26 Abstract

- 27 Whole-genome duplication (WGD) is hypothesized to be an important evolutionary
- 28 mechanism that can facilitate adaptation and speciation. Genomes that exist in states of both
- 29 diploidy and residual tetraploidy simultaneously are of particular interest, as understanding the
- 30 mechanisms that maintain this mosaic of ploidy after WGDs may provide important insights into
- 31 evolutionary processes. Salmonids are a useful model to study the effect of WGDs due to the
- 32 extensive diversity that has evolved following an ancestral autotetraploidization event. Although
- 33 most of the salmonid genome has reverted to diploidy following WGD, approximately 25% of
- 34 the chromosomes continue to exist in a state of residual tetrasomy. In this study, we generate a
- 35 novel linkage map for cisco (*Coregonus artedi*) and conduct comparative genomic analyses to
- 36 refine our understanding of chromosomal fusion/fission history across salmonids. Additionally,
- 37 we propose a new naming strategy, protokaryotypes, that facilitates comparisons across
- 38 Salmonids by standardizing naming to ancestral chromosomes from northern pike (*Esox lucius*).
- 39 The female linkage map for cisco contains 20,450 loci, 3,383 of which are likely contained
- 40 within residually tetraploid regions of the genome. Comparative genomic analysis revealed that
- 41 patterns of residual tetrasomy are generally conserved across species, but there is interspecific
- 42 variation in the relative extent of the residual tetrasomy. Additionally, with the current reference
- 43 genomes available, we only find evidence of residual tetrasomy in seven of the eight
- 44 chromosomes that have been previously hypothesized to show this pattern. This interspecific
- 45 variation may have important implications for understanding salmonid evolutionary histories and
- 46 informing future conservation efforts.

50 Introduction

51 The evolutionary significance of whole-genome duplications (WGDs) has been 52 intensively debated for decades (e.g; Ohno 1970; Santini et al. 2009; Wood et al. 2009; Zhan et 53 al. 2014; Mayrose et al. 2015; Van de Peer et al. 2017). Multiple studies have hypothesized that 54 WGD is an important evolutionary mechanism that can facilitate adaptation on short- and long-55 term evolutionary timescales (Ohta 1989, Selmecki et al. 2015; Van de Peer et al. 2017). For example, genes found in polyploid regions are able to gain new function (i.e., 56 57 neofunctionalization) without the consequences of deleterious mutations affecting the main function of the second gene copy. This may facilitate adaptive molecular divergence and the 58 59 evolution of new phenotypes (Wittbrodt et al 1998; Wendel 2000; Rastogi and Liberles 2005). 60 However, other studies have hypothesized that WGD presents significant challenges for meiosis and mitosis (Hollister 2015) and may not have as much of an effect on evolution as originally 61 62 thought (Mayrose et al. 2011; Arrigo and Barker 2012; Vanneste et al. 2014; Clarke et al. 2016). 63 A consensus is therefore yet to be reached on the evolutionary impact of WGD relative to other 64 evolutionary forces. 65 Conducting genetic studies on organisms having underwent relatively recent WGD has been challenging due to the inability to differentiate alleles and sequences from the same 66 67 chromosome (homologs) from those on the duplicated chromosome (homeologs) (Limborg et al. 68 2016b). Fortunately, approaches leveraging gamete manipulation, high sequencing coverage, and long read sequencing have improved our ability to characterize duplicated regions. For example, 69 70 linkage mapping with haploids and doubled haploids has facilitated analysis of duplicated 71 regions in salmonids (Brieuc et al. 2014; Kodama et al. 2014; Lien et al. 2016; Waples et al. 72 2016). Further, long-read sequencing technologies, such as PacBio and Oxford Nanopore, have 73 made it possible to assemble complex genomes with convoluted duplication histories 74 (Kyriakidou et al. 2018). These technological advances have revolutionized our ability to 75 understand genomic architecture in that have adaptively radiated to form dozens of species 76 following an ancestral WGD in lineages such as salmonids (Lien et al. 2016; Robertson et al. 77 2017; Campbell et al. 2019) and many plant species (Alix et al. 2017). 78 Salmonids are derived from an ancestral species that underwent a WGD ~100 million 79 years ago (Ss4R, Allendorf and Thorgaard 1984; Berthelot et al. 2014; Macqueen and Johnston 80 2014; Lien et al. 2016) and have since diversified into a broad array of both ecologically and genetically distinct taxa. The Salmonidae family is comprised of three subfamilies: Salmoninae 81 (salmon, trout, and char), Thymallinae (graylings), and Coregoninae (whitefish and ciscoes) 82 (Norden 1961), and diversification of these subfamilies post-dates the Ss4R, occurring 40-50 83 84 million years ago (Campbell et al. 2013; Macqueen and Johnston 2014). Phylogenetic analysis 85 has thus far revealed that the majority of the salmonid genome returned to a diploid inheritance state prior to the basal split of each of the three subfamilies (Robertson et al. 2017). The 86 87 rediploidization process is still incomplete and approximately 20-25% of each salmonid genome 88 still shows signals of tetrasomic inheritance (i.e., residual tetrasomy, or the recombination

between homeologs that results in the exchange of alleles between homeologous chromosomes
(Allendorf et al. 2015; Lien et al. 2016; Robertson et al. 2017)).

91 Evidence for residual tetrasomy in the salmonids was found using allozyme studies in 92 experimental crosses (Allendorf and Danzmann 1997) and, more recently, by linkage maps, 93 sequenced genomes, and sequence capture (Kodama et al. 2014; McKinney et al. 2017; 94 Robertson et al. 2017; Christensen et al. 2018b; Pearse et al. 2018). High-density linkage maps 95 that include both duplicated and non-duplicated markers have revealed that eight pairs of 96 homeologous chromosomes display evidence of conserved residual tetraploidy despite 97 independent fusion and fission events, as well as general evolutionary history across species 98 (Brieuc et al. 2014; Kodama et al. 2014; Sutherland et al. 2016). These chromosomes, referred to 99 as the "magic eight," have been found in linkage mapping studies of coho salmon Oncorhvnchus 100 kisutch (Kodama et al. 2014), Chinook salmon O. tshawytscha (Brieuc et al. 2014; McKinney et al. 2016; McKinney et al. 2019), pink salmon O. gorbuscha (Tarpey et al. 2017), chum salmon 101 O. keta (Waples et al. 2016), and sockeye salmon O. nerka (Larson et al. 2015). Additionally, 102 103 previous mapping studies have revealed that at least one of the two homeologs exhibiting 104 residual tetraploidy in these pairs is within a fusion, suggesting that chromosomal structure may 105 play a role in maintenance of residual tetraploidy (Brieuc et al. 2014; Kodama et al. 2014; 106 Sutherland et al. 2016). Analysis of sequenced genomes for Atlantic salmon (Salmo salar) and 107 rainbow trout (O. mykiss) has revealed similar patterns, although in these studies only seven of 108 these pairs were identified as displaying clear signals of conserved residual tetraploidy (Lien et 109 al. 2016; Campbell et al. 2019). Sequence capture analysis also suggests that seven of the pairs 110 display conserved signals of residual tetrasomy across species (Robertson et al. 2017). This led 111 to the definition of two types of homeologous regions: 1) ancestral ohnologue resolution (AORe) 112 regions with relatively low sequence similarity with ancestral homeologs that likely 113 rediploidized prior to species diversification; and 2) lineage ohnologue resolution (LORe) 114 regions with high sequence similarity among homeologs, likely maintained by residual 115 tetraploidy (Robertson et al. 2017). Collectively, these studies have provided important insights 116 into the salmonid WGD, but many unresolved questions related to the rediploidization process 117 and maintenance of residual tetrasomy still exist.

118 Over the past decade, a proliferation of genomic resources has occurred within 119 salmonids. Currently, linkage maps that include duplicated regions are available for five 120 Oncorhynchus species, and genome assemblies are available for grayling Thymallus thymallus 121 (Savilammi et al. 2019), Atlantic salmon (Lien et al. 2016), Arctic char Salvelinus alpinus 122 (Christensen et al. 2018b), rainbow trout (Pearse et al. 2018), and Chinook salmon (Christensen 123 et al. 2018a). These resources permit investigation into the processes of rediploidization and 124 residual tetrasomy across the salmonid family. However, the genome resources for some of the 125 lineages, such as the Coregoninae subfamily, remain undercharacterized. In the current study, 126 we develop a high-density linkage map for North American cisco (Coregonus artedi), the first 127 haploid linkage map for the Coregoninae subfamily, and analyze existing genomic resources for 128 other salmonids with the goal of investigating patterns of residual tetrasomy and chromosomal

- 129 fusion and fission history across the salmonid family, with particular focus on the coregonines.
- 130 Our results suggest that (1) interspecific patterns of residual tetrasomy differ more than
- 131 previously observed; (2) binary definitions of chromosome ploidy status may not adequately
- 132 capture variation within and among species; (3) linkage maps and sequenced genomes identify
- 133 slightly different patterns regarding residual tetrasomy; and (4) a large number of fissions and
- 134 fusions are specific to the base of the Coregoninae subfamily, and species-specific fusions of this
- 135 lineage are rare. This study uses new and existing resources to conduct the most comprehensive
- analysis of residual tetrasomy across the salmonid phylogeny to date, revealing important
- 137 patterns that likely impacted the evolutionary history of this diverse and important taxonomic
- 138 group.
- 139

140 Methods

141 Experimental crosses for linkage mapping

142 Genotypes from diploid and haploid families were used to build sex-specific linkage 143 maps. Diploid crosses were constructed from cisco collected in northern Lake Huron (45° 144 58'51.6" N -84 °19'40.8" W, USA) during spawning season (November 2015) by U. S.Fish and 145 Wildlife Service crews using standardized gill net assessment methods. Gametes for haploid 146 crosses were collected following the same methods, from the same location and month but in 147 2017. Gametes were extracted from mature fish and eggs were combined directly with sperm to 148 produce diploid crosses or with sperm that had been irradiated with 300,000 µJ/cm² UV light for 149 two minutes to break down the DNA to produce haploid crosses. UV irradiation leaves the sperm 150 intact so that the egg can be activated but no paternal genetic material is contributed (i.e., 151 gynogenesis, Chourrout 1982), resulting in haploid embryos developing with maternal genetic 152 material only. Crosses were made in the field and transported to the U.S. Geological Survey-153 Great Lakes Science Center, Ann Arbor, Michigan (USA) for rearing. Tissue samples (fin clips) 154 were taken from adult parents, from offspring of the diploid crosses at age two, and from 155 haploids approximately 50 days post fertilization. All samples were preserved in a combination 156 of 95% ethanol and 5% EDTA and sent to the University of Wisconsin, Stevens Point Molecular 157 Conservation Genetics Lab for processing. Laboratory and field collections were conducted 158 under the auspices of the U.S. Fish and Wildlife Service and U.S. Geological Survey-Great 159 Lakes Science Center and all necessary animal care and use protocols were filed by these

- 160 agencies.
- 161

162 DNA extraction and RAD-sequencing library preparation

163 DNA was extracted using DNeasy 96 Blood and Tissue Kits (Qiagen, Valencia,

164 California) per the manufacturer's instructions. Quality and quantity of the extracted genomic

- 165 DNA was measured using the Quant-iT PicoGreen double-stranded DNA Assay (Life
- 166 Technologies) with a plate reader (BioTek). To confirm ploidy of haploid samples, parents and
- 167 offspring were genotyped using six polymorphic microsatellite loci known to occur at diploid
- 168 sites developed by Angers et al. (1995), Patton et al. (1997), and Rogers et al. (2004), and

169 individuals were classified as haploids if only a single allele was present at all loci. The

- 170 probability of not detecting a diploid if a diploid was present is $\sim 1.09\%$ based on microsatellite
- 171 heterozygosity in the parental population (unpublished data, Wendylee Stott).
- 172 Genomic DNA from diploids and confirmed haploids was prepared for RAD sequencing
- 173 using the SbfI restriction enzyme following the methods outlined in Ali et al. (2016) except
- 174 shearing restriction digested DNA was done with NEBNext® dsDNA Fragmentase® (New
- 175 England Biolabs, Inc) instead of sonication. DNA was then purified and indexed using
- 176 NEBNext® UltraTM DNA Library Prep Kit for Illumina® per the manufacturer's instructions
- 177 (New England Biolabs, Inc). Libraries were sequenced on a HiSeq4000 with paired end 150bp
- 178 chemistry at the Michigan State Genomics Core Facility (East Lansing, MI).
- 179
- 180 SNP discovery and genotyping

181 Quality filtering, SNP identification, and genotyping was conducted using STACKS v.2.2 182 (Rochette and Catchen 2017). First, samples were demultiplexed with process radtags with 183 flags -c, -q, -r, -t 140, --bestrad. Markers were discovered de novo and genotyped within 184 individuals with ustacks (flags = -m 3, -M 5, -H --max locus stacks 4, --model type bounded, --185 bound high 0.05, --disable-gapped). A catalog of loci was created using a subset of the 186 individuals (diploid parents = 8, haploid parents = 5, wild fish = 38, total cisco = 51) with *cstacks* 187 (-n of 3, --disable-gapped). The 38 wild fish used in the catalog were collected from the same 188 geographic area using the same collection methods as listed above and were included to search 189

- 189 for a sex identification marker, which was unsuccessful (*data not shown*).
 190 Putative loci within each individual fish were matched against the cata
- Putative loci within each individual fish were matched against the catalog with *sstacks*(flag = --*disable-gapped*), *tsv2bam* was used with only the forward reads to orient the data by
- 192 SNP, and *gstacks* was used to combine genotypes across individuals. Only the forward reads
- 193 from the paired-end data were used in *gstacks* due to variable read depth in reverse reads and
- 194 thus less reliable genotyping. *gstacks* was also run separately with the forward and reverse reads
- using *tsv2bam* to assemble longer contigs for sequence alignment and annotation. Final genotype
- calls were output as VCF files with *populations* (flags = -r 0.75), with each family grouped as a
 separate population in the *popmap* sample interpretation file. VCFtools (Danecek et al. 2011)
 was used to identify and remove individuals from the study that were missing more than 30% of
- 199 data.

200 Maximum likelihood-based methods developed by Waples et al. (2016) were used to 201 identify loci that could be mapped in haploid crosses and to identify potentially duplicated loci. 202 Custom Python scripts available on GitHub (Python Software Foundation version 2.7) (see Code 203 Availability), were used to filter the haplotype VCF file output from the *populations* module to 204 identify loci that could be mapped in the diploid families. Loci missing more than 25% of data 205 and loci that were genotyped as heterozygous in both parents of diploid families (and therefore 206 could not be reliably mapped) were removed (as in Larson et al. 2015). Individual genotypes 207 were exported with the custom Python scripts as *LepMap3* input files. As a final step before 208 linkage mapping, genotypes from all seven families (haploid and diploid) were combined into a

6

single dataset to form the final female *LepMap3* input file and the four diploid families were combined into a single dataset to form the final male *LepMap3* input file.

- 211
- 212 *Linkage mapping*

213 The program LepMap3 (Rastas 2017) was used to construct linkage maps following the 214 methods of McKinney et al. (2016). Due to heterochiasmy (i.e., recombination rate differences 215 between males and females) that occurs in the Salmonidae family (Sakamoto et al. 2000), a 216 separate map was constructed for each sex. Loci were filtered and clustered into linkage groups 217 (LGs) based on recombination rates by calculating logarithm of the odds (LOD) scores between 218 all pairs of loci with the SeparateChromosomes2 module. The LOD scores were chosen by 219 increasing the LOD value by one until the number of LGs stabilized and was similar to that 220 expected based on the haploid karyotype of cisco (N=40, Phillips et al. 1996). The final LOD 221 scores used to generate the map were LOD = 15 and 5 for the female and the male maps, 222 respectively. Loci were then ordered within LGs by utilizing paternal and maternal haplotypes as 223 inheritance vectors with the OrderMarkers2 module. We used a minimum marker number per 224 LG of 100 for the female map and 40 for the male map. LGs were reordered and markers 225 removed until no large gaps remained (Rastas 2017).

226

227 Comparative analysis of syntenic regions of linkage maps via MAPCOMP

228 MAPCOMP can be used to compare syntenic relationships among markers between 229 linkage maps of any related species using a genome intermediate from another related species 230 (Sutherland et al. 2016). Here, MAPCOMP was used to compare the cisco map with other 231 Coregonus spp.; lake whitefish C. clupeaformis (Gagnaire et al. 2013), European whitefish C. 232 lavaretus "Albock" (De-Kayne and Feulner 2018), as well as other representative species from 233 other salmonid genera (i.e., Atlantic salmon (Lien et al. 2016), brook trout S. fontinalis 234 (Sutherland et al. 2016), and Chinook salmon (Brieuc et al. 2014) and a representative of the 235 outgroup to the salmonid WGD, northern pike Esox lucius (Rondeau et al. 2014). All code to 236 collect and prepare maps, and run the analysis are available on GitHub (see *Code Availability*). 237 MAPCOMP pairs loci between the two compared linkage maps if they align at the same

- locus or close to each other on the same contig or scaffold (Sutherland et al. 2016). Due to the
- 239 large phylogenetic distance covered in this analysis, two reference genomes; grayling
- 240 (Savilammi et al. 2019) and Atlantic salmon (Lien et al. 2016) were used for comparisons. As
- salmonid chromosomal evolution is typified by Robertsonian fusions (Phillips and Rab 2001),
- fused chromosome arms in cisco, lake whitefish, and European whitefish were identified by
- 243 aligning cisco markers to multiple salmonid resources to identify cases where one cisco LG
- corresponded with at least two chromosome arms in another species. The fusion and fission
- 245 phylogenetic history was plotted based on the most parsimonious explanation of common fusions
- among *Coregonus* spp. basing the approximate timings of fusions on shared fusions among
- 247 species. Fusion history shared at the base of the Salmoninae lineage was taken from earlier work
- 248 (Sutherland et al. 2016).

249

250 Homeolog identification, similarity and inheritance mode

Homeologous chromosome arms can be identified in haploid crosses by mapping multiple alleles of duplicated markers as described in Brieuc et al. (2014). Duplicated markers in cisco were mapped using this method, and data obtained on duplicated markers from previously constructed linkage maps for coho salmon (Kodama et al. 2014), Chinook salmon (McKinney et al. 2019), pink salmon (Tarpey et al. 2017), chum salmon (Waples et al. 2016), and sockeye salmon (Larson et al. 2015). Homeologs were then ranked based on the number of markers supporting each known homeologous relationship.

258 Homeology was assessed by comparing DNA sequence similarity between homeologous 259 arms from chromosome-level genome assemblies. Genomes included in this analysis were 260 grayling (GCA 004348285.1, Savilammi et al. 2019) Atlantic salmon (GCF 000233375.1, Lien 261 et al. 2016), Arctic char (GCF 002910315.2, Christensen et al. 2018b), rainbow trout 262 (GCA 002163495.1, Pearse et al. 2018), and Chinook salmon (GCF 002872995.1, Christensen 263 et al. 2018a). Homeologous pairs of chromosomes originating from the Ss4R duplication were known from original studies or through MAPCOMP comparisons and whole chromosomes 264 265 containing the target chromosome pairs to be compared in each contrast were aligned to each other with LASTZ v1.02 (Harris 2007) following methods outlined in Lien et al. (2016). Options 266 267 specified with LASTZ included --chain --gapped --gfextend --identity=75.0..100. --268 ambiguous=iupac --exact=20. The analysis was restricted to alignments with minimum percent 269 match values of 75%, and a minimum length of 1,000 base pairs to minimize the likelihood of 270 spurious alignments. Overall similarity of a homeologous pair was represented by the median 271 percent similarity of all alignments, weighted by alignment length, and summarized with 272 boxplots for each homeologous pair in each species ordered based on descending median 273 percentage sequence similarity.

274 Each homeologous pair was classified into one of two categories, tetrasomic or disomic, 275 using a machine learning approach. From the 25 homeologous pairs originating at the Ss4R for 276 each species, a training set was constructed containing the four highest and lowest sequence 277 similarity homeolog pairs. A k – nearest neighbor classification (knn) approach was then applied 278 to the dataset using this training set. The k nearest-neighbors was determined by using a repeated 279 10-fold cross validation of 100 iterations with the trainControl function in the R package caret (v6.0-84, Kuhn 2019). The k for each species with the largest number of neighbors exhibiting the 280 281 highest accuracy with the training set was selected. This k was then used to classify homeologous pairs as disomic or tetrasomic, along with the predefined training set (knn function, Ripley and 282 283 Venables 2019). Overall, similarity between the two predicted categories from the knn 284 classification was tested with a Wilcoxon test (R Core Team 2018) incorporating percent 285 similarity from all alignments to determine whether the categories displayed significantly 286 different sequence similarity between homeologs (alpha = 0.01). All scripts used in this analysis 287 are available on GitHub (see Code Availability). 288

289 Results

290 RADseq, SNP discovery, and data filtering

291RADseq data were obtained from 746 cisco across seven families, with an average of 4.1292M reads per individual (range: 1.1 - 30.8 M reads per individual). Individuals that were293genotyped at more than 30% of loci and loci that were genotyped in more than 75% of the total294individuals were retained, resulting in a dataset of 676 individuals (n = 333 diploid offspring;295330 haploid offspring; and 13 parents) and 49,998 unique loci (Supplementary file S1).

296

297 *Linkage Mapping*

298 A total of 22.459 unique loci were identified in the female (Figure 1) and male linkage 299 maps (Supplementary file S2). The female map included 20,450 loci distributed across 38 LGs 300 (Table 1), the male map included 6,340 loci distributed across 40 LGs, and 4,012 loci were 301 present on both maps (Supplementary file S3). A total of 40 chromosomes was expected from karyotyping of coregonine fishes from the Great Lakes (Phillips et al. 1996), which matches the 302 303 number of LGs mapped in males. However, male LGs 39 and 40 in males contained relatively 304 few markers and may be fragments of other linkage groups rather than the two linkage groups 305 that were not mapped in females. Eight LGs (i.e., Cart01 - Cart08) were identified as 306 metacentric based on homology to two chromosome arms in other salmonids using MAPCOMP 307 (see below). In the female map, metacentric LGs were on average 85.44 cM (57.72 – 101.35 cM) 308 and contained 739 loci (range: 685 - 867). Putative acrocentric LGs in the female map were on 309 average 59.12 cM (50.97 - 64.53 cM) and contained 484 loci (range: 296 - 585). The total length 310 of the female map was 2,456.98 cM. The average lengths of metacentric LGs on the male map 311 were 66.76 cM (51.62 – 87.14 cM) and they contained 212 loci on average (range: 159 – 278). 312 Putative acrocentric LGs in the male map were on average 57.00 cM (40.54 - 83.66 cM) and 313 contained 145 loci (range: 41 - 224). The total length of the male map was 2,357.97 cM. We 314 identified 3,383 putatively duplicated loci on the female linkage map, and of these, 2,671 loci 315 mapped to one paralog and 709 loci mapped to both paralogs.

316

317 Comparative analysis of syntenic regions of linkage maps via MAPCOMP

318 The main focus of our comparative analysis was to define the homologous and 319 homeologous relationships among the linkage maps available for the coregonines, specifically in 320 cisco (current study), lake whitefish (Gagnaire et al. 2013), and European whitefish (De-Kayne 321 and Feulner 2018), and bring these species into the context of the broader chromosomal 322 correspondence by identifying the homologous chromosome arms in brook trout, Atlantic 323 salmon, and Chinook salmon, as well as the non-duplicated northern pike (Table 2, 324 Supplementary file S4). To facilitate these comparisons, we have defined the term 325 protokaryotype (PK). PKs correspond to hypothetical ancestral salmonid chromosomes pre-326 duplication inferred from observing a representative genome of the non-duplicated sister lineage 327 of salmonids from the Esociformes and are ordered 01-25. Protokaryotypes correspond 1:1 with

328 the northern pike genome but have two descendant homeologous regions within salmonid

329 genomes. For example, PK 01 corresponds to northern pike chromosome 01 and was an ancestral

- 330 pre-duplication salmonid chromosome which gave rise to homeologous Atlantic salmon
- 331 chromosomes Ssa09c (PK 01.2) and Ssa20b (PK 01.1) and to homeologous rainbow trout
- 332 Omy27 (PK 01.1) and Omy24 (PK 01.2) (Supplemental file S7). PKs in the previously
- 333 hypothesized "magic eight" from linkage mapping studies are PKs 02, 06, 09, 11, 20, 22, 23, 25.
- PKs defined as LORes by Robertson et al. (2017) and those that displayed residual tetraploidy in 334
- 335 previous genome-based studies (Lien et al. 2016; Campbell et al. 2019) are the same as these
- 336 with the exception of PK 06. The use of this naming system corresponds to the identifiers used in 337
- Sutherland et al. (2016), maintaining the correspondence of PK .1 or .2.
- Most PKs were identifiable in the MAPCOMP analysis, with some notable exceptions for 338 339 each coregonine species. In cisco, chromosome arms PK 22.2, 25.1 and 25.2 were unidentified;
- 340 two of these arms (PK 25.1 25.2) were also unidentified in the European whitefish linkage map
- 341 (De-Kayne and Feulner 2018). Additionally, it was difficult to determine correspondences for
- 342 PK 09 and 23. In European whitefish, five chromosome arms were unidentifiable (i.e., PK 09.1,
- 343 09.2, 23.2, 25.1 and 25.2), and there were homeology ambiguities for PK 02, as well as
- homology ambiguities for PK arm 05.2 (Table 2). In lake whitefish, five arms were 344
- 345 unidentifiable (i.e., PK 09.2, 11.2, 20.2, 22.1, and 25.2), and there were homeology ambiguities
- for PK 02.2 and 06.2. In multiple species, arms where it was difficult to determine homologous 346
- 347 relationships often had a high proportion of duplicated loci, presumably making distinguishing
- 348 homologs and homeologs challenging. Nonetheless, most homologs and homeologs (42/50) were 349 identified in all three coregonine species. This information was then leveraged to characterize the 350 fusion/fission history within the Coregoninae lineage using the methods outlined in Sutherland et
- 351 al. (2016).
- 352 The fusion/fission analysis indicated far fewer species-specific fusions than identified for 353 salmonids in Sutherland et al. (2016), with most fusions occurring prior to the divergence of the 354 coregonines (Figure 2). This difference in species-specific fusions may also be related to the
- 355 general lower number of fusions in coregonines relative to Salmo and Oncorhynchus
- 356 (Supplementary file S5); although, in the coregonines the majority of fusions were observed in
- 357 more than one species, which was not observed in most other species previously characterized.
- 358 Two strongly supported fusions were observed in all three coregonine species: fusions PK 05.1-
- 359 06.1 and 10.2-24.1. PK 11.1-21.1 was fused in both cisco and European whitefish, which
- 360 presumably underwent a fission in lake whitefish (Figure 2). The full characterization of fissions 361 will require the resolution of those ambiguous arms that are considered as probable in the current 362 analysis, and this may be further clarified in future work.
- In summary, five fusions were likely shared among all three species, and one was shared 363 364 between cisco and European whitefish (PK 11.1-21.1). Cisco had two species-specific fusions 365 (PK 10.2-20.1 and 22.1-20.2), bringing the total count of observed fusions to eight. European
- 366 whitefish had one species-specific fusion (PK 20.2-10.2), bringing the total count of observed
- 367 fusions to seven. Lake whitefish also had one species-specific fusion (PK 20.1-23.2), bringing
- 368 the total count to six. Interestingly, the PK 09.2-17.1 fusion that was originally proposed to be

369 shared among all known salmonids (Sutherland et al. 2016), was found not to be fused in any of

the species here, suggesting either that this fusion occurred after the divergence of Coregonus

371 from the ancestor of the rest of the salmonids, or that a fission occurred at the base of the

- 372 coregonines (Figure 2).
- 373

374 Homeolog identification, similarity, and inheritance mode

375 A second major goal of this study was to compare homeologous relationships and modes 376 of inheritance within and among species. We identified 17 of the 25 homeologous chromosome 377 pairs (PK) in cisco using the markers that could be mapped to both homeologs in the linkage 378 map, and each homeologous pair shared between one and 86 duplicated loci (Fig. 3, 379 Supplementary file S6). Of the 17 homeolog pairs, six (PK 02, 06, 09, 11, 20, 23) had many loci 380 (42-86) supporting homeology; these are six of the "magic eight" discussed above. The other 11 381 had few markers supporting homeology (i.e., 1-6) and are not members of the "magic eight". The other two arms found in the magic eight were not identifiable in cisco, potentially because they 382 383 contained a large number of duplicated loci. All of the previously constructed linkage maps for 384 salmonids that included duplicated regions had a large number of markers supporting homeology 385 for the "magic eight" with the exception of pink salmon, where seven of the eight PKs had high 386 support (34 – 68 loci) but one pair (PK25) displayed substantially lower support (nine loci) 387 (Tarpey et al. 2017) (Figure 3, Supplementary file S6).

388 To better understand the genetic similarity between homeologs and infer inheritance 389 mechanisms (i.e., residual tetrasomy or disomy), all 25 known homeologous relationships were 390 compared in reference genomes for grayling, Atlantic salmon, Arctic char, rainbow trout, and 391 Chinook salmon (Figures 3 and 4, Supplementary file S7). Using the machine learning algorithm 392 (see Methods), the optimal k – nearest neighbor for each species was identified as five. Those 393 five nearest neighbors from the training sets voted on the assignment of a particular PK to either 394 putatively tetrasomic or disomic classes (Figure 4), and the proportion of votes supporting each 395 assignment are reported in Supplemental Document S8. The highest observed vote proportion for 396 assignment to a class is 4 of 5 as a result of the limit on training set size to four of each class and 397 the five optimal k – nearest neighbors indicated for accuracy.

398 For Atlantic salmon and all Oncorhynchus spp. (i.e., rainbow trout and Chinook salmon), 399 the same eight PKs (i.e., PK 01, 02, 09, 11, 20, 22, 23, 25) were classified as tetrasomic using the 400 machine learning approach. This list of PKs includes all of those defined as LORes by Robertson 401 et al. (2017), and one additional (i.e., PK 01), but does not include PK 06, which is considered to be part of the "magic eight" using linkage map evidence. Arctic char showed evidence for 402 403 residual tetrasomy in seven of these eight PKs, with the exception of PK 11 (see below for 404 details regarding this discrepancy due to other chromosome arms in this fusion). Grayling also 405 shared seven of the eight residually tetraploid homeolog pairs, with the exception of PK 01. Most 406 PKs received the highest possible vote proportions for their classifications (0.8), however, PK01 407 in Atlantic salmon and rainbow trout demonstrated a lower vote proportion (0.6) (Figure 4,

408 Supplemental Document S8), suggesting reduced support for this homeologous pair being

409 tetrasomic. Additionally, PK 19 in grayling, didn't have the highest vote proportion and was 410 assigned as diploid but had the highest sequence similarity in that class (Figure 4, Supplemental 411 Document S8). Sequence similarity was significantly higher for the tetrasomic PKs across all 412 species (P < 0.0001).

413 Although the group of tetrasomic PKs was largely conserved across species, there was substantial variation in the relative sequence similarity between these homeolog pairs (i.e., order 414 415 of highest to lowest similarity) among species. PK 01 consistently displayed the lowest sequence 416 similarity of all the PKs in all five species where it was classified as tetrasomic and did not 417 always receive the highest observed vote proportion (see above). However, there were a number 418 of other homeolog pairs that displayed highly variable sequence similarity rankings across 419 species (Figure 4). For example, PK 09 had the highest sequence similarity in the grayling 420 genome, the sixth highest in the rainbow trout genome, and the fourth or fifth highest in the other 421 genomes. This variation suggests that the frequency of tetravalent meiosis for each PK may 422 differ across species and that the process of diploidization has occurred in a species-specific 423 manner post WGD as suggested in the mechanisms proposed by Robertson et al (2017).

424

425 **Discussion**

426 The amount of genomic resources available for salmonids has increased drastically over 427 the last decade. However, many previous studies investigating genome evolution in salmonids 428 focus on one or a few species, with fewer studies considering broader subsets of available taxa to 429 understand patterns of genome evolution across the Salmonidae family (but see Sutherland et al. 430 2016; Robertson et al. 2017). Here, we utilize genomic resources along with a newly generated 431 high-density linkage map for cisco to compare patterns of homology, fusion/fission events, 432 homeology, and residual tetrasomy across species. The cisco linkage map incorporates 433 duplicated regions and contains 20,450 loci, making it denser than most RAD-based haploid 434 linkage maps that have previously been constructed for salmonids (typically built from 3,000 to 435 5,000 loci). Higher marker density helped identify orthologous relationships between 436 coregonines and other salmonids as well as to identify homeologous chromosomes in cisco. We 437 also demonstrate the use of the protokaryotype ID, defined here but first used in Sutherland et al. 438 (2016), for comparative analyses in salmonids in order to unify and facilitate comparative 439 approaches in salmonid linkage maps and chromosome-level assemblies. Comparisons across 440 Salmonidae revealed that patterns of rediploidization are relatively similar across genera and 441 loosely correspond with phylogeny. However, we did identify substantial variation in sequence 442 similarity between homeologs both within species across homeolog pairs, and among species, 443 suggesting that frequently used binary classifications such as AORe/LORe and "magic eight" 444 may be oversimplified. 445

446 Protokaryotype identifiers to facilitate comparative genomics in salmonids

447 Comparative genomics within Salmonidae is important for the interpretation of the 448 effects of rediploidization after WGD on genome evolution (e.g. Berthelot et al. 2014; Kodama

449 et al. 2014: Lien et al. 2016). However, most studies use independent naming schemes for each 450 species, making it difficult to directly compare studies without complicated lookup tables or 451 alignments to confirm homology (e.g. Brieuc et al. 2014; Kodama et al. 2014). Recently 452 developed methods for connecting linkage maps through reference genomes (Sutherland et al. 453 2016) facilitated description of homologous relationships for most or all linkage group arms 454 across salmonids (with a few exceptions in coregonines). Additionally, Sutherland et al. (2016) 455 and Savilammi et al. (2019) have explored the utility of naming chromosomes based on 456 homology to northern pike, which as a representative of the non-duplicated sister lineage of 457 salmonids can be used to represent the ancestral (pre-duplication) state of salmonid genomes. 458 Each northern pike chromosome is represented by two homeologous chromosome arms in 459 salmonids, which are designated with a .1 or .2 following the ancestral chromosome number. 460 This naming system, if applied broadly, will facilitate comparative genomics in salmonids by creating a "Mueller element"-like system (reviewed in Schaeffer 2018), where each chromosome 461 462 arm has a universal identifier. However, there also remains value in species-specific identifiers; 463 for example, Cart03 is the third named linkage group in the Cisco linkage map (Table 2). By comparison, Cart03 named via the PK system could be Cart03 (PK 08.2-09.1) or Cart03_{PK08.2-09.1} 464

465 as Cart03 represents the fusion of two ancestral salmonid chromosome arms 08.2 and 09.1 466 (Figure 1, Table 2).

467 The PK system allows for simple comparison across species and genera. A case study of 468 the utility of this system is the comparison of the chromosome containing the sex determining

469 gene in salmonids (sdY), which is known to move between chromosomes (see Table 1 in

470 Sutherland et al. 2017). This comparison demonstrated that some chromosome arms more

471 frequently contain the sex determining gene than would be expected by chance or explainable by

phylogenetic conservation (i.e., PK 01.2 (AC04q), PK 03.1 (Cclu25, Co30, So09), PK 19.1 472

473 (So09.5, AC04q.1), PK 15.1 (AC04q.2, BC35), Sutherland et al. 2017). Even more intriguing is

474 that the northern pike naming was based on the threespine stickleback Gasterosteus aculeatus

475 (Rondeau et al. 2014), and PK 19 is the sex determining chromosome in three spine stickleback

476 (Peichel et al. 2004). As observed above, this chromosome is often fused with sex chromosomes 477 in salmon (Sutherland et al. 2017). By comparison, using the naming system, it is easy to observe

478 that LG24 in northern pike (i.e., PK 24 in salmon), recently identified to hold the sex

479 determining gene in Northern pike (Pan et al. 2019), does not appear to contain the sex-

480 determining locus in any tested salmonids. Deriving this information would be more difficult

481 without the PK system and would require extensive cross-referencing.

Other applications for the PK naming system include facilitating comparisons of the 482 correspondence of chromosomes containing genes for adaptive potential in sockeye salmon 483

484 (So13_{PK18.2}, TULP4, Larson et al. 2017), for run timing in Chinook (Ots28_{PK03.2}, GREB1L,

485 Prince et al. 2017), and for age-at-maturity in Atlantic salmon (Ssa25_{PK16.2}, VGLL3, Barson et al.

486 2015). While there may be some sections of the PK that are not always retained (e.g., some

487 transposition of sections), as long as the majority of the chromosome is preserved, then the PK

488 system enables general comparisons. The PK system proposed here will facilitate quick and

489 accurate comparisons across taxa, adding significant value to the myriad studies searching for 490 adaptively important genes and regions in salmonids by leveraging comparative approaches.

491

492 Homology and fission/fusion history in coregonines

493 Comparisons using linkage maps for three coregonine species, cisco, lake whitefish 494 (Gagnaire et al. 2013), and European whitefish (De-Kayne and Feulner 2018), allowed us to 495 assess homology and variation in karyotypes across the genus. Ambiguity in homologous 496 relationships remained for at least five chromosome arms in all three coregonines; this degree of 497 uncertainty was much higher than documented across the Salmo, Oncorhynchus, and Salvelinus 498 genera by Sutherland et al. (2016), where there were only two ambiguities across these groups. 499 Coregonines appear to have a number of relatively small acrocentric chromosomes (Phillips and 500 Rab 2001), some of which contain a high degree of duplicated loci, making constructing linkage 501 maps more difficult than for other salmonids (Gagnaire et al. 2013; De-Kayne and Feulner 502 2018). For example, PK 25 has never been successfully mapped in coregonines, likely because it 503 is small, submetacentric or acrocentric, and contains many duplicates. In other salmonids, where 504 PK 25 is part of larger and/or metacentric chromosome, mapping becomes easier as there are 505 many disomically inherited markers on the chromosome. Interestingly, the fact that PK 25 506 displayed evidence of residual tetrasomy in cisco, even though it is likely an acrocentric or 507 submetacentric chromosome, suggests that metacentric chromosomes are not required for 508 homeologous recombination. This contradicts previous theory which suggests that homeologous 509 recombination requires at least one chromosome arm to be metacentric (Kodama et al. 2014). 510 Additionally, PK 25.2 in grayling is a submetacentric chromosome and also displays signals of 511 residual tetrasomy (Savilammi et al. 2019), providing further evidence that a small secondary 512 arm may be sufficient to facilitate tetrasomic meiosis.

513 The fusion history in coregonines differs substantially from many other members of the 514 salmonid family. Members of the Coregonus, Salvelinus, and Thymallus genera possess the "A 515 karyotype," with a diploid chromosome number (2N) ~80 and many acrocentric chromosomes, 516 whereas Oncorhynchus and Salmo, possess the "B karyotype," with 2N ~60 and many 517 metacentric chromosomes (Phillips and Rab 2001). Given that these both come from an ancestral 518 type of n = 50 chromosome arms, species with the "A karyotype" have undergone fewer fusions 519 than other lineages. Interestingly, it appears that "A karyotype" species also generally contain a lower proportion of species-specific fusions compared to "B karyotype" species, suggesting that 520 521 the "B karyotype" status comes from species-specific fusions. Sutherland et al. (2016) investigated fusion history within many species from the Oncorhynchus genus and found that 522 523 most species had many species-specific fusions (e.g., 17 species-specific fusions in pink salmon). 524 However, Sutherland et al. (2016) only investigated one species from the Coregonus and 525 Salvelinus genera as this was all that was available at the time of publication, and no species 526 from *Thymallus*. Our current study is the first to investigate fusion history across multiple 527 coregonines and illustrates that most fusions are shared among species in the Coregonus genus,

528 contrasting the pattern observed in *Oncorhynchus* (Sutherland et al. 2016). The functional effect

529 of differing fusion histories is yet to be determined, and remains an important question

530 differentiating species within the *Coregonus*, *Salvelinus*, and *Thymallus* genera from other

salmonids. Further information from genome sequencing projects, for example the European

532 whitefish genome (De Kayne et al. 2019) should facilitate important future studies contrasting

- 533 genomic processes and structure in species with differing fusion histories.
- 534

535 Patterns of homeology and residual tetrasomy across salmonids

536 Although patterns of residual tetrasomy were generally conserved, variation within and 537 among species was observed when examining results from linkage maps versus reference 538 genomes. Sequence similarity analyses using reference genomes suggested that all species 539 showed evidence for residual tetrasomic inheritance in seven homeologous pairs (PK 02, 09, 11, 540 20, 22, 23, and 25) with the exception of PK11 in Arctic char (see below). Using linkage maps, 541 these same seven homeologous pairs have been found to be tetrasomic in Oncorhynchus (Kodama et al. 2014; McKinney et al. 2019), Salvelinus (Sutherland et al. 2016; Nugent et al. 542 2017), Salmo (Robertson et al. 2017), and likely Coregonus (results reported herein), strongly 543 suggesting that tetravalent meioses can and do form between these homeologs in all investigated 544 545 species to date. However, evidence for residual tetrasomy differed between linkage maps and 546 genomes for multiple PKs, most notably PK 06, which was classified as tetrasomic in linkage 547 mapping studies but not in genome analyses, and PK 01 which was classified as tetrasomic in 548 genome analyses but not linkage maps. It is likely that some of these differences are the result of 549 methodological limitations of the current approach and point to future analysis approaches that 550 may be able to improve upon the framework presented here. This is further described below.

551 The observation that PK11 did not display high sequence similarity in Arctic char might 552 suggest a difference in diploidization rates in char compared to other salmonids for this 553 homeologous pair, but it is more likely that methodological limitations prevented us from 554 detecting residual tetrasomy, as a linkage map study in Arctic char found a high number of 555 duplicated markers on this PK (Nugent et al. 2017). The percentage similarity analysis applied in 556 the present study uses complete chromosome alignments and requires post-filtering to remove 557 non-homeologous alignments. This method appears to be robust when chromosome arms are 558 well defined but, PK 11 in Arctic char appears to be composed of four chromosome arms that 559 have come together in a series of species-specific fusions (inferred from Christensen et al. 560 2018b). Since arm boundaries were not well defined, alignments in this PK produced a wide 561 interquartile range, suggesting that, while some regions of the PK are likely undergoing residual 562 tetrasomy, the alignments may have masked these regions by integrating over multiple chromosome arms. This would be particularly problematic if the chromosomes being compared 563 564 both contained non-target chromosomes that were homeologous. To improve upon the method 565 applied here, better definition of the breaks between chromosome fusions could be applied and 566 this could prevent such ambiguities or noise in the sequence similarity calculated. We therefore 567 conclude that PK 11 is likely tetrasomic in Arctic char, but that we were unable to classify it as 568 such due to methodological limitations. The sequence similarity method applied here is generally robust, but the fusion history of the species being analyzed needs to be considered to avoid unexpected and erroneous similarity values. Ideally, only the section containing the ancestral chromosome of interest would be being compared between the homeologs. This is an avenue of method development that will be valuable for future work.

573 Contrastingly, the finding that PK 06 is not tetrasomic does not appear to be due to 574 methodological limitations of our genome analysis but may be due to differences in estimating 575 extent of residual tetraploidy between linkage mapping and genome assembly approaches. 576 Linkage mapping in Oncorhynchus and Salvelinus consistently finds support for tetrasomic 577 inheritance at PK 06 (Larson et al. 2017; Nugent et al. 2017), but the genome analysis conducted 578 here and that conducted for rainbow trout (Campbell et al. 2019) found that this PK displayed 579 intermediate sequence similarity consistent with disomic homeologs. One of the ways the two 580 approaches differ is the length of the sequence used during each analysis. The genome analysis 581 conducted here calculated similarity by using alignments of at least 1,000 bp, whereas linkage 582 maps compare alleles within ~100-150 bp RADtags. The short sequences analyzed by software 583 such as STACKs (Rochette and Catchen 2017; Rochette et al. 2019) make it possible to collapse 584 sequences into a single locus that can be mapped at both paralogs, even when sequence 585 divergence in a given region is relatively large. This therefore makes linkage maps a less 586 conservative characterization method for determining residual tetrasomy. In addition, many 587 genome assemblers applied to salmonid genomes (e.g. Chin et al. 2016; Koren et al. 2017; Ruan 588 and Li 2019) are not optimized for paralogous regions in polyploid genomes. This could be 589 especially problematic for genomes that combine both disomic and tetrasomic regions, such as in 590 salmonids. The end results are that duplicated regions may be detected as single copies as a 591 result of sequence collapse during the assembly process (Alkan et al. 2011; Varadharajan et al. 592 2018). If sequences do not collapse during assembly, contigs might be fragmented and 593 misassembled in the genome, making it difficult to differentiate between homologs and 594 homeologs (Kyriakidou et al. 2018). This could lead to homeologous regions being missed 595 altogether in genome sequences, particularly in comparisons that require chromosome-level 596 assemblies. However, the fact that support for tetrasomic inheritance in other PKs identified as 597 tetrasomic through linkage mapping was consistent with that observed in genome analysis 598 strongly suggests that there is something unique with PK 06 rather than a fault with the genome 599 analyses conducted here. Perhaps, as suggested by Campbell et al (2019), the PK 06 600 chromosome arms are returning to a diploid state faster than the other seven tetrasomic 601 homeolog pairs or the tetrasomically inherited portion of PK 06 is smaller than other tetrasomic 602 PKs.

Another notable difference between linkage mapping and genome analysis was the
consistent classification of PK 01 as tetrasomic in the genome analysis (five of six species) but
not in any linkage map. PK 01 uniformly exhibited the least similarity between tetrasomic
homeologous pairs and was assigned to the putatively tetrasomic class of PKs with less certainty
by the machine learning algorithm. This suggests that PK 01 may have low levels of tetrasomy.
We also observed some consistent patterns of variation in sequence similarity within disomic

markers. For example, homeolog pairs for PK 24 and 21 generally displayed the lowest sequence

- 610 similarity, and homeolog pairs for PK 07 and 19 displayed higher similarity. Our study therefore
- 611 presents additional nuances into the rediploidization process by identifying a core group of
- 612 conserved tetrasomic homeologs, potentially intermediate homeologs (PK 01, 06) and
- 613 consistently diverged homeologs (PK 21, 24). Future investigations can be refined to examine
- 614 four well-defined categories across PKs: tetrasomic, intermediate, disomic, and most diverged.
- 615 This enhanced refinement should reduce noise from the incorrect pooling of homeologs and aid
- 616 in understanding the rediploidization process in salmonids.
- 617 Interestingly, more variation in sequence similarity was observed within tetrasomic 618 homeologs than was observed in disomic homeologs. For example, PK 23 has the second highest 619 sequence similarity in Arctic char, the fourth highest in rainbow trout, the sixth highest in Atlantic salmon, and the seventh highest in grayling. While this may be in part due to differences 620 in genome assembly method and quality, the fact that variation exists even among the highest 621 622 quality genomes (Atlantic salmon and rainbow trout) suggests that rediploidization rates at 623 tetrasomic PKs may vary among species, even though the same seven PKs are consistently 624 classified as tetrasomic. In other words, although there appears to be a large amount of conservation of tetrasomic inheritance between species, our genome analyses also suggest some 625 626 independence in the return to disomy since the three subfamilies of salmonid split ~ 50MYA.
- 627

628 Conclusions

629 Here we provide the most compete analysis of chromosomal rearrangements in 630 Coregonine using the currently available genomic resources as well and a newly developed 631 haploid linkage map for cisco. We also suggest a naming system, PK, to facilitate a comparative analysis of all currently available salmonid genomes and linkage maps. Our study revealed that 632 633 patterns of tetrasomic inheritance are largely conserved across the salmonids, but that there is 634 substantial variation in these patterns both within and among species. For example, while the 635 same seven PKs appear to be tetrasomically inherited across all species examined, their relative 636 rates of sequence similarity differ within species, suggesting the potential of independent 637 evolutionary trajectories following speciation. Additionally, we documented that analyses based 638 on linkage maps do not identify the same tetrasomically inherited PKs as genome analyses and 639 postulate that this may be due to inconsistencies with genome assemblies or due to differences 640 the length of sequence used in comparisons. When inferring genomic patterns, more robust 641 results can be obtained by using comparative approaches as opposed to a single resource. We therefore urge researchers to be cautious when inferring patterns based on a single resource and 642 643 to integrate across resources when possible. In conclusion, our study presents important insights 644 about the WGD in salmon and also provides a framework that can be built upon to improve our 645 understanding of WGDs both within and beyond salmonids.

Table 1. Results for the female and male cisco linkage maps. Duplicated and singleton loci are from the female linkage map, and % duplicated is the percentage of duplicated loci on each female linkage group (LG). LG type is denoted with acrocentric (A) and metacentric (M).

Table 2. MAPCOMP results documenting homologous chromosomes for the three coregonines; cisco, lake whitefish (Gagnaire et al. 2013), and European whitefish (De-Kayne and Feulner 2018), integrated with Atlantic salmon (Lien et al. 2016), brook trout (Sutherland et al. 2016), and Chinook salmon (Brieuc et al. 2014). Homologous chromosomes for all species are named according to the corresponding Northern Pike linkage group as a reference (Rondeau et al. 2014), as per Sutherland et al. (2016), here termed protokaryotype ID (PK). ^ indicates weak evidence and * indicates uncertainty between homeologs.

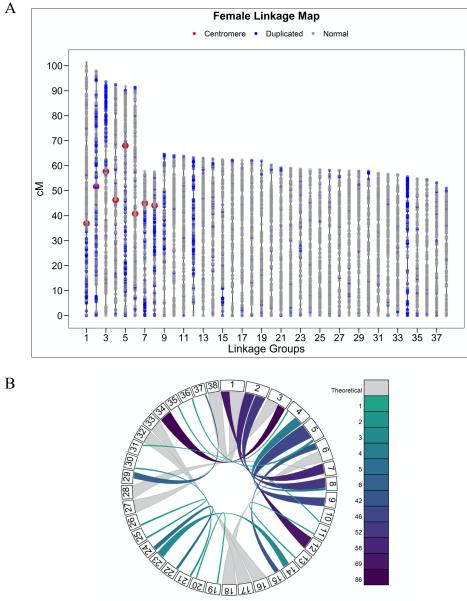

Figure 1. A) Female linkage map for cisco containing 20,450 loci. Each dot represents a locus, duplicated loci are blue and singleton loci are gray. Lengths are in centimorgans (cM). Approximate location of centromeres for metacentric LGs are denoted in red. Metacentric LGs were identified through homologous relationships of chromosome arms with other Salmonids via MAPCOMP. B) Circos plot of cisco LGs highlighting 17 supported homeologous regions within the linkage map. Included in the 17 homeologus regions are six of the eight regions that are likely still residually tetrasomic across the Salmonids. Colors represent the number of markers supporting relationship, with darker colors representing higher marker numbers (maximum support = 86 markers).

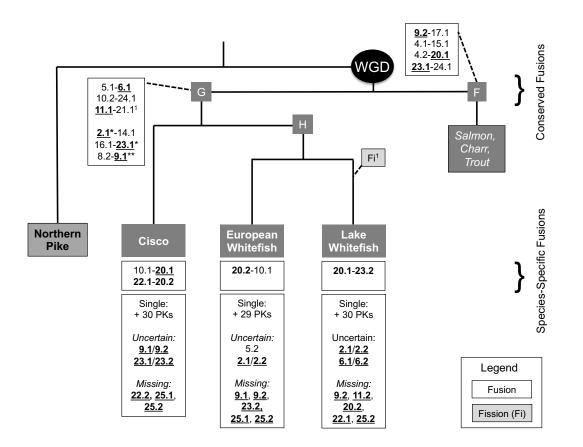

Figure 2. Fusions and fissions in the Coregoninae and Salmoninae lineages. This is an extension of Figure 4 from Sutherland et al. (2016). White boxes display the fusion events, where the homologous chromosomes for all species are named according to the protokaryotype ID. Bold and underlined chromosome numbers are the homeologous pairs that exhibit residual tetraploidy (i.e "magic eight"), * indicate uncertainty in one species, and ** indicates uncertain in two species (i.e., *C. artedi* is ambiguous for homeolog 9.1 or 9.2 while *C. lavaretus* is missing 9.1 and 9.2). Above the species names are conserved fusions, whereas below are the species-specific fusions. The phylogenetic distance, only relative phylogenetic position.

¹Arms 11.1-21.1 were fused in both cisco and European whitefish, but likely underwent fission in lake whitefish.

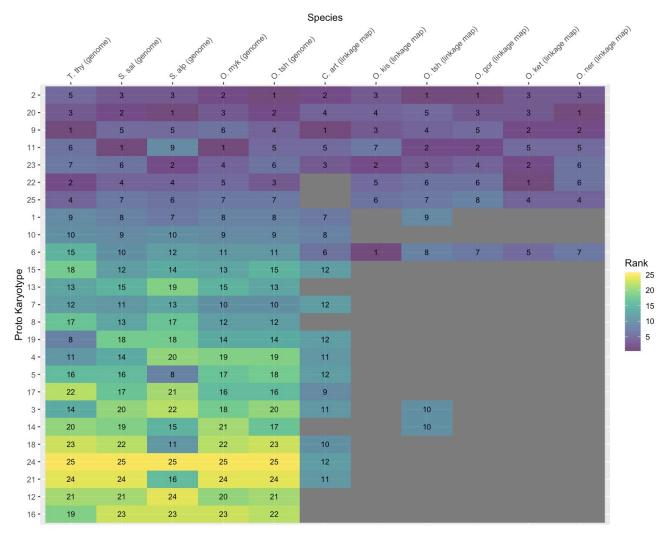

Figure 3. Ranking of homeologous chromosome pairs based on putative residual tetrasomic inheritance as measured by the number of markers shared among homeologs for linkage maps or percent sequence similarity for genomes. A lower rank represents more marker pairs supporting a homeolog and or a higher sequence similarity. Chromosomes for all species are named according to the protokaryotype ID (PK). PKs are ordered in the figure by averaging the ranks across all species and then sorting the averages from smallest to largest (i.e., ordered from highest support for residual tetrasomy to lowest). Grey indicates that no duplicated loci could be mapped to both homeologs. Species abbreviations are grayling (T. thy), Atlantic salmon (S. sal), Arctic char (S. alp), rainbow trout (O. myk), Chinook salmon (O. tsh), cisco (C. art), and coho salmon (O. kis).

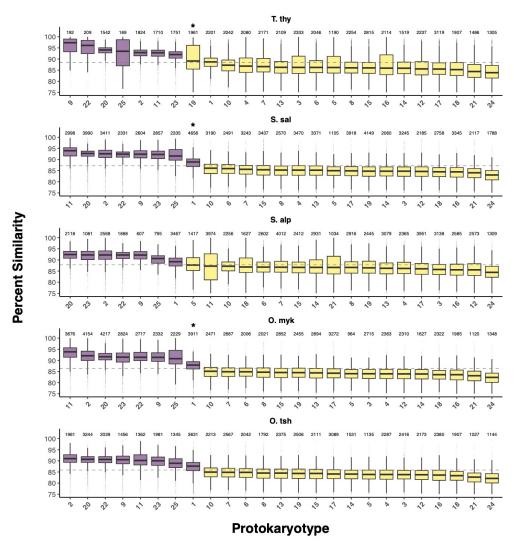

Figure 4. Distribution of protokaryotypes (PK) similarity across salmonids based on genome assemblies. For each species with a genome sequence, the percent similarity (y – axis) of the 25 PK pairs as shown as box plots. PK pairs are ranked from highest to lowest median similarity for each species (x – axis), with the average similarity of protokaryotypes presented as a dashed line. The classification of protokaryotypes by the machine learning approach described in the main text into putatively tetrasomic and disomic pairs is shown through coloring of the boxplots into purple (putatively tetrasomic) and yellow (putatively disomic). The number of alignments used in computing similarity is presented at the top of each bar. Those protokaryotypes that did not receive the highest observed voting proportion for the assigned class are indicated with an asterisk (*). PKs with high variance (e.g. PK 11 in S. alp) may be due to methodological limitations that have caused additional non-homeologous chromosome arms to be included in the comparisons (see discussion). Species abbreviations are grayling (T. thy), Atlantic salmon (S. sal), Arctic char (S. alp), rainbow trout (O. myk), and Chinook salmon (O. tsh)

Supplementary tables and figures:

S1. Sampling information for cisco (*Coregonus artedi*) families collected from Lake Huron the number of individuals used. The number of offspring shown only includes those used for mapping after the removal of individuals with low sequencing coverage. The numbers of SNPs shown include those retained following quality control filtering but before inclusion in linkage mapping.

S2. Male linkage map for cisco (*Coregonus artedi*) containing 6340 loci. Each dot represents a locus. Lengths are in centimorgans (cM).

S3. Information for each marker on the female and male cisco (*Coregonus artedi*) linkage maps. Tag is the RAD tag, and marker name is the tag followed by a designation used to differentiate duplicated loci. The "Sequence P1 column" is the sequence from the single end read for each RAD tag, and the "Sequence PE" is the sequence obtained from paired-end assemblies.

S4. MAPCOMP determination of homologous chromosome arms. The cisco male and female maps were compared with markers paired through the Atlantic salmon genome to identify homology between chromosome arms. This shows the inconsistencies and poor resolution of the male map relative to the female map, which is expected given low male recombination

S5: Probable metacentric chromosomes from the MAPCOMP analysis for coregonines. S6. Homeologous chromosome pairs for currently available haploid linkage maps and the number of maker pairs supporting homeology (Kodama et al. 2014; Larson et al. 2015; Waples et al. 2016; Tarpey et al. 2017). Homologous chromosomes are named according to the corresponding Northern Pike linkage group Protokaryotype ID (PK).

S7. Homeologous chromosome pairs for all available salmonid genomic resources.

S8. Support for classifications from k – nearest neighbor machine learning algorithm. Cross validation indicated five nearest neighbors should be used for classification across species. The vote proportion for assignment to either putatively tetrasomic or putatively disomic categories are presented as the proportion of votes out of five at the top of each bar. Median percent similarity for each protokaryotype pair is presented as the y – axis and protokaryotype pairs are ranked from most similar to least (x – axis).
