processing commonly observed during perception do not generalize to memory-evoked responses. Interestingly, the interaction between perception/memory and ROI yielded highly divergent perception and memory responses in the earliest visual areas but equivalent responses in the latest

visual areas (Fig. 4c, right). For example, V1 responses during memory had an average FWHM of 131.0° (95% 172 CI: [66.9°, 225.0°]), and were thus 3.45 times wider than V1 responses during perception. In V2 and V3, memory 173 FWHM exceeded perception FWHM by an average of 1.98 times and 1.67 times, respectively. Unlike in V1-V3. 174 confidence intervals for perception and memory were highly overlapping in hV4. LO, and V3ab (Fig. 4c, right). In 175 these later areas, memory responses were only 0.84-1.04 times wider during memory than during perception. 176 These data raise the interesting possibility that later stages of perceptual processing serve as a bottleneck on 177 mnemonic activity precision. Taken together, these results provide evidence for reliable and striking differences in 178 the precision of perception and memory activity across different levels of the visual system. More broadly, these 179 findings indicate that there are fundamentally different constraints on the properties of feedforward perceptual 180 activity and top-down mnemonic activity in human visual cortex. 181

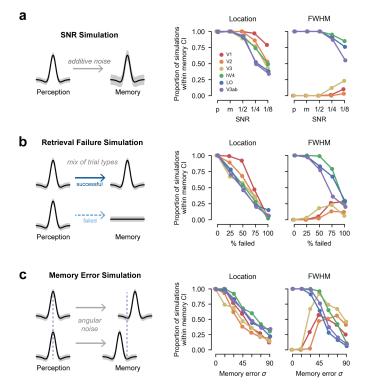

### 182 Differences between perception and memory responses are not explained by noise

One important consideration in interpreting our results is whether the differences we observed between perception 183 and memory could be caused by differences in noise. For example, is it possible that perception and memory 184 responses were actually equivalent other than noise level, but due to greater trial-to-trial noise, memory responses 185 appeared to have systematically different tuning? In particular, we sought to understand whether differences in 186 memory responses could be explained by three types of noise: 1) reduced fMRI signal-to-noise; 2) retrieval failure 187 on a subset of trials; 3) memory error. If perception and memory have the same fundamental response properties, 188 but memory is subject to more noise, then adding noise to the perception data should yield responses that look 189 like what we observed during memory. Thus, we started with perception data (mean and variance of each voxel's 190 activity during perception) and tested whether we could generate responses that looked like memory data by adding 191 one of the three types of noise. To simulate reduced fMRI signal-to-noise, we introduced additive noise to each 192 voxel's perception response (Fig. 5a, left; see Methods). To simulate retrieval failure, we created some trials where 193 the mean response was zero (Fig. 5b, left). To simulate memory error, we added angular noise to the peak location 194 of the perception responses (Fig. 5c, left). For each of these types of simulation, we considered multiple levels of 195 noise. To assess the simulation results, we analyzed all simulated datasets with the same procedures used for the 196 real data and then counted the proportion of times the von Mises parameters derived from a simulation fell within 197 the 95% confidence interval of the actual memory data (Fig. 5a-c, right). 198

First, using bootstrapped parameter estimates, we confirmed that the estimated signal-to-noise ratio (SNR) 199 for perception parameter estimates was higher than for memory parameter estimates in every ROI. Perception 200 SNR was between 1.3 and 1.6 times higher than memory SNR in each ROI, and between 2.2 and 4.3 times higher 201 in vertices closest to the stimulus location. Given this, we simulated new perception data that precisely matched 202 the empirical memory SNR for every surface vertex. We also simulated data with even lower SNR (higher noise) 203 than what we observed during memory. As expected, simulating perception data with reduced SNR increased 204 variance in the location, amplitude, and FWHM of the von Mises fits (Supplementary Fig. 1a). However, no level of 205 SNR produced response profiles that matched the memory data well. In V1-the region where we observed the 206 largest difference in FWHM between perception and memory—0% of the FWHM parameters in the memory SNR 207 simulation approximated the actual memory data (Fig. 5a, right). In the noisiest simulation we performed (1/8 of 208 the memory SNR), this figure was still only 10% (Fig. 5a, right). Similar results occurred for V2 and V3. These 209 simulations demonstrate that low SNR cannot explain the pattern of memory responses we observed in early visual 210 cortex. 211

Our SNR simulations also demonstrate that there are fundamental tradeoffs between capturing memory FWHM in early visual cortex and in capturing other aspects of the data. First, at high levels of noise (low levels of SNR), any modest increase in ability to capture V1-V3 FWHM was accompanied by a *decrease* in ability to capture FWHM in later visual areas (Fig. 5a, right). In these regions, FWHM was already equivalent during perception and memory, and artificially adding noise to the perception data harms this equivalence. Second, high noise simulations generated more noise in the location parameters than was actually observed in the memory data (Fig. 5a, right), resulting in unreliable location parameters in all ROIs.

<sup>219</sup> We observed a similar pattern of results in the retrieval failure simulations. Very high rates of retrieval failure

**Figure 5. Differences between perception and memory are not explained by noise (a)** Left: We simulated the effect of low SNR by introducing additive noise to our perception data and asked whether this was sufficient to produce responses similar to what we observed during memory. Right: Proportion of simulations that produce location and FWHM parameters within the 95% confidence intervals of the memory data are plotted for decreasing signal-to-noise ratios (SNR) and for each ROI. SNR values ranged from the empirical SNR of the perception data (p), the empirical SNR of the memory data (m), or 1/2, 1/4, or 1/8 of the empirical SNR of the memory data. Even at extremely high noise levels, very few simulations generate FWHM parameters within the confidence intervals of the memory data in V1–V3. (b) Left: We simulated the effect of failing to perform the retrieval task by generating a perception dataset where a subset of trials had a mean BOLD response of zero. Right: Data are plotted as in a, with increasing large numbers of failed trials on the x axis. As in a, even at extremely high rates of failed retrieval, FWHM parameters in V1–V3 rarely fall within the memory confidence interval (c) Left: We simulated the effect of memory error on the x axis. Implausibly large amounts of memory error are needed to generate FWHM parameters that fall within the memory confidence intervals >= 50% of the time in V1–V3. In all panels, increased noise produced a worse match to memory FWHM in hV4, LO and V3ab, as well as unreliable location parameters in all ROIs.

were required to generate any FWHM parameters that were sufficiently wide to match the memory data in V1 220 (Supplementary Fig. 1b). Only when simulating retrieval failure in >=50% of all trials, did this number exceed 221 0% (Fig. 5b, right). Similar to the SNR simulation, any improvement in ability to capture the V1 FWHM data with 222 increased retrieval failure was offset by a decline in ability to capture FWHM in late visual areas (Fig. 5b, right), 223 where responses became much wider than what was observed empirically during memory. Again, as in the SNR 224 simulation, high rates of retrieval failure were also associated with location parameters that were far noisier than 225 what we observed (Fig. 5b, right). Thus, subjects experiencing retrieval failure on a subset of trials does not explain 226 our memory data. 227

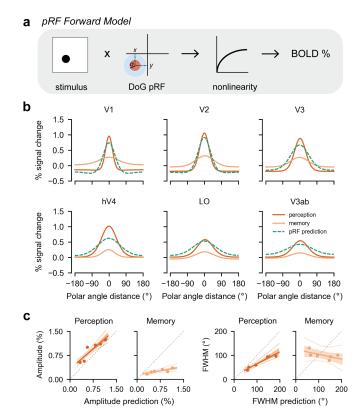

Finally, we considered the memory error simulation. Compared to the other simulations, this simulation produced 228 a better match to memory FWHM in V1 when assuming high levels of noise (Supplementary Fig. 1c). Still, in the 229 best performing simulation only 57% of the V1 FWHM parameters approximated the memory data (Fig. 5c, right). 230 Critically, the magnitude of memory error in this simulation was implausibly high. The standard deviation of memory 23 errors around the true value was 45°, meaning that simulated memories were within the correct quadrant only 68% 232 of time. Given that subjects were trained to discriminate remembered locations up to 15° (see Methods), errors 233 of this magnitude and frequency are exceedingly unlikely. At a more plausible 15° standard deviation of memory 234 error, 0% of simulations approximated the memory data (Fig. 5c, right). Further, similar to the other simulations, 235 improvements in the ability to capture V1 FWHM with high levels of angular error were accompanied by decreases 236

in the ability to capture FWHM in later areas and by decreases in location parameter reliability beyond what we observed empirically (Fig. 5c, right). Thus, subjects experiencing a small, variable amount of memory error does explain our memory data.

Collectively, these simulations demonstrate that our results are unlikely to be caused by a simple source of measurement noise (reduced SNR) or cognitive noise (failed retrieval, memory error). In each of the three simulations, the amount of noise required to make even modest gains in our ability to account for the V1 memory FWHM was implausibly large. Further, in all three cases, increases in the ability to account for V1 FWHM were accompanied by decreases in the ability to account for FWHM in higher visual areas and to recover location parameters that were as reliable as our actual data.

### pRF models accurately predict perception but not memory responses

Next, we evaluated how well perception and memory responses matched the predictions of a pRF model. To do 247 this, we used a modified version of each subject's pRF model to generate predicted cortical responses to each of 248 the four experimental stimuli (Fig. 6a; see Methods). The pRF model we used to generate predictions is a novel 249 variant of existing pRF models: we added a Difference of Gaussian pRF shape (Zuiderbaan et al., 2012) with a 250 fixed positive to negative Gaussian size ratio (1:2) and amplitude ratio (2:1) to our solved nonlinear compressive 251 spatial summation (CSS) model (Kay et al., 2013b). The predictions from the model were analyzed with the same 252 procedure as the data, yielding von Mises fits to the predicted data (Fig. 6b). Model predictions from simpler pRF 253 models are shown in Supplementary Figure 2. 254

**Figure 6. pRF forward model captures perception but not memory responses. (a)** We used our pRF model to generate the predicted BOLD response to each of our experimental stimuli. The model assumes a Difference of Gaussians pRF shape, with a fixed positive to negative Gaussian size ratio (1:2) and amplitude ratio (2:1). The model also incorporates a compressive nonlinearity. **(b)** Predicted polar angle response functions are plotted for the pRF model (green dashed lines), alongside the functions fit to the perception and memory data (dark and light orange, reproduced from Fig. 4b). The model predictions are closer to the perception data than the memory data in all visual areas. **(c)** Predicted versus observed amplitude (left) and FWHM (right), plotted separately for perception and memory. Each dot represents an ROI. The shaded region is the 68% CI from bootstrapping linear fits across participants, and the thin lines indicate the 95% confidence intervals. For both the amplitude and FWHM, the perception data lie relatively close to the pRF model predictions (dashed grey lines), whereas the memory data do not.

Qualitatively, the pRF model predictions agree with the perception data but not the memory data (Fig. 6b). 255 Several specific features of the perception data are well captured by the model. First, the model predicts the highest 256 amplitude response at cortical sites with pRFs near the stimulus location (peak at 0°). Second, the model predicts 257 increasingly wide response profiles from the early to late visual areas. Third, it predicts higher amplitudes in early 258 compared to late areas. Finally, the model predicts negative responses in the surround locations of V1-V3 but not 259 higher visual areas. This is particularly interesting given that all voxel pRFs were implemented with a negative 260 surround of the same size and amplitude relative to the center Gaussian. This suggests that voxel-level parameters 261 and population-level responses can diverge (Sprague & Serences, 2013, see also). Though not the focus of this 262 analysis, we note that the model predictions are not perfect. The model predicts slightly lower amplitudes and 263 larger FWHM than is observed in the perception data (Fig. 6b). These discrepancies may be due to differences 264 between the stimuli used in the main experiment and those used in the pRF experiment or to differences in the task 265 (attending fixation during the pRF experiment vs attending the stimulus during the main experiment). 266

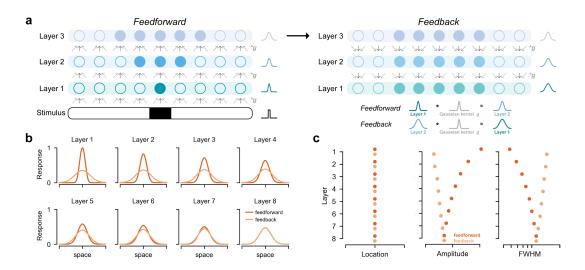

Critically, the model accurately captures the properties of memory responses that are shared with perception 267 responses (the peak location), but not the distinct properties (Fig. 6b). These failures are especially clear when 268 comparing the predicted amplitude and FWHM from the pRF model with the observed amplitudes and FWHMs for 269 perception and memory. While there is a positive slope between the predicted amplitude and both the perception ( $\beta$ 270 = 0.84, 95% CI: [0.56, 1.15]) and memory amplitudes ( $\beta$  = 0.17, 95% CI: [0.056, 0.32]), the slopes differ substantially 271 (Fig. 6c). The perception amplitudes have a slope closer to 1, indicating good agreement with the model predictions, 272 while the memory data have a slope closer to 0, indicating weak agreement. Similarly, the predicted FWHM is 273 strongly and positively related to the perception FWHM ( $\beta = 0.50, 95\%$  CI: [0.36, 0.76]), but weakly and negatively 274 related to the memory FWHM ( $\beta$  = -0.20, 95% CI: [-0.67, 0.26]; Fig. 6c). These analyses strongly support our 275 interpretation of the data in Figure 4b,c to mean that memory and perception have distinct spatial tuning properties. 276 The critical advantage of using pRF models is that they explicitly incorporate known properties of feedforward spatial 277 processing in visual cortex. Because our pRF model fails to account for the memory responses we observed, we 278 can conclude that memory reactivation violates the assumptions of feedforward processes that well characterize 279 perceptual activation. A plausible explanation for this failure is that memory retrieval involves a fundamentally 280 different origin and cascade of information through visual cortex, a possibility we explore in detail in the next section. 28

# 282 Perception and memory responses can be simulated with a bidirectional hierarchical model

Cortical activity during perception arises from a primarily feedforward process that originates with the retina and that 283 accumulates additional spatial pooling in each cortical area, resulting in increasingly large receptive fields (Gattass 284 et al., 2005; Wandell & Winawer, 2015). In contrast, memory reinstatement is hypothesized to begin with the 285 hippocampus (Marr, 1971; O'Reilly & McClelland, 1994), a region bidirectionally connected to high-level visual areas 286 in ventral temporal cortex via the medial temporal lobe cortex (Van Hoesen & Pandya, 1975; Felleman & Essen, 287 1991; Suzuki & Amaral, 1994). Reinstated cortical activity is then thought to propagate backwards through visual 288 cortex (Naya et al., 2001; Linde-Domingo et al., 2019; Dijkstra et al., 2019; Hindy et al., 2016). Here, we explored 289 whether a simple hierarchical model with spatial pooling could be adapted to account for both our perception and 290 memory results by manipulating the direction of information flow. 291

We first constructed a linear feedforward hierarchical model of spatial processing in neocortex. In this model, the activity in each layer was created by convolving the activity from the previous layer with a fixed Gaussian kernel (Fig. 7a; see Methods). Beginning with a boxcar stimulus, we cascaded this convolutional operation to simulate 8 layers of the network (Fig. 7b). In this simple demonstration, the size of the convolutional kernel was fixed, not fit to the data. Nonetheless, the pattern of feedforward responses qualitatively matches our fMRI observations during perception. The location of the peak response is unchanged across layers, but response functions become wider and lower in amplitude in higher layers (Fig. 7b,c)–precisely as we observed in our actual data (Fig. 4b,c).

We then explored whether backwards propagation of reinstated activity in our hierarchical model could account for our memory data. To do this, we assumed that feedforward and feedback connections in the model were reciprocal, meaning that the convolutional kernel was the same in feedforward and feedback direction. We assumed perfect reinstatement in the top layer, and thus began the feedback simulation by duplicating the feedforward activity

**Figure 7. Perception and memory responses can be simulated with a bidirectional hierarchical model. (a)** Illustration of stimulus-driven activity propagating through a linear hierarchical network model in the feedforward direction (left) and mnemonic activity propagating through the model in the feedback direction (right). In both cases, a given layer's activity is generated by convolving the previously active layer's activity with a fixed Gaussian kernel. The feedforward simulation began with a boxcar stimulus. The feedback simulation began with duplication of the feedforward activity from the final layer. (b) Results from feedforward and feedback simulations in an 8 layer network, plotted in the conventions of Figure 4b. The feedforward simulation parallels our observations during perception, and the feedback simulation parallels our observations during memory. (c) Location, amplitude, and FWHM parameters for each layer, plotted separately for feedforward and feedback simulations. Location is preserved across layers in the feedforward and feedback direction. Note that FWHM become progressively wider in later layers in the feedforward direction and in earlier layers in the feedback direction. This results in large differences in FWHM between feedforward and feedback activity in early layers. These trends closely follow our observations in Figure 4c.

from the final layer. Starting with this final layer activity, we convolved each layer's activity with the same Gaussian 303 kernel to generate earlier layers' activity (Fig. 7a). The properties of the simulated activity (Fig. 7b.c) bear a 304 striking resemblance to the those of the observed memory data (Fig. 4b,c). First, simulated feedback activity had 305 a preserved peak location across layers (Fig. 7c, left), similar to the memory data. Second, simulated feedback 306 activity was wider and lower amplitude than feedforward activity overall (Fig. 7c, middle and right)-just as the 307 memory data had wider and lower amplitude responses than the perception data. Third, the increase in FWHM 308 across layers was smaller in the feedback direction than in the feedforward direction, and it reversed direction with 309 respect to the visual hierarchy (Fig. 7c, right). This small effect of reversal is particularly interesting given that 310 this trend was numerically present in our memory data but not statistically reliable at our sample size. Finally, the 311 difference between feedforward and feedback FWHM was maximal in the earliest layers (Fig. 7c, right), just as 312 the difference between our perception and memory data was maximal in V1. This simulation suggests that the 313 distinct spatial profile of mnemonic responses in visual cortex may be a straightforward consequence of reversing 314 the flow of information in a system with hierarchical structure and reciprocal connectivity, and that spatial pooling 315 accumulated during feedforward processing may not be inverted during reinstatement. More broadly, these results 316 demonstrate that models of the visual system may be useful for probing the mechanisms that support and constrain 317 visual memory. 318

# 319 Discussion

In the current work, we combined empirical and modeling approaches to explore how long-term spatial memories 320 are represented in the human visual system. By using computational models of spatial encoding to compare 321 perceptual and mnemonic BOLD activity, we provide strong evidence that visual memory, like visual perception, 322 produces retinotopically-mapped activation throughout visual cortex. Critically, however, we also identified systematic 323 differences in the population spatial tuning properties of perceptual and mnemonic activity. Compared to perceptual 324 responses, mnemonic responses were lower in amplitude in all visual areas. Further, while we observed a three-325 fold change in spatial precision from early to late visual areas during perception, mnemonic responses violated 326 this pattern. Instead, mnemonic responses displayed consistent spatial precision across visual areas. Notably, 327 simulations showed that neither reduced SNR, nor failure to retrieve on some trials, nor memory error could 328 account for this difference. We speculate, instead, that this difference arises from a reversal of information flow in a 329 hierarchically organized and reciprocally connected visual cortex. To support this, we show that top-down activation 330 in a simple hierarchical model elicits a systematically different pattern of responses than bottom-up activation. These 331 simulations reproduce the properties we observe during both perception and memory. Together, these results reveal 332 novel properties of memory-driven activity in visual cortex that suggest specific computational processes governing 333 visual cortical responses during memory retrieval. 334

### Advantages of using encoding models to parameterize memory representations

Much work in neuroscience has been dedicated to the question of how internally-generated stimulus representations 336 are coded in the brain. Early neuroimaging work established that sensory cortices are recruited during imagery and 337 memory tasks (Kosslyn et al., 1995; O'Craven & Kanwisher, 2000; Wheeler et al., 2000), moving the field away 338 from purely symbolic accounts of memory (e.g. Pylyshyn, 2002). More recently, memory researchers have favored 339 decoding and pattern similarity approaches over univariate activation analyses to examine the content of retrieved 340 memories (Polyn et al., 2005; Kuhl et al., 2011; Favila et al., 2018). While these approaches are powerful, they do 341 not explicitly specify the form mnemonic activity should take, and many activation schemes can lead to successful 342 decoding or changes in pattern correlations. In the present work, we leveraged encoding models from visual 343 neuroscience, specifically stimulus-referred pRF models, to examine and account for memory-triggered activity in 344 visual cortex. In contrast to decoding or pattern similarity approaches, encoding models predict the activity evoked 345 in single voxels in response to sensory or cognitive manipulations using a set of explicit mathematical operations 346 (Naselaris et al., 2011). Spatial encoding models have proved particularly powerful because space is coded in the 347 human brain at a scale that is well-matched to the millimeter sampling resolution of fMRI (Engel et al., 1994; Sereno 348 et al., 1995; Dougherty et al., 2003). Despite the power of such encoding models, relatively little work has applied 349 these models to questions about long-term memory (c.f. Thirion et al., 2006; Naselaris et al., 2015; Breedlove et al., 350 2018). Here, using this approach, we revealed novel properties of memory responses in visual cortex that decoding 351 approaches have missed. Most notably, we found that memory activity was characterized by a different pattern 352 of spatial precision across regions than perceptual activity. Because spatial parameters such as polar angle are 353 explicitly modeled in pRF models, we were able to quantify and interpret these differences. 354

Our results have important implications for the study of memory reactivation. First, our findings suggest that the 355 specific architecture of a sensory system may constrain what memory reactivation looks like in that system. Though 356 memory reactivation is often studied in sensory domains, the architecture of these systems is not usually considered 357 when interpreting reactivation effects. Here, we propose that hierarchical spatial pooling in visual cortex produces a 358 systematic and distinct pattern of memory reactivation that cannot be attributed to retrieval failure or memory error. 359 However, whether this architecture has any consequences for memory behavior is not clear from the present study. 360 This question will be critical for future studies to address. Second, our results advocate for shifting away from the 36 concept of memory reactivation as it has been understood and applied in the field of neuroimaging. Most previous 362 work has focused on identifying similarities between the neural substrates of visual perception and visual memory. 363 These studies have been successful in that they have produced many positive findings of memory reactivation 364 in human visual cortex (Kosslyn et al., 1995; O'Craven & Kanwisher, 2000; Wheeler et al., 2000; Slotnick et al., 365 2005; Polyn et al., 2005; Kuhl et al., 2011; Bosch et al., 2014; Waldhauser et al., 2016; Lee et al., 2018; Bone 366

et al., 2018). However, much of this work implicitly assumes that any mismatch between perception and memory 367 is due to the fact that memory reactivation is either inherently low fidelity or susceptible to noise (Pearson et al., 368 2015), or is a subset of the perceptual response (Wheeler et al., 2000). Our results demonstrate that, at least 369 in the spatial domain, this is not the case, and that systematic differences beyond noise exist. These results are 370 broadly consistent with other recent findings suggesting computational differences between perception and memory 371 derived from behavior (Bloem et al., 2018) and multivoxel pattern differences in perceived and remembered object 372 representations measured with fMRI (Lee et al., 2012). Ultimately, the field should strive to identify, quantify, and 373 explain these differences in order to fully understand the neural basis of memory. Using encoding models borrowed 374 from sensory neuroscience to parameterize the differences between perception and memory may prove a fruitful 375 way of making progress on this goal. 376

# 377 Why do perceptual and mnemonic representations differ in visual cortex?

Despite the usefulness of encoding models like pRF models for quantifying neural responses in a stimulus-referred 378 space, these models may not provide a natural explanation for why perception and memory responses differ. 379 We show in Figure 6 that pRF models fail to capture the aspects of memory responses that are distinct from 380 perceptual responses: namely, the dramatic change in spatial precision. While it would be possible to fit separate 381 pRF parameters to memory data to improve the ability of the model to accurately predict memory responses, this still 382 would not explain why these parameters or responses differ. How then can we account for this? We were particularly 383 intrigued by the possibility that differences between memory and perception activity are a direct consequence of the 384 direction of processing in hierarchically-organized cortex. Hierarchical structure and feedback processing are not 385 typically directly simulated in a pRF model but there is considerable evidence to suggest these factors are of interest. 386 Studies of anatomical connectivity provide evidence that the visual system is organized approximately hierarchically 387 (Felleman & Essen, 1991; Barone et al., 2000; for other perspectives see Zeki, 2015; Hilgetag & Goulas, 2020). 388 and that most connections within the visual system are reciprocal (Felleman & Essen, 1991). Studies also show 389 that the hippocampus sits atop the highest stage of the visual hierarchy, with reciprocal connections to high-level 390 visual regions via the medial temporal lobe cortex (Van Hoesen & Pandya, 1975; Felleman & Essen, 1991; Suzuki 391 & Amaral, 1994). These observations make the prediction that initial drive from the hippocampus during memory 392 retrieval should propagate backwards through the visual system. Neural recordings from the macague (Nava et al., 393 2001) and human (Hindy et al., 2016; Linde-Domingo et al., 2019; Dijkstra et al., 2019), as well as computational 394 modeling (Horikawa & Kamitani, 2017) support this idea. 395

Based on these observations and our hypothesis, we constructed a hierarchical network model in which we could 396 simulate top-down activity. Though this model shares some features of hierarchical models of object recognition 397 (Riesenhuber & Poggio, 1999; Serre et al., 2007), we emphasize that it is much simpler. Our model is entirely 398 linear, its parameters are fixed a priori (not the result of training), and it encodes only one stimulus feature: space 399 (Kay et al., 2013b). Critically, in contrast to pRF models, which express each region's activity as a function of the 400 stimulus, our model expresses each region's activity as a function of the previous region's activity (Fukushima, 1980; 401 Riesenhuber & Poggio, 1999), and can therefore simulate both feedforward and feedback processes (Heeger, 2017). 402 While highly simplified, the simulations we performed in this network captured the dominant features of our data. 403 providing a parsimonious explanation for our observations. Interestingly, our simulations also indicate that some 404 trends present in our data warrant further investigation. For instance, while we could not conclude that the earliest 405 visual cortical areas had the least precise responses during memory (a reversal of the perception pattern), our 406 simulations suggest that this effect should be present, albeit significantly weaker than in the feedforward direction. 407 Future work should target this small effect with a sufficiently powered experiment. 408

Our simulations also raise interesting questions and predictions about the consequences of visual cortical architecture for cognition. First, why have a hierarchical architecture in which the detailed information present in early layers cannot be reactivated? The hierarchical organization of the visual system is thought to give rise to the low-level feature invariance required for object recognition (Riesenhuber & Poggio, 1999; Serre et al., 2007). Our results raise the possibility that the benefits of such an architecture for recognition outweigh the cost of reduced precision in top-down responses. Whether the extent of this tradeoff differs between healthy individuals or between healthy and neuropsychiatric populations, and what consequences this structure has for behavior, are interesting

questions for future research. Second, how is it that humans have spatially precise memories if visual cortical 416 responses do not reflect this? One possibility is that read-out mechanisms are not sensitive to all of the properties 417 of mnemonic activity we measured. For instance, memory decisions could be driven exclusively by the neural 418 population with the strongest response (e.g. those at the peak of the polar angle response functions). Another 419 possibility is that regions without hierarchical structure do not exhibit these properties and reactivation in these 420 other regions is preferentially used to guide memory-based behavior. These, and other possibilities should be 421 directly explored in future work. Finally, our hierarchical simulations highlight the need to carefully separate the 422 contribution of visual cortical architecture on reactivation from the effects of cognitive manipulations or effects 423 occurring upstream of visual cortex (e.g. in the hippocampus). 424

### 425 Relation to other forms of memory and attention

Sensory reactivation during long-term memory retrieval has parallels to sensory engagement in other forms of 426 memory such as iconic memory and working memory. Nonetheless there may also be differences in the specific 427 way that sensory circuits are used across these forms of memory. One critical factor may be how recently the 428 sensory circuit was activated by a stimulus at the time of memory retrieval. In iconic memory studies, very detailed 429 information can be retrieved if probed within a second of the sensory input (Sperling, 1960). In working memory 430 studies, sensory activity is thought to be maintained by active mechanisms from stimulus encoding through a 431 seconds-long delay. Using similar methods to the ones we use here (Sprague & Serences, 2013; Ester et al., 2013), 432 many working memory studies have shown that early visual areas contain retinotopically specific signals throughout 433 a delay period (Sprague & Serences, 2013; Sprague et al., 2014; Rahmati et al., 2017), paralleling our findings. In 434 imagery studies, eye-specific circuits presumed to be in V1 can be re-engaged if there is a delay of 5 minutes or 435 less from when the subject viewed stimuli through the same eve, but not if there is a delay of 10 minutes (Ishai 436 & Sagi, 1995). Hippocampally-dependent memory retrieval is thought to be capable of engaging visual cortex at 437 much longer delays. Given that the mechanism for engaging sensory cortex may differ across these different forms 438 of memory, the question of how similar sensory activation is across these timescales remains an important open 439 question. For example, shorter-term forms of memory might, in principle, cause more spatially-specific reactivation 440 in early visual cortex than what we observed in long-term memory. Informal comparisons between our data and 441 stimulus reconstructions made from working memory delay period activity (Sprague & Serences, 2013; Rahmati 442 et al., 2017; Rademaker et al., 2019) suggest this may be the case, but a direct comparison is warranted. The 443 current study offers a quantitative approach for directly comparing spatial tuning properties across different cognitive 444 processes, and could be extended to include multiple forms of memory within the same experiment. 445

Are the spatial responses we observed during memory retrieval better characterized as long-term memory 446 reactivation or as a special case of (memory-guided) spatial attention? Our results raise interesting guestions 447 about whether long-term spatial memory and endogenous spatial attention share mechanisms for modulating the 448 response of visual cortical populations. In typical endogenous spatial attention tasks, subjects are explicitly cued to 449 the most likely location of an upcoming stimulus prior to being presented with a difficult visual judgment (Carrasco, 450 2011). fMRI studies have repeatedly found that spatial attention enhances visually-evoked responses in visual 451 cortex (Somers et al., 1999; Gandhi et al., 1999; Buracas & Boynton, 2007; Li et al., 2008). Similar to our results, 452 spatial attention has also been shown to elicit spatially localized activation in the absence of any visual stimulation 453 (Luck et al., 1997; Kastner et al., 1999; Chawla et al., 1999; Ress et al., 2000). It is at least logically possible for 454 attention and memory to dissociate. Most endogenous attention tasks have no memory component since the cue 455 explicitly represents the attended location. In contrast, in most episodic memory tasks the association between a 456 cue and a stimulus is intentionally arbitrary so that it must be acquired and retrieved in a hippocampally-dependent 457 manner. However, it is possible that spatial attention and memory processes only differ in their dependency on 458 the hippocampus to retrieve the target location. Once this target location is determined, the same mechanisms 459 could be used to initiate enhanced processing of the target location in sensory areas. Future experiments and 460 modeling efforts should determine whether memory-driven and attention-driven activations in visual cortex differ. 46 and whether it's possible to develop a model of top-down processing in visual cortex that can account for both sets 462 of observations. 463

### 464 Conclusion

In the current work, we provide novel empirical evidence that memory retrieval elicits systematically different activation in human visual cortex compared to visual perception. Using simulations and a network model of cortex, we argue that these distinctions arise from a reversal of information flow within a hierarchically structured visual system. Collectively, this work makes progress on providing a detailed account of reactivation in visual cortex and sheds light on the broader computational principles that guide top-down processes in sensory systems.

### 470 Methods

### 471 Subjects

Nine human subjects participated in the experiment (5 males, 22–46 years old). All subjects had normal or correct-to-normal visual acuity, normal color vision, and no MRI contraindications. Subjects were recruited from the New York University community and included author S.E.F and author J.W. All subjects gave written informed consent to procedures approved by the New York University Institutional Review Board prior to participation. No subjects were excluded from data analysis.

### 477 Stimuli

Experimental stimuli included nine unique radial frequency patterns (Fig. 1a). We first generated patterns that 478 differed along two dimensions: radial frequency and amplitude. We chose stimuli that tiled a one dimensional 479 subspace of this two dimensional space, with radial frequency inversely proportional to amplitude. The nine chosen 480 stimuli took radial frequency and amplitude values of: [2, .9], [3, .8], [4, .7], [5, .6], [6, .5], [7, .4], [8, .3], [9, .2], [10, 481 .1]. We selected four of these stimuli to train subjects on in the behavioral training session and to appear in the 482 fMRI session. For every subject, those stimuli were: [3, .8], [5, .6], [7, .4], [9, .2]; (radial frequency, amplitude). The 483 remaining five stimuli were used as lures in the test trials of the behavioral training session. Stimuli were saved as 484 images and cropped to the same size. 485

### 486 Experimental procedure

The experiment began with a behavioral training session, during which subjects learned four paired associates (Fig. 487 1). Specifically, subjects learned that four colored fixation dot cues were uniquely associated with four spatially 488 localized radial frequency patterns. An fMRI session immediately followed completion of the behavioral session 489 (Fig. 2a). During the scan, subjects participated in two types of functional runs (approximately 3.5 min each): (1) 490 perception, where they viewed the cues and associated spatial stimuli; and (2) memory, where they viewed only the 491 fixation cues and recalled the associated spatial stimuli. Details for each of these phases are described below. A 492 separate retinotopic mapping session was also performed for each subject (Fig. 2b), which is described in the next 493 section. 494

### 495 Behavioral training

For each subject, the four radial frequency patterns were first randomly assigned to one of four polar angle locations in the visual field (45°, 135°, 225°, or 315°) and to one of four colored cues (orange, magenta, blue, green; Fig. 1b). Immediately before scanning, subjects learned the association between the four colored cues and the four spatially localized stimuli through interleaved study and test blocks (Fig. 1c). Subjects alternated between study and test blocks, completing a minimum of four blocks of each type. Subjects were required to reach at least 95% accuracy, and performed additional rounds of study-test if they did not reach this threshold after four test blocks.

<sup>502</sup> During study blocks, subjects were presented with the associations. Subjects were instructed to maintain central <sup>503</sup> fixation and to learn each of the four associations in anticipation of a memory test. At the start of each study trial <sup>504</sup> (Fig. 1c), a central white fixation dot (radius = 0.1 dva) switched to one of the four cue colors. After a 1 sec delay, <sup>505</sup> the associated radial frequency pattern appeared at 2° of eccentricity and its assigned polar angle location in the visual field. Each pattern image subtended 1.5 dva and was presented for 2 sec. The fixation dot then returned
 to white, and the next trial began after a 2 sec interval. No subject responses were required. Each study block
 contained 16 trials (4 trials per association), presented in random order.

During test blocks, subjects were presented with the colored fixation dot cues and tested on their memory for the 509 associated stimulus pattern and spatial location. Subjects were instructed to maintain central fixation and to try to 510 covertly recall each stimulus when cued, and then to respond to the test probe when prompted. At the start of each 511 test trial (Fig. 1c), the central white fixation dot switched to one of the four cue colors. This cue remained on the 512 screen for 2.5 sec while subjects attempted to covertly retrieve the associated stimulus. At the end of this period, 513 a test stimulus was presented at 2° of eccentricity for 2 sec. Then, subjects were cued to make two consecutive 514 responses to the test stimulus: whether it was the correct radial frequency pattern (yes/no) and whether it was 515 presented at the correct polar angle location (yes/no). Each test stimulus had a 50% probability of being the correct 516 pattern. Incorrect patterns were drawn randomly from the three patterns associated with other cues and the five lure 517 patterns (Fig. 1a). Each test stimulus had a 50% probability of being in the correct polar angle location, which was 518 independent from the probability of being the correct pattern. Incorrect polar angle locations were drawn from the 519 three locations assigned to the other patterns and 20 other evenly spaced locations around the visual field (Fig. 1a). 520 This placed the closest spatial lure at 15° of polar angle away from the correct location. Responses were solicited 521 from the subject with the words "Correct pattern?" or "Correct location?" displayed centrally in white text. The order 522 of these queries was counterbalanced across test blocks. Subjects responses were recorded on a keyboard with 523 a maximum response window of 2 sec. Immediately after a response was made or the response window closed, 524 the color of the text turned black to indicate an incorrect response if one was made. After this occurred for both 525 queries, subjects were presented with the colored fixation dot cue and correct spatially localized pattern for 1 sec as 526 feedback. This feedback occurred for every trial, regardless of subject responses to the probe. Each test block 527 contained 16 trials (4 trials per association), presented in random order. 528

### 529 fMRI session

<sup>530</sup> During the fMRI session, subjects participated in two types of functional runs: perception and memory retrieval (Fig. <sup>531</sup> 2a). Subjects completed 5–6 runs each of perception and memory in an interleaved order. This amounted to 40–48 <sup>532</sup> repetitions of perceiving each stimulus and of remembering each stimulus per subject.

During perception runs, subjects viewed the colored fixation dot cues and the radial frequency patterns in their 533 learned locations. Subjects were instructed to maintain central fixation and to perform a one-back task on the 534 stimuli. The purpose of the one-back task was to encourage covert stimulus-directed attention on each trial. At 535 the start of each perception trial (Fig. 2a, top), a central white fixation dot (radius = 0.1 dva) switched to one of 536 the four cue colors. After a 0.5 sec delay, the associated radial frequency pattern appeared at 2° of eccentricity 537 and its assigned polar angle location in the visual field. Each pattern subtended 1.5 dva and was presented for 2.5 538 sec. The fixation dot then returned to white and the next trial began after a variable interval. Intervals were drawn 539 from an approximately geometric distribution sampled at 3, 4, 5, and 6 sec with probabilities of 0.5625, 0.25, 0.125, 540 and 0.0625 respectively. Subjects indicated when a stimulus repeated from the previous trial using a button box. 541 Responses were accepted during the stimulus presentation or during the interstimulus interval. Each perception run 542 contained 32 trials (8 trials per stimulus). The trial order was randomized for each run, separately for every subject. 543

During memory runs, subjects viewed the colored fixation dot cues and recalled the associated patterns in 544 their learned spatial locations. Subjects were instructed to maintain central fixation, to use the cues to initiate 545 recollection, and to make a subjective judgment about the vividness of their memory on each trial. The purpose of 546 the vividness task was to enforce attention to the remembered stimulus on each trial. At the start of each memory 547 trial (Fig. 2a, top), the central white fixation dot switched to one of the four cue colors. This cue remained on the 548 screen for a recollection period of 3 sec. The fixation dot then returned to white and the next trial began after a 549 variable interval. Subjects indicated whether the stimulus associated with the cue was vividly remembered, weakly 550 remembered, or not remembered using a button box. Responses were accepted during the cue presentation or 551 during the interstimulus interval. Each memory run contained 32 trials (8 trials per stimulus). For a given subject, 552 each memory run's trial order and trial onsets were exactly matched to one of the perception runs. The order of 553 these matched memory runs was scrambled relative to the order of the perception runs. 554

#### Retinotopic mapping procedure 555

Each subject completed either 6 or 12 identical retinotopic mapping runs in a separate fMRI session from the 556 main experiment (Fig. 2b. top). Stimuli and procedures for the retinotopic mapping session were based on those 557 used by the Human Connectome Project (Benson et al., 2018) and were identical to those reported in Benson & 558 Winawer (2018). During each functional run, bar apertures on a uniform gray background swept across the central 559 24 degrees of the subject's visual field (circular aperture with a radius of 12 dva). Bar apertures were a constant 560 width (1.5 dva) at all eccentricities. Each sweep began at one of eight equally spaced positions around the edge 561 of the circular aperture, oriented perpendicularly to the direction of the sweep. Horizontal and vertical sweeps 562 traversed the entire diameter of the circular aperture while diagonal sweeps stopped halfway and were followed by 563 a blank period. A full-field sweep or half-field sweep plus blank period took 24 s to complete. One functional run 564 contained 8 sweeps, taking 192 s in total. Bar apertures contained a grayscale pink noise background with randomly 565 placed faces, scenes, objects, and words at a variety of sizes. Noise background and stimuli were updated at a 566 frequency of 3 Hz. Each run of the task had an identical design. Subjects were instructed to maintain fixation on a 567 central dot and to use a button box to report whenever the dot changed color. Color changes occurred on average 568 every 3 s. 569

#### **MRI** acquisition 570

Images were acquired on a 3T Siemens Prisma MRI system at the Center for Brain Imaging at New York University. 571 Functional images were acquired with a T2\*-weighted multiband EPI sequence with whole-brain coverage (repetition 572 time = 1 s, echo time = 37 ms, flip angle = 68°, 66 slices, 2 x 2 x 2 mm voxels, multiband acceleration factor 573 = 6, phase-encoding = posterior-anterior) and a Siemens 64-channel head/neck coil. Spin echo images with 574 anterior-posterior and posterior-anterior phase-encoding were collected to estimate the susceptibility-induced 575 distortion present in the functional EPIs. Between one and three whole-brain T1-weighted MPRAGE 3D anatomical 576 volumes (.8 x .8 x .8 mm voxels) were also acquired for seven subjects. For two subjects, previously acquired 577 MPRAGE volumes (1 x 1 x 1 mm voxels) from a 3T Siemens Allegra head-only MRI system were used. 578

#### MRI processing 579

#### Preprocessing 580

Anatomical and functional images were preprocessed using FSL v5.0.10 (Smith et al., 2004) and Freesurfer v5.3.0 581 (Fischl, 2012) tools implemented in a Nipype workflow (Gorgolewski et al., 2011). To correct for head motion, each 582 functional image acquired in a session was realigned to a single band reference image and then registered to 583 the spin echo distortion scan acquired with the same phase encoding direction. The two spin echo images with 584 reversed phase encoding were used to estimate the susceptibility-induced distortion present in the EPIs. For each 585 EPI volume, this nonlinear unwarping function was concatenated with the previous spatial registrations and applied 586 with a single interpolation. Freesurfer was used to perform segmentation and cortical surface reconstruction on 587 each subject's average anatomical volume. Registration from the functional images to each subject's anatomical 588 volume was performed using boundary-based registration. Preprocessed functional time series were then projected 589

onto each subject's reconstructed cortical surface. 590

#### GLM analyses 591

Beginning with each subject's surface-based time series, we used GLMdenoise (Kay et al., 2013a) to estimate the 592 neural pattern of activity evoked by perceiving and remembering every stimulus (Fig. 2a). GLMdenoise improves 593 signal-to-noise ratios in GLM analyses by identifying a pool of noise voxels whose responses are unrelated to the 594 task and regressing them out of the time series. This technique first converts all time series to percent signal change 595 and determines an optimal hemodynamic response function for all vertices using an iterative linear fitting procedure. 596 It then identifies noise vertices as vertices with negative  $R^2$  values in the task-based model. Then, it derives noise 597 regressors from the noise pool time series using principal components analysis and iteratively projects them out of 598 the time series of all vertices, one noise regressor at a time. The optimal number of noise regressors is determined 599

based on cross-validated  $R^2$  improvement for the task-based model. We estimated two models using this procedure. We constructed design matrices for the perception model to have four regressors of interest (one per stimulus), with events corresponding to stimulus presentation. Design matrices for the memory model were constructed the same way, with events corresponding to the the cued retrieval period. These models returned parameter estimates reflecting the BOLD amplitude evoked by perceiving or remembering a given stimulus versus baseline for every vertex on a subject's cortical surface (Fig. 2a, bottom).

### 606 Fitting pRF models

Images from the retinotopic mapping session were preprocessed as above, but omitting the final step of projecting 607 the time series to the cortical surface. Using these time series, nonlinear symmetric 2D Gaussian population 608 receptive field (pRF) models were estimated in Vistasoft (Fig. 2b), as described previously (Dumoulin & Wandell, 609 2008; Kay et al., 2013b). We refer to this nonlinear version of the pRF model as the compressive spatial summation 610 (CSS) model, following Kay et al. (2013b). Briefly, we estimated the receptive field parameters that, when applied to 611 the drifting bar stimulus images, minimized the difference between the observed and predicted BOLD time series. 612 First, stimulus images were converted to contrast apertures and downsampled to 101 x 101 grids. time series 613 from each retinotopy run were resampled to anatomical space and restricted to gray matter voxels. time series 614 were then averaged across runs. pRF models were solved using a two stage coarse-to-fine fit on the average 615 time series. The first stage of the model fit was a coarse grid fit, which was used to find an approximate solution 616 robust to local minima. This stage was solved on a volume-based time series that was first temporally decimated. 617 spatially blurred on the cortical surface, and spatially subsampled. The parameters obtained with this fit were 618 interpolated and then used as a seed for subsequent nonlinear optimization, or fine fit. This procedure yielded four 619 final parameters of interest for every voxel: eccentricity (r), polar angle  $(\theta)$ , sigma  $(\sigma)$ , exponent (n). The eccentricity 620 and polar angle parameters describe the location of the receptive field in space, the sigma parameter describes the 621 size of the receptive field, and the exponent describes the amount of compressive spatial summation applied to 622 responses from the receptive field. Eccentricity and polar angle parameters were converted from polar coordinates 623 to rectangular coordinates (x, y) for some analyses. Variance explained by the pRF model with these parameters 624 was also calculated for each voxel. All parameters were then projected from each subject's anatomical volume to 625 the cortical surface (Fig. 2b, bottom). 626

# 627 ROI definitions

Regions of interest were defined by hand-drawing boundaries at polar angle reversals on each subject's cortical surface, following established practice (Wandell et al., 2007). We used this method to define six ROIs spanning early to mid-level visual cortex: V1, V2, V3, hV4, LO (LO1 and LO2), and V3ab (V3a and V3b).

<sup>631</sup> We further restricted each ROI by preferred eccentricity in order to isolate vertices responsive to our stimuli. We <sup>632</sup> excluded vertices with eccentricity values less than  $0.5^{\circ}$  and greater than  $8^{\circ}$ . This procedure excluded vertices <sup>633</sup> responding primarily to the fixation dot and vertices near the maximal extent of visual stimulation in the scanner. We <sup>634</sup> also excluded vertices whose variance explained by the pRF model ( $R^2$ ) was less than 0.1, indicating poor spatial <sup>635</sup> selectivity. All measures used to exclude vertices from ROIs were independent of the measurements made during <sup>636</sup> the perception and memory tasks.

# 637 Analyses quantifying perception and memory activity

Our main empirical analyses examined the evoked BOLD response to our experimental stimuli during perception 638 and memory as a function of visual field parameters estimated from the pRF model. Our first step was to visualize 639 evoked activity during perception and memory in visual field coordinates (Fig. 3a). Transforming the data in this 640 way allowed us to view the activity in a common reference frame across all brain regions, rather than on the 641 cortical surface, where comparisons are made difficult by the fact that surface area and cortical magnification differ 642 substantially from one area to the next. To do this, we selected the (x, y) parameters for each surface vertex from the 643 retinotopy model and the  $\beta$  parameters from the GLM analysis. Separately for a given ROI, subject, stimulus, and 644 task (perception/memory), we interpolated the  $\beta$  values over (x, y) space. We rotated each of these representations 645

according to the polar angle location of the stimulus so that they would be aligned at the upper vertical meridian.
 We then *z*-scored each representation before averaging across stimuli and subjects. We used these images to gain
 intuition about the response profiles and to guide subsequent quantitative analyses.

Before quantifying these representations, we simplified them further. Because our stimuli were all presented 649 at the same eccentricity, we reduced our 2D stimulus coordinate representations to 1D dimensional responses 650 functions on the polar angle dimension (Fig. 4a). We did this by selecting surface vertices whose (x, y) coordinates 651 were within one  $\sigma$  of the stimulus eccentricity (2°) for each ROI. We then binned the evoked BOLD response into 652 18 bins of polar angle distance from the stimulus and averaged within each bin to produce polar angle response 653 functions for each subject. We divided each subject's response function by the norm of the response vector before 654 averaging across subjects and then multiplying by the average vector norm to get the correct units back. This 655 procedure prevents a subject with a high BOLD response across all polar angles from dominating the average 656 response. The resulting average polar angle response functions showed clear surround suppression for polar 657 angles near the stimulus during perception. Given this, we fit a difference of two von Mises distributions to the 658 average data, with the location parameters ( $\mu$ ) for the two von Mises distributions fixed to be equal, but the spread 659  $(\kappa)$  and scale allowed to differ. 660

We quantitatively assessed the similarities and differences between perception and memory responses using 661 these fits. We examined the location parameter of the two von Mises distributions, and also computed the amplitude 662 and FWHM of the fit. We repeated the fitting procedure 500 times, drawing subjects with replacement, to create 663 bootstrapped 68% and 95% confidence intervals for both perception and memory location, amplitude, and FWHM 664 parameters. To assess main effects of ROI, main effects of perception vs memory, and the interaction of these 665 variables on location, amplitude, and FWHM values, we ran two-way ANOVAs. In all models, ROI was coded as an 666 ordinal variable (V1 < V2 < V3 < hV4 < LO < V3ab) and perception/memory as a categorical variable. Because 667 location, amplitude, and FWHM, were computed at the group-level and not at the single-subject level, we ran these 668 ANOVAs using group-level values. We re-ran the ANOVAs for all 500 subject resamplings to create bootstrapped 669 confidence intervals for ANOVA regression coefficients. We computed p-values for these effects by performing 670 randomization tests. To create null distributions, we randomly shuffled the assignment of the location, amplitude, 671 or FWHM values with respect to the independent variables of interest (ROI, perception/memory). We did this 672 for every possible shuffling or a subset of 10,000 different shufflings, whichever was smaller. We then computed 673 two-tailed p-values according to the position of the true regression coefficient in the null distribution. Statistical data 674 visualizations for these analyses and those subsequently described were made using seaborn v0.9.0 (Waskom 675 et al., 2018). 676

### 677 Noise simulations

We performed three simulations designed to test whether differences in noise between perception and memory data could explain differences in the responses we observed. To this end, we identified three potential types of noise that were present in our memory data but not our perception data: 1) reduced SNR; 2) retrieval failure; 3) memory error. We then simulated the effect of these types of noise on our perception data and asked whether these noise sources could produce responses similar to the ones we observed during memory.

### 683 SNR simulation

To simulate reduced SNR, we created artificial datasets with different amounts of additive noise introduced to 684 every vertex's perception parameter estimate. Noise was added in five levels: noise needed to generate the 685 empirical SNR of the perception data (p), noise needed to generate the empirical SNR of the memory data (m), or 686 noise needed to generate 1/2, 1/4, or 1/8 the empirical SNR of the memory data. For each of these values, we 687 simulated 100 independent datasets for every subject and ROI. We determined the amount of signal and noise 688 actually observed for each vertex during perception and memory by examining bootstrapped parameter estimate 689 distributions produced by GLMdenoise. We defined the median parameter estimate across bootstraps as the 690 amount of signal and the standard error of this distribution as the amount of noise. To simulate new data for a 69 vertex, we randomly drew a new parameter estimate from a normal distribution defined by the true signal value 692

(median) and the noise value (SE) needed to produce the target SNR. Critically, we made the draws correlated 693 across vertices for each simulation. We did this by selecting a scale factor from a standard normal distribution 694 which determined how many SEs away from the median every vertex's simulated value would lie. This scale factor 695 was shared across all vertices in an ROI for a given simulation. This procedure overcompensates for the spatial 696 correlation present in BOLD data by assuming that SNR is 100% correlated across all vertices in an ROI. Note 697 that if the noise were uncorrelated across vertices, it would have a much smaller effect on the population tuning 698 curves. For each noise value and each of the 100 simulations, we analyzed the simulated data using the same 699 procedure we applied to the actual data. This yielded 100 yon Mises fits to the simulated data for each noise value 700 and ROI (Supplementary Fig. 1a). We extracted the location, amplitude, and FWHM values from these fits. We 701 evaluated whether location and FWHM values approximated the ones we observed during memory by calculating 702 the proportion of simulations that fell within the 95% confidence intervals derived from the memory data (Fig. 5a). 703

### 704 *Retrieval failure simulation*

To simulate retrieval failure, we created artificial datasets that contained a variable number of perception trials 705 with no signal. Retrieval failure was simulated in five levels: 0%, 25%, 50%, 75%, and 100% of trials. For each 706 of these values, we simulated 100 independent datasets for every subject and ROI. Depending on the level of 707 retrieval failure, zero, one, two, three, or all four stimuli were randomly designated as 'failed' in each simulated 708 dataset. For the failed stimuli, new parameter estimates were drawn from a distribution defined by zero signal during 709 perception for every vertex. For the remaining stimuli, new parameter estimates were drawn from a distribution 710 defined by the true perception signal for every vertex. Noise was equated for both trial types; for each vertex, we 711 used the the amount of noise observed during perception. As in the SNR simulation, simulated data were correlated 712 across vertices in an ROI and simulated data were analyzed using the same procedures as for the actual data. We 713 evaluated whether simulated location and FWHM values approximated the ones we observed during memory by 714 calculating the proportion of simulations that fell within the 95% confidence intervals derived from the memory data 715 (Supplementary Fig. 1b and Fig. 5b). 716

### 717 Memory error simulation

To simulate memory error, we created artificial datasets that contained a variable amount of angular error in the peak 718 location of the perception polar angle response functions. Memory error was simulated in seven levels of standard 719 deviation: 0, 15, 30, 45, 60, 75, and 90 degrees. For each of these values, we simulated 100 independent datasets 720 for every subject and ROI. We assigned the amount of memory error for a given subject and stimulus by drawing a 721 random value from a normal distribution centered at the true angular location of the stimulus and with the current 722 standard deviation. We then used these memory error values to misalign simulated perception data. Specifically, 723 we created new perception datasets based on the true signal and noise characteristics of our perception data 724 (equivalent to SNR simulation with 'p' noise or 0% retrieval failure simulation). As in prior simulations, simulated data 725 were correlated across vertices in an ROI, and simulated data were analyzed according to the same procedure as 726 for the actual data. Before averaging the simulated data across stimuli and subjects, we rotated each response by 727 the chosen memory error value rather than by the location of that stimulus. That is, instead of rotating the response 728 to a 45 $^{\circ}$  stimulus by 45 $^{\circ}$  to align all stimuli at 0 $^{\circ}$  (as we did in our main analysis), we rotated the response by a 729 value either close (generating using small standard deviations, representing small errors) or potentially quite far 730 away (generating using large standard deviations, representing large errors). After averaging, we extracted location 731 and FWHM values. We then evaluated whether simulated location and FWHM values approximated the ones we 732 observed during memory by calculating the proportion of simulations that fell within the 95% confidence intervals 733 derived from the memory data (Supplementary Fig. 1c and Fig. 5c). 734

### 735 pRF forward model

We evaluated the ability of our pRF model to account for our perception and memory measurements. To do this, we
 used our pRF model as a forward model. This means that we took the pRF model parameters fit to fMRI data from
 the retinotopy session (which used a drifting bar stimulus) and used them to generate predicted BOLD responses
 to our four experimental stimuli. The model takes processed stimulus images as input, and for each of these

<sup>740</sup> images, outputs a predicted BOLD response (in units of % signal change) for every cortical surface vertex. Before
 <sup>running</sup> the model, we transformed our experimental stimuli into binary contrast apertures with values of 1 where
 <sup>running</sup> the stimulus was and values of 0 everywhere else. These images were downsampled to the same resolution as the

<sup>743</sup> images used to fit the pRF model (101 x 101).

### 744 Model specification

The pRF forward model has two fundamental operations. In the first operation, a stimulus contrast aperture image is 745 multiplied by a voxel's pRF. In the CSS and linear models, this pRF is defined as a circular symmetric 2D Gaussian, 746 parameterized by a location in the visual field (x, y) and a size  $(\sigma)$ . In the DoG+CSS version of the model, this pRF 747 is defined as the difference of two such Gaussians, centered at the same location (see next paragraph). The second 748 operation applies a power-law exponent (n) to the result of the multiplication, effectively boosting small responses. 749 This nonlinear operation is the key component of the CSS model and improves model accuracy in high-level visual 750 areas that are known to exhibit subadditive spatial summation (Kay et al., 2013b; Mackey et al., 2017). The values 751 of the exponent range from 0 to 1, where a value of 1 returns the model to linear. The output of this nonlinear stage 752 is multiplied by a final scale parameter ( $\beta$ ), which returns the units to % signal change (Fig. 6a). 753

Because we observed negative surround responses in V1–V3 during perception, we focused mainly on the 754 results of the DoG+CSS model. Prior work has shown that difference-of-Gaussians (DoG) pRF models can account 755 for the center-surround structure we observed (Zuiderbaan et al., 2012). In order to construct DoG pRFs, we 756 converted each pRF from the CSS model we fit to the retinotopy data to a DoG pRF. We chose this approach after 757 encountering difficulty in fitting a DoG pRF model to the retinotopy data. First, we took every 2D Gaussian pRF from 758 the CSS model, and we subtracted from it a second 2D Gaussian pRF that was centered at the same location but 759 was twice as wide and half as high. This ratio of  $2\sigma$  and  $.5\beta$  between the negative and positive Gaussians was fixed 760 for all voxels. In order to prevent the resulting DoG pRF from being systematically narrower and lower in amplitude 761 than the original pRF, we rescaled the  $\sigma$  and  $\beta$  of the original pRF before converting it to a DoG. We multiplied 762 the original  $\sigma$  by  $\sqrt{2}$  and the original  $\beta$  by 2, resulting in a DoG pRF with equivalent FWHM and amplitude as the 763 original pRF. Thus, the DoG pRF differed from the original pRF only in the presence of a suppressive surround. 764

We compared the predicts of the DoG+CSS model to the results of the CSS model and to a linear model that we fit separately to the retinotopy data. In this linear model, no exponent parameter was fit. After generating a prediction for each subject, stimulus, and surface vertex, for each of our three forward models, we carried these predictions forward through the same analysis pipeline used to analyze our task-based data. This generated predicted polar angle response functions for each of the three pRF forward models (Fig. 6b and Supplementary Fig. 2). We generated bootstrapped predictions by conducting the same procedure on the bootstrapped datasets.

### 771 Evaluating model predictions

We next compared how well the DOG+CSS model predictions matched our perception versus memory measure ments. We correlated the predicted location, amplitude, and FWHM parameters for each ROI with the actual
 perception and memory parameters. We evaluated these relationships by fitting a linear model to the predicted
 versus observed observations. To generate confidence intervals on these fits, we fit linear models to the 500
 bootstrapped perception and memory datasets and the yoked pRF predictions (Fig. 6c).

<sup>777</sup> We also compared the model accuracy of the DoG+CSS and CSS predictions alongside a linear prediction <sup>778</sup> with no exponent parameter (Supplementary Fig. 2a). We calculated the coefficient of determination ( $R^2$ ) for the <sup>779</sup> predicted polar angle response functions in each ROI, separately for the observed perception and memory polar <sup>780</sup> angle response functions (Supplementary Fig. 2b). Under this measure, a model that predicts the mean observed <sup>781</sup> response for every value of polar angle distance will have an  $R^2$  of zero, with better models producing positive values <sup>782</sup> and worse models producing negative values. We generated confidence intervals for these accuracies by computing <sup>783</sup>  $R^2$  values for each of the 500 bootstrapped perception and memory datasets and the yoked pRF predictions.

### 784 Hierarchical network model

We assessed whether a simple instantiation of a single neural network model could account for both the perception 785 and memory data. We implemented a fully linear hierarchical model of neocortex in which the activity from each 786 layer was created by pooling activity from the previous layer. This model encodes 1D space only and its parameters 787 are fixed (i.e. it is not trained). For the feedforward simulation, we began with a 1D square wave stimulus, which 788 spanned -20 to 20 degrees of polar angle. We created a fixed Gaussian convolution kernel ( $\mu = 0, \sigma = 15$ ), which 789 we convolved with the stimulus to create the activity in layer 1. This layer 1 activity was convolved with the same 790 Gaussian kernel to create the layer 2 activity, and this process was repeated recursively for 8 layers (Fig. 7a, left). 791 In order to simulate memory-evoked responses in this network, we made two assumptions. First, we assumed 792 that the feedback simulation began with the layer 8 activity from the feedforward simulation. That is, we assumed 793 no information loss or distortion between perception and memory in the last layer. Second, we assumed that 794 all connections were reciprocal and thus that the same Gaussian kernel was applied to transform layers in the 795 feedback direction as in the feedforward direction (Fig. 7a, right). Thus, in the feedback simulation, we convolved 796 the layer 8 activity with the Gaussian kernel to produce the layer 7 activity and repeated this procedure recursively, 797 ending at layer 1 (Fig. 7b). Note that these computations can be performed with matrix multiplication rather than 798 convolution by converting the convolutional kernel to a Toeplitz matrix, which is how we implemented it. In this case, 799 the transpose of the Toeplitz matrix (itself, as it is symmetric) is used in the feedback direction. We plot the location, 800 amplitude and FWHM for each layer's activation in the same convention as the data (Fig. 7c). 801

# 979 Supplementary Figures

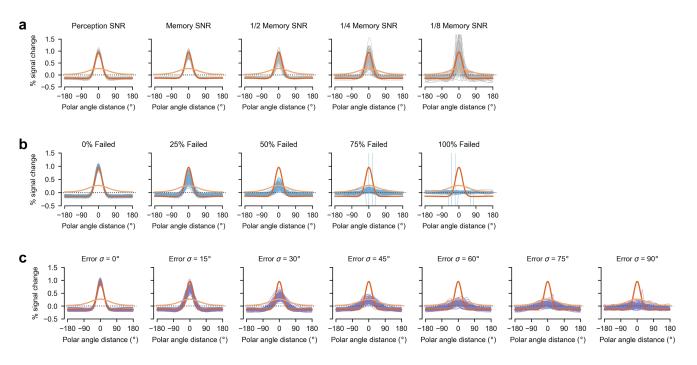

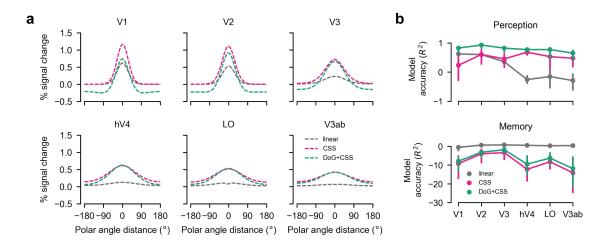

Figure 1. Simulated V1 datasets with different noise levels. (a) Gray lines represent the fits to simulated V1 perception datasets with different levels of SNR. Each panel contains 100 independently simulated datasets with the same noise level. Orange lines represent the fits to the actual perception and memory data, reproduced from Figure 4b, and are the same for each SNR value. (b) Purple lines represent the fits to simulated V1 perception datasets with different frequencies of failed retrieval. Other conventions as in (a). (c) Blues lines represent the fits to simulated V1 perception datasets with different amounts of memory error. Other conventions as in (a).

**Figure 2. pRF model comparisons. (a)** Predicted polar angle response functions are plotted for three pRF models: linear, CSS, and DoG+CSS. Comparing these responses to perception data plotted in Figure 4b, the linear model did the poorest job of predicting perception responses. Linear predictions underestimated the amplitude of the observed response, particularly in later visual areas. Both nonlinear models (CSS and DOG+CSS) avoided this magnitude of failure. The DoG+CSS model selectively captured negative responses in V1–V3. **(b)** Model accuracy ( $R^2$ ) of the predicted polar angle response functions for each pRF model, evaluated separately for perception and memory data in each ROI. Error bars indicate 68% bootstrapped confidence intervals. Accuracy of the linear model in predicting perception data dropped steadily moving away from V1, indicating poor fit. Model accuracies for the the CSS and DoG+CSS models were higher and more stable across ROIs, with the DoG+CSS performing slightly better in every region. With the exception of the linear model in late visual areas, accuracy for all three models was far worse for memory data than perception data.
