DESCRIPTIVE ABSTRACT

Background: Cancer-associated muscle wasting (CAW), a symptom of cancer cachexia, is associated with approximately 20% of lung cancer deaths, and remains poorly characterized on a mechanistic level. Current animal models for lung cancer-associated cachexia are limited in that they: 1) primarily employ flank transplantation methods, 2) have short survival times not reflective of the patient condition, and 3) are typically performed in young mice not representative of mean patient age. This study investigates a new model for lung cancer-associated cachexia that can address these issues and also implicates muscle regeneration as a contributor to CAW.

Methods: We used tail vein injection as a method to introduce tumor cells that seed primarily in the lungs of mice. Body composition of tumor bearing mice was longitudinally tracked using magnetic resonance imaging (MRI). These data were combined with histological and molecular assessments of skeletal muscle to provide a complete analysis of muscle wasting.

Results: In this new lung CAW model we observed 1) progressive loss in whole body weight, 2) progressive loss of lean and fat mass, 3) a circulating cytokine/inflammatory profile similar to that seen in other models of CAW, 4) histological changes associated with muscle wasting, and 5) molecular changes in muscle that implicate suppression of muscle repair/regeneration. Finally, we show that survival can be extended without lessening CAW by titrating injected cell number.

Conclusions: Overall, this study describes a new model of CAW that could be useful for further studies of lung cancer-associated wasting and accompanying changes in the regenerative capacity of muscle. Additionally, this model addresses many recent concerns with existing models such as immunocompetence, location of tumor, and survival time.

INTRODUCTION

Cancer cachexia is a complex syndrome associated with approximately 20% of lung cancer deaths; a hallmark symptom of cancer cachexia is cancer-associated muscle wasting (CAW) [1, 2]. Although this syndrome is associated with negative patient outcomes, it remains poorly understood on a mechanistic level. Many groups have investigated the inflammatory environment associated with CAW, in particular, inflammatory cytokines such as tumor necrosis factor alpha (TNFα) and interleukin 6 (IL6). Despite considerable time invested in this area, clinical trials targeting the inflammatory microenvironment alone have been unsuccessful [3, 4]. Other groups have focused on the proteolytic environment in muscle, as a potential driver of CAW, implicating both autophagy and ubiquitin-mediated pathways as potential drivers of CAW [5-7]. The current mechanistic understanding of CAW is largely based off of work done in mouse models, most notably the Lewis lung carcinoma (LLC) and C-26 models.

The LLC model of CAW relies on transplantation of LLC1 non-small cell lung cancer cells, derived from C57/B6 mice, into syngeneic, and thus immunocompetent, C57/B6 recipient mice. The LLC model is one of the few syngeneic and reproducible models for lung cancer/lung-cancer associated wasting available today [8]. Most commonly, LLC1 cells are implanted via flank injection, which results in large primary tumors around 7 days post implantation. A second popular model for CAW, the C26 model, was first described in 1990 and utilizes flank injection of colon 26 carcinoma cells [9]. Like the LLC model, this model displays elevated expression of proteasome components, which contribute to loss of muscle mass [10]. The C26 model presents with longer median survival (25 days) than the LLC model [10]. Notably, both the C26 and LLC models share a common weakness in that tumors do not arise in the tumor tissue of origin. Although recent studies have attempted to correct this issue using autochthonous genetically engineered mouse models (GEMMS), their utility and flexibility are limited. For example, in pancreatic cancer, there have been multiple efforts to create CAW models that focus on tumors arising in their

3

58 native tissue via either genetic manipulation or orthotopic implantation [11-15].

59 The benefits and limitations of these models are addressed in more depth in the

60 discussion. Despite these advances in the context of pancreas cancer, lung

61 cancer models have lagged behind. Orthotopic transplantation has been

62 established in rodent models, but requires an invasive surgery [16] [17].

63 Furthermore, genetic methods to derive orthotopic tumors in lungs require viral

64 delivery of Cre recombinase [18]. Complications arising in both these models are

65 high and prompted us to develop a simple, reproducible, and scalable model of

66 lung CAW.

67 We identified the need for better models of CAW that met the following criteria: 1)

68 immunocompetent environment, 2) tumors arising in the appropriate/matching

69 tissue of origin, and 3) ability to modulate the timing/duration of wasting. Here,

70 we present studies on a novel mouse model for lung CAW, which has met these

71 criteria. This model utilizes syngeneic, immunocompetent mice and tail-vein

72 injection of cells as a modality for lung tumor seeding; shows a median survival

73 of approximately 26 days that can be modulated as a function of injected cell

74 number; and exhibits hallmarks of lung CAW. The model presented herein fills a

75 gap in models for studying CAW, and will be a valuable resource for the wasting

76 community moving forward.

RESULTS

Development of a transplantable model for lung cancer-associated tissue loss

Given the increasing need in the CAW field for models featuring tumors arising in their natural location, we sought to develop such a model in the context of lung cancer. To accomplish this, we used tail vein injection as a method whereby injected lung tumor cells implant primarily in the lungs [19]. Cells were derived from a murine lung adenocarcinoma and cultured more than 10 passages prior to injection. Cells were suspended in PBS for the injection and control animals were injected with PBS vehicle only. Throughout the course of the study we assessed body composition via magnetic resonance imaging (MRI) until humane endpoint (see experimental schematic in **Figure 1A**). We performed survival studies on 3 cohorts of mice (total n=10 vehicle and 15 tumor) and observed significantly decreased survival for tumor bearing mice (average survival tumor=26.2 days) (**Figure 1B**). Upon macroscopic inspection of the lungs, tumor bearing mice had many small nodules, fibrotic tissue, and increased tissue density (**Figure 1C**). Upon microscopic inspection of the lungs in tumor-bearing mice, alveolar fields were replaced by multiple, coalescing tumor nodules (>70% in 3 animals, 40-50% in 2 animals assessed). The tumor nodules consisted of loosely packed, vacuolated cells and in some cases were associated with small clusters of intra-tumoral lymphocytes, usually at the margins of blood vessels or nodules. Lastly, the pleural surface was roughened by projecting fronds / plaques of tumor cells. In comparison, vehicle animals displayed expanded alveolar spaces and a smooth pleural surface (**Figure 1D**). Furthermore, we observed a statistically significant increase in total lung weight in tumor-bearing mice (**Figure 1E**).

Concurrent with evaluations of tumor effects on overall survival, we performed longitudinal body composition analyses. First, we observed a significant difference in time and treatment co-variance for body weight, which was highlighted by significant decreases in body weight at 10, 14, and 17 days post tumor implantation (**Figure 1F**). Next, we observed a significant difference in time and treatment co-variance for total fat mass, which was highlighted by significant

5

107   decreases in fat mass at 14, 17, and 21 days post tumor implantation (**Figure**

108   **1G**). Lastly, we observed a significant difference in time and group co-variance in

109   total lean mass, although individual days had no significant difference (**Figure**

110   **1H**). Overall, there were decreases in total body weight, total fat mass, and total

111   lean mass as the tumor progressed (the latter two measured by MRI) (**Figure 1F-**

112   **H**).

113   <u>Lung cancer-associated inflammation</u>

114   Loss in both body weight and lean mass are hallmarks of CAW. Many studies

115   have implicated heightened inflammatory signaling as a driver of CAW [20-22].

116   We quantitatively assessed concentrations of 31 cytokines in the serum of tumor-

117   bearing and vehicle animals (EveTechnologies) (n=5 vehicle and 4 tumor).

118   Ranked analysis (vertically by their average in the tumor-bearing animals;

119   highest to lowest) revealed substantial differences between experimental groups

120   (**Figure 2A).** Specifically, we observed significant differences in 4 factors:

121   Eotaxin (down~2 fold), C-X-C motif chemokine 5 (LIX, down ~10 fold), TNFα (up

122   ~30 fold) and vascular endothelial growth factor (VEGF, up ~190 fold) (**Figure**

123   **2C**). Of note, TNFα accumulation has been previously implicated in CAW [20,

124   23].

125   <u>Lung cancer-associated muscle loss</u>

126   Considering both the loss of lean mass by MRI analysis and the accumulation of

127   classical markers of CAW in the serum, we next performed a histological and

128   molecular assessment of skeletal muscle. First, we assessed tibialis anterior (TA)

129   muscle cross sections by immunofluorescent staining for laminin, a marker of

130   myofiber membranes, and DAPI (nuclei) (**Figure 3A**). Minimum feret diameters

131   were measured, compiled, and calculated using myovision (mean feret diameter:

132   3 million = 40.4 um, vehicle = 44.4 um, and found a statistically significant

133   decrease in the non-linear regressions fit to the histograms of minimum feret

134   diameter distribution of tumor-bearing mice(**Figure 3B**) [24]. Additionally, we

135   observed a significant decrease in TA weight in tumor bearing animals; this was

136   not due to a reduction in the total number of myofibers in the TA of these animals

6

137   (**Figure 3C-D**). Since we observed a reduction in myofiber size, but not total

138   number of myofibers, we postulated that this could be due to a decrease in the

139   regenerative capacity of muscle. Using immunofluorescent staining, we queried

140   the number of Pax7 positive muscle progenitor cells. We observed a statistically

141   significant increase in Pax7 positive cells per millimeter squared of tissue (**Figure**

142   **3E**). Additionally, we assessed the number of centrally located nuclei (CLN),

143   which mark actively regenerating myofibers containing recently fused muscle

144   progenitor cells. We did not see any difference in the number of CLN per

145   millimeter squared of tissue between vehicle and tumor-bearing mice (**Figure**

146   **3F**). Lastly, to acquire a molecular understanding of regenerative capacity of

147   muscle from tumor-bearing animals, we used quantitative RT-PCR to measure

148   several transcripts associated with early myogenesis, late myogenesis/fusion,

149   and muscle atrophy. Visualized in a heat map, we see a trend toward higher

150   expression of atrophy transcripts (Trim63 and Fbxo32) and early makers of

151   myogenesis (Pax7 and Myod1), and lower expression of late markers of

152   myogenesis (**Figure 3G**).

153   Transplanted cell number correlates with survival and CAW progression

154   Upon establishing that our lung cancer model induces loss in total body weight,

155   lean mass, and is also associated with an impaired muscle regeneration

156   phenotype, we sought to determine if survival time/CAW progression could be

157   experimentally modulated. To accomplish this, we varied the number of cells

158   injected as follows: 3 million cells (used in all previous figures), 1 million cells,

159   300,000 cells, and vehicle. We also tested 30,000 and 3,000 cells but found

160   inconsistent inoculation of tumors and omitted these groups from further study

161   (data not shown). We assessed survival of animals in each group and found that

162   lowering the number of cells injected prolonged survival as evidenced by a

163   statistical increase in survival from 3 million to 1 million cells (p=0.0208), 1 million

164   to 300,000 cells (p=0.0024), and 300,000 cells to vehicle (p=0.0046) (**Figure 4A-**

165   **B)**. We also observed changes in lung condition, as evidenced by increased lung

166   weight in 3 and 1 million injected cells, and macroscopic changes in lung

167   condition similar to those observed previously (**Figure 4C-D**).

7

168   We next performed body composition and muscle morphometrics analyses in

169   mice receiving variable numbers of tumor cells. As before, we observed

170   decreasing trends in body mass, lean mass and fat mass in tumor bearing mice

171   of all groups (**Figure 5A-C**). Specifically, we observed significant difference in

172   time and treatment co-variance for body weight, in 3 million, 1 million, and

173   300,000 implanted cell groups compared to vehicle (**Figure 5A**). We also

174   observed significant difference in time and treatment co-variance for total lean

175   mass in 3 million and 1 million implanted cell groups compared to vehicle (**Figure**

176   **5B**). In lower implantation doses, we did not observe significant differences in

177   total fat mass. Because tumors were restricted primarily to the lungs (with the

178   exception of some metastases) (**Table 1**), it was not possible to discount tumor

179   mass from MRI measurements. Evaluation of TA muscles from tumor-bearing

180   mice revealed statistically decreases in TA mass in the 300,000 cells group,

181   similar to the 3 million cells group (**Figure 5D**). Additionally, myovision-based

182   assessment of minimum feret diameters revealed increasingly significant

183   decreases as the cell injection number decreased (mean feret diameter: 1 million

184   = 41.3 um, 300,000 = 32.6 um, vehicle = 44.4 um)(**Figure 5E**).

8

DISCUSSION

In order to gain a more thorough understanding of CAW, there is a need for models that more accurately capture the patient condition. This new and novel model for CAW meets several needs in the field such as: 1) immunocompetence (i.e. a syngeneic model), 2) exhibits both heightened catabolism and suppressed regeneration 3) exhibits both lean and fat mass loss, 4) exhibits an inflammatory microenvironment, 5) is flexible in timing and severity, 6) arises in the tumor's organ of origin. To the last point, recent studies have highlighted the importance of tumor location on both tumor development and CAW [25-27]. Our model is an easy and effective method to induce tumor formation in the lungs and concomitant CAW, using lung adenocarcinoma cells.

With regard to points two through four, developing therapeutics for CAW is ultimately dependent on mouse models that reflect the complex molecular nature of this syndrome. We showed that this model exhibits an inflammatory signature similar to published signatures of CAW patients [20, 21, 28-30]. Additionally, our model supports numerous studies linking both elevated catabolism and impaired skeletal muscle regeneration as contributors to CAW [5-7, 31]. Our observation that there is an accumulation of Pax7+ cells in the TA muscle, but no change in the number of centrally located nuclei may be indicative of increased progenitor cell expansion, with failure to incorporate into the damaged/cachectic muscle. Although we probed genes related to fusion and progenitor cell maturation by qPCR and did not observe differences in expression, a more detailed assessment of the progenitor cell population would be necessary to make definitive conclusions about suppressed muscle regeneration in this model.

A major weakness of many CAW mouse models is the age of wasting onset. Genetic models, such as the KPC model, are predisposed to spontaneously develop tumors, which gives investigators little control over the age of onset. With cachectic cancers affecting a primarily elderly population, it is critical that new models are able to account for this confounding factor. For pancreatic cancer, this problem has largely been solved by the KPP mouse, which

9

216 expresses pancreas-specific oncogenes under Cre recombinase control [13].

217 However, for lung cancer, this is only beginning to be addressed[15]. Although

218 our model has not yet been adapted for use in aged mice, the transplantable

219 nature of the model permits use in any age of animal. Our model has the added

220 attraction that it does not require a major surgery or viral infection, which could

221 affect inflammatory status, making it more amenable for aged animals with higher

222 frailty than young animals [32].

223 The lack of CAW models that accurately assess the effects of age highlights a

224 second issue, which is the difference between muscle atrophy and the absence

225 of growth. A primary concern with the KPC pancreatic cancer mouse model is

226 that these mice are significantly smaller than littermate controls prior to palpable

227 tumor development. This suggests that fetal expression of the oncogenes is

228 contributing to impaired muscle development [13]. Although spontaneous genetic

229 models, such as the KPC model, are dramatic examples of the difference

230 between atrophy and absence of growth, this principle implicates many

231 transplantation models [33]. Even in the study presented here, with age-matched

232 controls, it is evident that mice in the 3-6 month age group are still growing

233 (gaining total body weight and fat mass). Although muscle development is

234 typically considered complete at 3 months and lean mass is essentially stabilized

235 in our animals, this anabolic state is unrepresentative of the patient population

236 [13, 34, 35]. The model presented here is amenable to assessing CAW in aged

237 animals (greater than one year), which may lead to a better understanding of

238 CAW mechanisms and more efficient translatability to the clinic.

239 Another aspect of the patient condition poorly modeled in rodents is the severity

240 and duration of wasting symptoms. Recently, it was established that the cachexia

241 syndrome could be divided into three clinical stages: pre-cachexia, cachexia, and

242 refractory cachexia. Although refractory cachexia is marked by a short (only three

243 months) survival, wasting is present for much longer – an important observation

244 that is difficult to study in rapidly progressing rodent CAW models. Importantly,

245 with respect to intervention, some suggest that it is in the earlier stages (non-

246 refractory) that therapeutics may be more effective [36]. Despite these features in

247   patients, mouse models like LLC and C26 have rapid symptom onset and short

248   survival times. Failing to capture the earlier stages of cachexia is likely a

249   contributor to the failed clinical trials based on pre-clinical data derived using

250   these models. The ability of our model to be titrated by cell dosage provides an

251   important opportunity explore the timing and duration of wasting symptoms more

252   thoroughly.

253   Despite the many strengths highlighted in this study, the model presented herein

254   does have limitations. Perhaps the most notable limitation is one common to all

255   orthotopic lung cancer models, which is the difficulty for assessing tumor burden

256   in living animals. This could be remediated by stably transfecting cells with a

257   fluorescent reporter and utilizing *in vivo* imaging modalities. Additionally, in some

258   cohorts, we observed high levels of metastasis outside the thoracic cavity. This

259   may be representative of patients that exhibit metastases, but also complicates

260   data interpretation. Nevertheless, the model presented here is an important step

261   forward as CAW research progresses and will be a valuable resource for future

262   research aimed at understanding the etiology of lung cancer-associated muscle

263   and fat wasting.

METHODS

Animals

Mice were bred and housed according to NIH guidelines for the ethical treatment of animals in a pathogen-free facility at the Mayo Clinic (Rochester, MN campus). Mayo Clinic's Institutional Animal Care and Use Committee (IACUC) approved all animal protocols. For 393P-induced CAW model, 150 uL 393P cells (containing 3×10^6, 1×10^6, or 3×10^5 cells depending on group), or an equal volume of PBS (Gibco, 14190-144) (control) was injected via tail vein into 7-week-old male 129S2/SvPasCrl mice (Jackson Laboratories, Bar Harbor, ME). Development of cachexia was monitored twice weekly by body weight, fat, and lean mass. Mice were euthanized when endpoint criteria (weight loss greater than or equal to 20% of body weight, inability to ambulate, inability to reach food and/or water, tumors greater than or equal to 10% of body weight, tumors that have ulcerated, a body condition score of 1 or less using the IACUC approved scoring system) was reached. Blood serum, heart muscle, lungs, tibialis anterior (TA), gastrocnemius (GR) and epididymal fat pad were collected immediately for analyses. Exact n for each experiment included in the figure legends.

Animal imaging

Body weight, lean mass, and fat mass were measured twice weekly until endpoint. A baseline measurement was taken prior to start of study. Body composition was measured using magnetic resonance imaging (EchoMRI-100/130) system, EchoMRI, Houston, TX, USA).

Cell culture

393P cells were grown on tissue culture treated dishes in growth media consisting of DMEM media (Gibco #11995-065, lot 2051518) supplemented with 10% fetal bovine serum (Gibco #10099131, lot 2017488) and antibiotics. Cells were validated by IDEXX analytics and confirmed to be a pure culture and

19

409   murine in origin. Cells were removed from plate with TrypLE (Gibco, 12604-013),

410   counted, and resuspended in PBS prior to injection.

Immunostaining

412   Left TA whole muscle was prepared for O.C.T embedding and cryosectioned.

413   Tissue sections (8-10um) were post-fixed in 4% paraformaldehyde for 5 minutes

414   at room temperature prior to immunostaining. Once fixed, isolated tissue

415   sections were permeabilized with 0.5% Triton-X100 in PBS, followed by blocking

416   with 3% BSA in PBS. Primary antibody incubations occurred at RT for 90

417   minutes or overnight in 4 degrees, and secondary antibody incubations followed

418   at RT for 45 minutes in 3% BSA in PBS. The following antibodies were used in

419   this study: Laminin (Sigma 4HB-2) and Pax7 (developmental hybridoma bank).

420   Secondary antibodies were all Alexa fluorescent conjugates (488, 555, or 647)

421   from Invitrogen or Jackson ImmunoResearch. Stained tissue sections were

422   imaged on a (Nikon Eclipse Ti-U camera and microscope system). Acquired

423   images were analyzed for myofiber feret diameters using myovison and manual

424   colocalization quantification using ImageJ.

Cytokine Studies

426   Blood serum was collected from mice at endpoint. The MD31 cytokine panel was

427   performed by Eve Technologies (Eve Technologies, Calgary, AB Canada) and

428   samples were prepared as recommended by Eve Technologies. All samples

429   were run in technical duplicate.

Q-PCR

431   Total gastrocnemius RNA was isolated, purified, and DNase I treated using Trizol

432   and purified on RNeasy Mini kit columns (Qiagen, Mississauga, ON, Canada).

433   RNA was quantified using a NanoDrop Spectrophotometer (ThermoScientific,

434   Wilmington, DE, USA). Two ug of total RNA was reverse transcribed with

435   primers using the High-Capacity cDNA Reverse Transcription Kit (Life

436   Technologies, Carlsbad, CA, USA). QPCR was performed on a ViiA7

437 Quantitative PCR System (Applied Biosystems by Life Technologies, Austin, TX,

438 USA). All samples were run in technical triplicate. Standard delta delta CT

439 analysis was used post PCR. Primer sequences are available upon request.

440 **Lung, Heart and TA Histopathology**

441 At endpoint lung, heart and right TA whole muscle were fixed in 4%

442 paraformaldehyde. After 24 hours, tissue was moved to 70% ethanol. Tissue

443 was embedded in paraffin and tissue sections (6 um) were incubated at 37

444 degrees for 60 minutes prior to staining with hematoxylin and eosin (H&E).

445 Stained tissue sections were analyzed by GEMpath Inc. (Dr. Brad Bolon,

446 Longmont, CO) and imaged on a Nikon Eclipse Ts2 microscope. Samples could

447 be segregated with 100% reliability at using both the naked eye and the

448 microscope.

449 **Statistics**

450 Data are represented as the mean ± SD using GraphPad Prism (GraphPad

451 Software, San Diego, CA) unless noted otherwise in the figure legends.

452 Quantification of muscle cross sections using minimum feret diameter

453 measurements was analyzed by non-linear regression (least squares method)

454 and compared between conditions using an extra-sum-of-squares F test. All

455 other comparisons between groups were performed using unpaired two-tailed

456 student's t tests or mixed-effects analysis, as noted in figure legends. For all

457 analyses, a $p < 0.05$ was considered significant (denoted with *)

458 **Data availability**

459 Datasets generated during the current study are available from the

460 corresponding author upon request.
