Running title: TTR protection of amyloid-beta cytotoxicity

Keywords: Amyloid, Cytotoxicity, Fibrillization, Transthyretin, Peptide

## Abstract

The protective effect of transthyretin (TTR) on cellular toxicity of amyloid-beta (A $\beta$ ) has been previously reported. TTR is a tetrameric carrier of thyroxine in blood and cerebrospinal fluid, whose pathogenic aggregation causes systemic amyloidosis. In contrast, many reports have shown that TTR binds amyloid-beta (A $\beta$ ), associated with Alzheimer's disease, alters its aggregation, and inhibits its toxicity both *in vitro* and *in vivo*. In this study, we question whether TTR amyloidogenic ability and its anti-amyloid inhibitory effect are associated. Our results indicate that the dissociation of the TTR tetramer, required for its amyloid pathogenesis, is also necessary to prevent cellular toxicity from A $\beta$  oligomers. These findings suggest that the A $\beta$  binding site of TTR may be hidden in its tetrameric form. Aided by computational docking and peptide screening, we identified a TTR segment that is capable of altering A $\beta$  aggregation and toxicity, mimicking TTR cellular protection. This segment inhibits A $\beta$  oligomer formation and also promotes the formation of non-toxic, non-amyloid, amorphous aggregates which are more sensitive to protease digestion. This segment also inhibits seeding of A $\beta$  catalyzed by A $\beta$  fibrils extracted from the brain of an Alzheimer's patient. Our results suggest that mimicking the inhibitory effect of TTR with peptide-based therapeutics represents an additional avenue to explore for the treatment of Alzheimer's disease.

## Introduction

The physiological importance of transthyretin in Alzheimer's disease was first reported by Schwarzman et al. in 1994 [1]. One of the hallmarks of Alzheimer's disease (AD) is the formation of brain plaques composed of amyloid-beta peptide (A $\beta$ ). Forty-two-residue long amyloid- $\beta$  peptide (A $\beta$ 42) is the predominant variant in neuritic plaques of AD patients, with higher amyloidogenicity and cellular toxicity *in vitro* [2, 3]. Many studies have shown that transthyretin (TTR) binds to A $\beta$ , alters its aggregation, and inhibits its toxicity both *in vitro* and *in vivo* [4–8]. *In vitro*, TTR co-aggregates with A $\beta$  oligomers into large non-toxic assemblies, thereby inhibiting cellular toxicity [9]{Garai et al., 2018, #17428}. *In vivo*, TTR sequesters A $\beta$  and facilitates its clearance in the brain [1]. More recently, Buxbaum laboratory showed that overexpression of wild-type human TTR suppressed disease progression in the APP23 transgenic AD mouse model [6]. They also showed that silencing the endogenous TTR gene in AD transgenic mice accelerated A $\beta$ 42 deposition [5].

What makes the pair of TTR and A $\beta$ 42 particularly interesting is the amyloid nature of the two elements. In transthyretin amyloidosis patients, dissociation of tetrameric TTR leads to amyloid fibril formation and systemic TTR amyloid deposition [10–12]. Whether the amyloidogenicity of TTR is linked to its interaction to A $\beta$ 42 is still under debate. Previous work showed that different aggregation propensities of TTR result in distinct interaction capabilities: less amyloidogenic variants had increased affinity for A $\beta$  [7]. However, this did

not impact on the levels of inhibition of A $\beta$  aggregation, and cytotoxicity protection was not assessed. Here we attempt to fill the experimental gap by studying the protective effect of TTR variants at different aggregated states over A $\beta$ 42 cellular toxicity. In addition, we show the identification and characterization of a segment of TTR that binds A $\beta$ 42 triggering the formation of non-amyloid amorphous aggregates that are more sensitive to protease digestion, therefore mimicking TTR inhibitory effect over A $\beta$ 42.

## Results

We first evaluated the protection against A $\beta$ 42 cytotoxicity by nine TTR variants with distinct aggregation propensities, in several aggregated states (Table 1). The amyloidogenic behavior of three representative TTR variants is shown in Fig 1A and 1B. For this assay, recombinant transthyretin was incubated at 37 °C, pH 4.3, protein aggregation was followed by immuno-dot blot of the insoluble fractions collected by centrifugation at several time points (Fig. 1A), and electron microscopy was performed after 4 days of incubation (Fig. 1B). We found that M-TTR, a monomeric-engineered form of transthyretin that is soluble at physiological pH [13], shows notable aggregation after one day of incubation at pH 4.3 (Fig. 1A-C). NSTTR is a mutated variant of TTR carrying the double mutation N99R/S100R that, although remains tetrameric in solution (Fig. 1C), shows a slower aggregation pattern than M-TTR (Fig. 1A and 1B). T119M is a very stable mutant that did not show any sign of aggregation in four days (Fig. 1A-C). We then incubated A $\beta$ 42 with the samples obtained from Fig. 1A for 16 hours and evaluated its cytotoxicity by following MTT reduction. Three observations were made. The first observation is that once aggregated, TTR does not prevent A $\beta$ 42 toxicity, for any of the variants (Fig. 1D). In addition, the variant NS-TTR, which aggregates at a slow pace, resulted to be cytoprotective longer than M-TTR (Fig. 1D). The third observation is that T119M, which does not dissociate and aggregate, does not prevent toxicity either (Fig. 1D). We observed the same phenomena when other six TTR variants were evaluated (Supplemental Fig. 1). Although variants S112I, M13R/L17R, or A108R/L110R are mainly monomeric or dimeric in solution, the cytotoxic protection at day 0 is not greater than NSTTR or L55P that are mainly tetrameric in solution (Fig. 1C and Supplementary Fig. 1B). This finding suggests that the capacity to protect from A $\beta$ 42 toxicity does not correlate with the initial oligomeric state of soluble variants (Fig. 1C, and Supplemental Fig. 1B), but rather with the dissociation state at the moment of the co-incubation with A $\beta$ 42 (Fig. 1A and 1B, and Supplemental Fig. 1C). A control experiment shows that the TTR variants used in this assay were not cytotoxic in the absence of A $\beta$ 42, with the exception of M-TTR, which resulted in a 20% reduction of cell viability (Supplementary Fig. 1D). Overall, our results indicate that dissociation of TTR is required for the inhibition of A $\beta$  cytotoxicity. In addition, the data suggest that a more stable dissociated TTR exerts more A $\beta$ 42 inhibition than a more amyloidogenic variant. These findings led us to wonder whether a segment of TTR that is only exposed when dissociated but not in the aggregate might be similarly capable of altering A $\beta$  toxicity.

Computational modeling of the interaction of a fibrillar segment of A $\beta$ 42 and the TTR monomer shows a tight packing of the thyroxine binding pocket and the fibrillar structure (Fig. 2). Others have shown that the amyloidogenic segment KLVFFA is protected when TTR is bound to A $\beta$  [14]. In previous studies, our lab determined the structures of three fibrillar polymorphs of KLVFFA by x-ray microcrystallography [15]. We used these three polymorphs as well as the monomeric form of wild-type TTR (4TLT.pdb, [16]) to perform protein-protein computational docking (Fig. 2). For every fibrillar form, the segment TTR(105-117) was the longest interacting TTR segment. The segment TTR(105-117) is only exposed in the monomeric or dimeric form of TTR. We wondered if this segment might mimic TTR protective effects when isolated.

The peptide TTR(105-117) was found to be highly amyloidogenic. We first analyzed the amyloidogenicity of TTR sequence by ZipperDB, which measures the propensity of every six-residue segment to form amyloid fibrils [17, 18] (Supplementary Fig.2A). TTR predictions show that the region that contains this segment is highly prone to form amyloid structures. In fact, we found the segment TTR(105-117) and the shorter peptide TTR(106-112) to be amyloidogenic in solution (Supplementary Fig. 2B), which may explain the lack of inhibitory effect in previous studies [19]. We then explored several sequence modifications to increase solubility, by eliminating the first tyrosine or adding a charged tag to the N-terminal end. The sequences and names of all the analyzed peptides are listed in Table 2. We found that TTR(105-117) amyloidogenicity was fully hindered by the addition of a poly-arginine tag (Supplemental Fig. 2B).

The soluble tagged derivatives of the segment TTR(105-117) inhibited A $\beta$ 42 fibril formation (Fig. 3 and Supplementary Fig. 3). We first evaluated the inhibitory effect of TTR-derived peptides over A $\beta$ 42 fibril formation in thioflavin T (ThT) assays (Fig. 3A and Supplementary Fig. 3). Out of all peptides that we analyzed, the best A $\beta$ 42 inhibitory effect was obtained with TTR-S (sequence YTIAALLSPYSYSRRRRR), which contains a 4-arginine tag followed by TTR(105-117) (Supplementary Fig. 3). After an incubation of 2 days, we analyzed the samples by electron microscopy, and found that the addition of TTR-S promoted the formation of amorphous aggregates (Fig. 3B) that were not birefringent when stained with Congo-red (Fig. 3C). Remarkably, we found that TTR-S also promoted the formation of amorphous species when incubated with preformed A $\beta$ 42 fibrils (Fig. 3B). These aggregates were also found to be thioflavin T negative (Fig. 3A), and non- birefringent when stained with Congo-red (Fig. 3C). The structural characterization of A $\beta$ 42 amorphous aggregates by circular dichroism showed that the addition of TTR-S to preform fibrils resulted in a significant structural shift from beta to helical secondary motifs (Fig. 3D). Additionally, we found that this structural modification results in cytotoxicity protection (Fig. 4). HeLa cells were subjected to A $\beta$ 42 in the absence and presence of TTR-S at different molar ratios, and cell metabolic activity was followed by MTT reduction (Fig. 4A). We found that the addition of TTR-S results in a significant reduction of A $\beta$ 42 cellular toxicity. This protective effect may be explained by the inhibition of the formation of A11-positive oligomers as

a result of the incubation with TTR-S (Fig. 4B). It is worth noting that the larger aggregates did not resolve in the SDS-page gel.

Next we found that the binding of TTR-S to soluble and fibrillar A $\beta$ 42 alters their protease resistance. Others have shown that TTR increases A $\beta$ 42 clearance *in vivo* [1]. We reasoned that the large assemblies that form upon binding to TTR might be more sensitive to proteolytic activity than amyloid fibrils, thereby facilitating clearance. This hypothesis would also explain the protective effect found *in vivo* [6]. We explored this hypothesis by analyzing proteolytic sensitivity of TTR-S-derived amorphous aggregates (Fig. 5). We incubated soluble and fibrillar A $\beta$ 42 with TTR-S over night, and collected the insoluble fractions by centrifugation. The immuno-dot blot of insoluble fractions showed that amorphous aggregates that result from the incubation of TTR-S with both soluble and fibrillar A $\beta$ 42 were easily digested by proteinase K after one hour (Fig. 5A and 5B). In contrast, A $\beta$ 42 fibrils showed a significantly higher resistance to proteinase K digestion. We included soluble A $\beta$ 42 in the assay as a control of proteolytic activity.

Finally, we evaluated TTR-S ability to hinder amyloid seeding caused by fibrils extracted from the brain of an AD patient (Fig. 5C). The extraction of A $\beta$  fibrils was performed by several cycles of homogenization and ultracentrifugation as described by Tycko and colleagues [20]. Amyloid seeding was measured by thioflavin T fluorescence and electron microscopy. As expected, we found that the addition of sonicated patient-derived fibrils to soluble A $\beta$ 42 resulted in the acceleration of fibril formation. In contrast, incubation with TTR-S resulted in full inhibition of A $\beta$ 42 fibril formation even in the presence of patient-derived A $\beta$  seeds.

## Discussion

Our results indicate that the dissociation of the TTR tetramer is required to prevent cytotoxicity from A $\beta$  oligomers. These results are consistent with the model proposed by Buxbaum and coworkers in where dissociated TTR monomers efficiently bind A $\beta$  oligomers, which are thought to be responsible for cellular A $\beta$ -associated toxicity [14, 21]. They also found that tetrameric TTR binds to soluble monomeric A $\beta$ , thereby suppressing aggregation *in vitro* [14]. Others have also found that the stabilization of the tetrameric form of TTR promotes A $\beta$  clearance in a mouse model of Alzheimer's disease [22]. In our study, we did not find any effect of tetrameric TTR on A $\beta$ 42 cytotoxicity. For instance, the tetrameric non-amyloidogenic T119M variant did not inhibit A $\beta$ 42 cytotoxicity (Fig. 1). Consistently, the non-amyloidogenic variant L55P/T119M did not inhibit cytotoxicity whereas the amyloidogenic L55P variant did (Supplementary Fig. 1). Taken together, other studies and our results suggest that tetrameric TTR may be protective *in vivo* perhaps not by recruiting toxic oligomers, but by sequestering and promoting clearance of A $\beta$  monomers. In contrast, dissociated TTR seems to inhibit A $\beta$  cytotoxicity by binding to toxic oligomeric species triggering the formation of large non-toxic assemblies.

Using computational tools, we generated a TTR-derived peptide that inhibits A $\beta$ 42 fibril formation and cellular toxicity (Fig. 3). This TTR-derived peptide, here called TTR-S, contains a poly-arginine tag followed by the highly amyloidogenic segment TTR(105-110) (Supplementary Fig. 3). Our results are consistent with previous NMR studies that show that the interaction of TTR residues Lys15, Leu17, Ile107, Ala108, Ala109, Leu110, Ala120, Val121 to A $\beta$  contributes to the inhibition of A $\beta$  fibril formation *in vitro* [14]. In addition, others have shown that the segment TTR(106-110), one residue shorter, was capable of binding A $\beta$  when immobilized on a membrane [8]. However, the same peptide was not effective inhibiting A $\beta$  aggregation in solution [19], unless the peptide was made cyclic therefore not amyloidogenic [23], probably because of the high amyloidogenicity of this segment (Supplemental Fig. 3). In our study, we solubilized TTR(105-110) by adding a charged tag, which confers higher solubility and also hinders self-aggregation (Supplementary Fig. 3). The addition of a poly-arginine tag was sufficient to convert a highly amyloidogenic peptide into an inhibitor of A $\beta$ 42 cellular toxicity even at substoichiometric concentrations (Fig. 4A).

TTR-S inhibits A $\beta$ 42 oligomer formation whilst promoting the formation of non-toxic, non-amyloid, amorphous aggregates. Previous studies of the inhibition of A $\beta$  cytotoxicity by TTR have revealed that TTR co-aggregates with A $\beta$  oligomers into large non-toxic assemblies, thereby inhibiting cellular toxicity *in vitro* [9]. TTR-S mimics this effect, and promotes the formation of large aggregates (Fig. 3B) that do not bind thioflavin T (Fig. 3A), do not show birefringence upon staining with Congo red (Fig. 3C), and display a non-beta secondary structure when subjected to CD (Fig. 3D). These amorphous species share some resemblance with the large unstructured aggregates found after the addition of EGCG to intrinsically disordered A $\beta$  and other amyloid proteins [24]. Similar to EGCG-derived A $\beta$  aggregates, TTR-S-derived aggregates display a unique secondary structure that results in reduced thioflavin T fluorescence and lack of birefringence upon binding to Congo red (Fig. 3A and 3C).

A $\beta$ 42 amorphous aggregates generated upon binding to TTR-S are more sensitive to protease digestion (Figs. 4 and 5). As discussed above, TTR inhibits A $\beta$  oligomer toxicity by co-aggregation into large non-toxic assemblies [9]. However, those studies did not assess protease sensitivity of A $\beta$  species. We observe that TTR-S-derived aggregates, both from soluble and fibrillar A $\beta$ , are more sensitive to proteinase K than preformed A $\beta$  fibrils. We speculate that TTR may promote A $\beta$  clearance *in vivo* by a similar mechanism; this is, the formation of large assemblies that are more prone to digestion and clearance.

Finally, we evaluated the inhibitory effect of TTR-S on A $\beta$  amyloid seeding. As shown previously, we found that the addition of *ex-vivo* fibril extracts to soluble A $\beta$  accelerates fibril formation [25, 26]. In contrast, we found that TTR-S inhibits amyloid seeding catalyzed by A $\beta$  extracted from the brain tissue of an AD patient (Fig. 5C).

In summary, our results suggest that the dissociation of the TTR tetramer into monomers is required to prevent cytotoxicity from A $\beta$  oligomers. In addition, we found that a segment derived from TTR, TTR-S,

exerts anti-amyloid activity, thereby inhibiting A $\beta$ 42 cytotoxicity and amyloid seeding. We also found that TTR-S binds to soluble and fibrillar species causing a structural rearrangement that leads to an increase of protease sensitivity. Finally, we found that TTR-S inhibits amyloid seeding catalyzed by A $\beta$  fibrils extracted from the brain of an AD patient. The present study represents an expansion of the current knowledge on the mechanism of protection of TTR over A $\beta$ 42 cellular toxicity and opens a potential therapeutic avenue.

### *Acknowledgments.*

We thank Dr. Harry V. Vinters for supplying the AD brain tissue and the patient who generously donated it. This work was supported by NIA, National Institutes of Health (NIH), Grants RF1 AG048120 (to D.S.E.), RF1 AG054022 (to D.S.E.), and R56 AG061847 (to D. S. ## Experimental Procedures

*Patients and Tissue Material.* Post-mortem brain tissue from the occipital lobe of an 83-year-old female patient of Alzheimer's disease was obtained from Dr. Vinters at UCLA Pathology Department. The patient was previously evaluated for the presence of amyloid plaques by immunohistochemistry and pathologically diagnosed for Alzheimer's disease. The University of California, Los Angeles Office of the Human Research Protection Program granted exemption from Internal Review Board review because the specimen was anonymized.

*Recombinant protein purification.* TTR mutants were cloned and purified as previously described [16]. Briefly, exponentially growing *E. coli* Rosetta™(DE3)pLysS Competent Cells (Millipore) were treated with 1 mM of IPTG for 3 h. Mutant TTR were purified by Ni-affinity chromatography using HisTrap columns (GE Healthcare), followed by gel filtration chromatography using a HiLoad 16/60 Superdex 75 column (GE Healthcare) running on an AKTA FPLC system. Amyloid- $\beta$  peptide (A $\beta$ 42) was overexpressed through *Escherichia coli* recombinant expression system and was purified as reported previously [27]. The fusion construct for A $\beta$ 42 expression contains an N-terminal His tag, followed by 19 repeats of Asn-Ala-Asn-Pro, TEV protease site and the human A $\beta$ 42 sequence. Briefly, the fusion construct was expressed into inclusion bodies in *E. coli* BL21(DE3) cells. 8 M urea was used to solubilize the inclusion bodies. Fusion proteins were purified through HisTrap HP Columns, followed by Reversed-phase high-performance liquid chromatography (RP-HPLC). After TEV cleavage, A $\beta$ 42 peptide was purified from the cleavage solution by RP-HPLC followed by lyophilization. To disrupt preformed aggregation, lyophilized A $\beta$ 42 was resuspended in 100% Hexafluoroisopropanol (HFIP) which was finally removed by evaporation.

*Size-exclusion chromatography with multi-angle light scatter and refractometer detection.* Components of 0.5  $\mu$ g protein samples were separated by a silica-based size-exclusion column (Toso Biosep G3000SWXL; 5  $\mu$ m beads, 7.8x300 mm with guard column). The elution buffer contained 0.025M NaH<sub>2</sub>PO<sub>4</sub>, 0.1 M Na<sub>2</sub>SO<sub>4</sub>, 1mM NaN<sub>3</sub>, weighed on an analytical scale, titrated together to pH 6.5 with NaOH, diluted to final volume in a 2 liter volumetric flask. The flow rate was 0.4 ml/min. Samples were 0.1  $\mu$ m filtered (Millipore UltraFree MC centrifugal filters). Each injection was 40-50  $\mu$ l. The peaks were detected by UV absorbance at 280 nm (Waters 2487), light scatter and index of refraction (Wyatt Technologies MiniDAWN and OPTILAB DSP). Molecular weights were calculated with Astra software, from the light scatter and refractometer signals, transferring the dn/dc and normalization parameters determined from the monomer peak of bovine serum albumin.

*TTR aggregation assay.* TTR aggregation assays were performed as previously described [28]. Briefly, 1 mg/ml TTR sample in 10 mM Sodium Acetate pH 4.3, 100 mM KCl, 10 mM EDTA was incubated at 37° C during a maximum of 7 days. TEM micrographs were taken after 7 days of incubation. Insoluble fractions were sampled and used to follow TTR aggregation by immuno-dot blot.

*Transmission electron microscopy (TEM).* TEM was performed to visualize TTR mutant aggregation and the fibrillation of A $\beta$ 42 in presence of TTR mutants or TTR-derived inhibitors. 5  $\mu$ l solution was spotted onto freshly glow-discharged carbon-coated electron microscopy grids (Ted Pella, Redding, CA). Grids were rinsed three times with 5  $\mu$ l distilled water after 3 min incubation, followed by staining with 2% uranyl acetate for 2 min. A T12 Quick CryoEM electron microscope at an accelerating voltage of 120 kV was used to examine the specimens. Images were recorded digitally by Gatan 2kX2k CCD camera.

*Cell lines.* HeLa, PC-12 Adh, and SH-SY5Y (ATCC; cat. # CRL-2, CRL-1721.1 and CRL-2266, respectively) cell lines were used for measuring the toxicity of A $\beta$ 42. HeLa cells were cultured in DMEM medium with 10% fetal bovine serum, PC-12 cells were cultured in ATCC-formulated F-12K medium (ATCC; cat. # 30-2004) with 2.5% fetal bovine serum and 15% horse serum.

*MTT-based cell assay.* We performed MTT-based cell viability assay to assess the cytotoxicity of A $\beta$ 42 with or without the addition of TTR mutants or TTR-derived peptide inhibitors. A CellTiter 96 aqueous non-radioactive cell proliferation assay kit (MTT) (Promega cat. #G4100, Madison, WI) was used. Prior to toxicity test, HeLa and PC-12 cells were plated at 10,000 cells and 15,000 cells cells per well, respectively, in 96-well plates (Costar cat. # 3596, Washington, DC). Cells were cultured in 96-well plates for 20 hr at 37°C in 5% CO<sub>2</sub>. For A $\beta$ 42 and inhibitors samples preparation, purified A $\beta$ 42 was dissolved in PBS at the final concentration of 10  $\mu$ M, followed by the addition of TTR mutants or TTR-derived inhibitors at indicated concentrations. The mixtures were filtered with a 0.2  $\mu$ m filter and further incubated for 16 hours at 37°C without shaking for fiber formation. To start the MTT assay, 10  $\mu$ l of pre-incubated mixture was added to each well containing 90  $\mu$ l medium. After 24 hours of incubation at 37°C in 5% CO<sub>2</sub>, 15  $\mu$ l Dye solution (Promega cat. #G4102) was added into each well. After incubation for 4 hours at 37°C, 100  $\mu$ l solubilization Solution/Stop Mix (Promega cat. #G4101) was added to each well. After 12 hours of incubation at room temperature, the absorbance was measured at 570 nm with background absorbance recorded at 700 nm. Three replicates were measured for each of the samples. The MTT cell viability assay measured the percentage of survival cell upon the treatment of the mixture of A $\beta$ 42 and inhibitors. The cell viability (%) after treatment with A $\beta$ 42 with and without TTR-derived peptide inhibitors

was calculated by normalizing the cell survival rate using the PBS buffer-treated cells as 100% viability and 2% SDS treated cells as 0% viability.

*Computational Docking of fibrillar KLVFFA and monomeric TTR.* Protein-protein docking between monomeric TTR and A $\beta$ 42 fibrillar segments was performed using the ClusPro server [29]. Monomeric TTR was generated by removing chain B of the asymmetric unit of 4TLT.pdb [16]. Three fibrillar polymorphs of the A $\beta$ 42 segment KLVFFA were analyzed: 2Y2A.pdb, 2Y21.pdb, and 3OW9.pdb ([15]). To increase binding surface, only one sheet of each polymorph was included in the modeling.

*Thioflavin T fibrillation assay.* Purified A $\beta$ 42 was dissolved in 10 mM NaOH at the concentration of 300  $\mu$ M. A $\beta$ 42 was diluted into PBS buffer at the final concentration of 30  $\mu$ M, and was mixed with 30  $\mu$ M Thioflavin T (ThT) and different concentrations of TTR mutants or TTR-derived peptide inhibitors. The reaction mixture was split into four replicates and placed in a 394-well plate (black with flat optic bottom). The ThT fluorescence signal was measured every 5 min using the Varioskan plate reader (Thermo Scientific, Inc.) or FLUOstar Omega plate reader (BMG Labtech) with excitation and emission wavelengths of 444 and 484 nm, respectively, at 37°C.

*Western and Immuno-Dot Blot.* The aggregation of His-tagged TTR mutants was followed by immuno-dot blot analysis as described in Saelices et al. 2015 using SuperSignal<sup>®</sup> West HisProbe<sup>™</sup> Kit following manufacturer's instructions (Life Technologies). Briefly, 100  $\mu$ l of samples was spun at 13,000 rpm during 30 minutes, the pellet resuspended in the same volume of fresh buffer, and spun again. The final pellet was resuspended in 6M guanidine chloride and dotted onto nitrocellulose membranes (0.2  $\mu$ m, Bio-Rad). We used a concentration of the HisProbe antibody of 1:10,000. The aggregation of A $\beta$ 42 was followed by western and immuno-dot blot analysis. For the western blots, 7.5  $\mu$ l of 6  $\mu$ M samples were separated by SDS-PAGE (NuPAGE 4-12% Bis-Tris Gel, Life Technologies) or native gels (NativePAGE 4-16% Bis-Tris Gel, Life Technologies) and transferred onto a nitrocellulose membrane (iBlot<sup>®</sup> 2 NC Mini Stacks, Life Technologies) by iBlot<sup>®</sup> 2 membrane transfer system (Life Technologies). For the Immuno-dot blot analysis, 2 to 15  $\mu$ l of samples were dotted onto a nitrocellulose membrane (Bio-RAD). We used a concentration of 6E10 antibody of 1:2000 (Biolegend<sup>®</sup>, [30]), OC antibody of 1:25,000 and A11 antibody of 1:500 (Millipore and Life Technologies, respectively; [31]). The HRP conjugated anti-mouse IgG antibody (Sigma-Aldrich) was used as secondary antibody at a concentration of 1:2000, and anti-rabbit IgG antibody (Thermo Scientific) was used to detect OC and A11 at a concentration of 1:1000. The membrane was finally developed using the SuperSignal<sup>®</sup> West Pico Chemiluminescent Substrate Kit (Life Technologies), following manufacturer's instructions.

*Circular Dichroism (CD).* Secondary structures of A $\beta$ 42 samples were analyzed by CD spectroscopy. Samples (200  $\mu$ l) were placed into a 1-mm path length quartz cell (Hellma Analytics). A Jasco J-810 UV-Vis spectropolarimeter was employed. Spectra were obtained in a wavelength range of 190 to 250 nm, with a time response of 2 s, a scan speed of 50 nm/min, and a step resolution of 0.1 nm. Each spectrum was the average of five accumulations. All the samples were assayed at a concentration of 50  $\mu$ g/ml in 15 mM phosphate buffer (pH 7.4). Spectra were recorded at 25° C. The results are expressed as the mean residue molar ellipticity,

$$[\theta] = \frac{\theta \times 100 \times M}{C \times l \times n}$$

Where  $\theta$  is the ellipticity in degrees,  $l$  is the optical path in cm,  $C$  is the concentration in mg/ml,  $M$  is the molecular mass and  $n$  is in the number of residues in of the sample molecule. The ellipticity of the samples of A $\beta$  after addition of TTR-S was normalized by using the ellipticity of TTR-S as a blank. The percentage of the various structural conformations was calculated by using the software package CDPro, which includes three programs to determine the secondary structure fractions: CONTIN, SELCON, and CDSSTR [32]. The results are displayed as the mean value and standard deviation of the three methods.

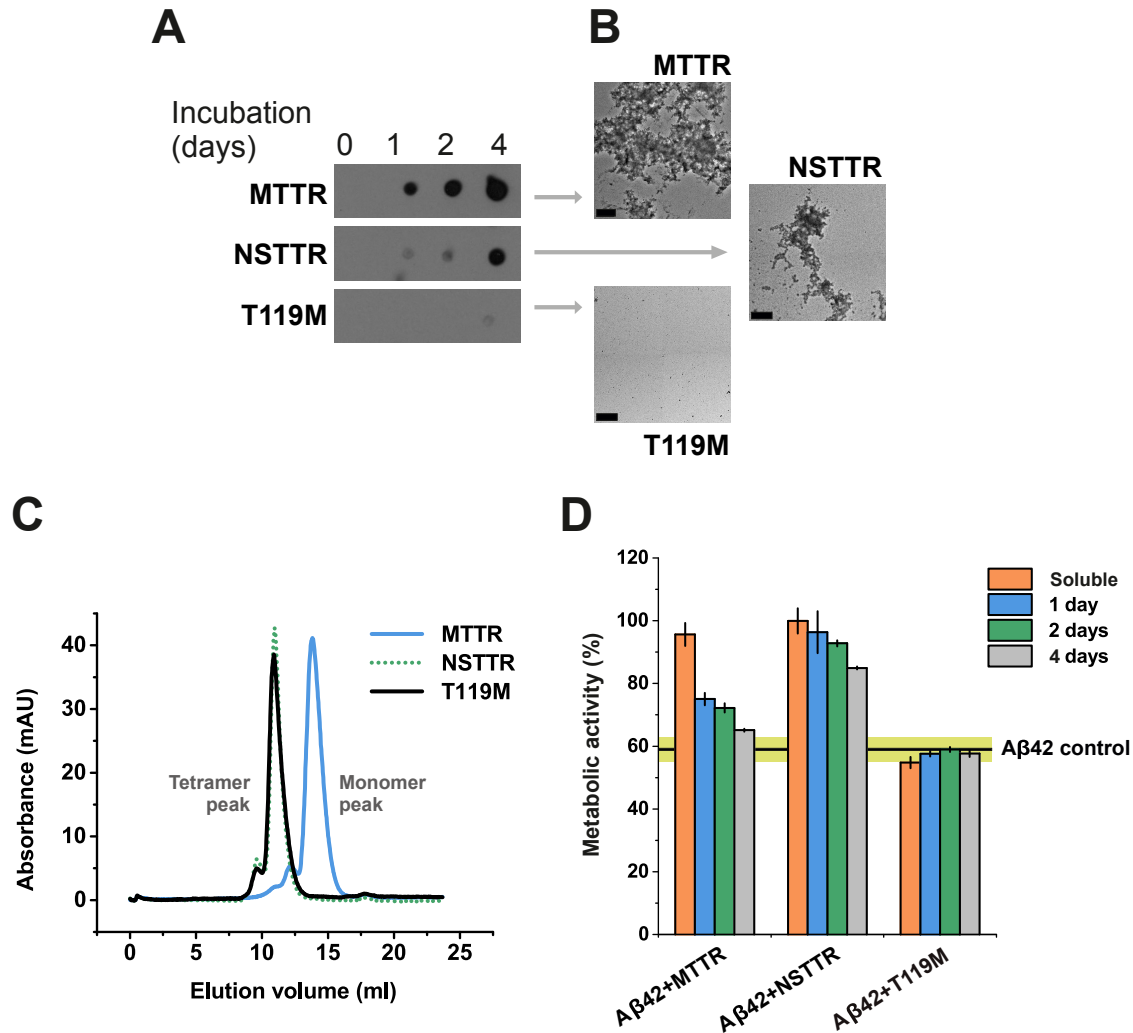

*Proteinase K assay.* Soluble A $\beta$ 42 was prepared in PBS and filtered (0.22  $\mu$ m). A $\beta$ 42 fibrils were obtained after 1-2 weeks of incubation in PBS at RT. Three-fold molar excess of TTR-S was added to soluble or fibrillar A $\beta$ 42 and incubated for 16 hours. Soluble and insoluble fractions were extracted by centrifugation of half of the sample prior to incubation. PK digestion was performed in a reaction volume of 100  $\mu$ l containing 10  $\mu$ M of A $\beta$ 42 samples, and varying concentrations of PK (from 0.2  $\mu$ g/ml to 50  $\mu$ g/ml) in 0.1 M Tris-HCl buffer, pH 7.5 for 1 h at 37 °C. Reactions were quenched with 1 mM PMSF, and samples were analyzed dot blot using E610 specific anti-A $\beta$ 42 antibody. As negative control, we included a sample with TTR-S alone. The signal was quantified using ImageJ.

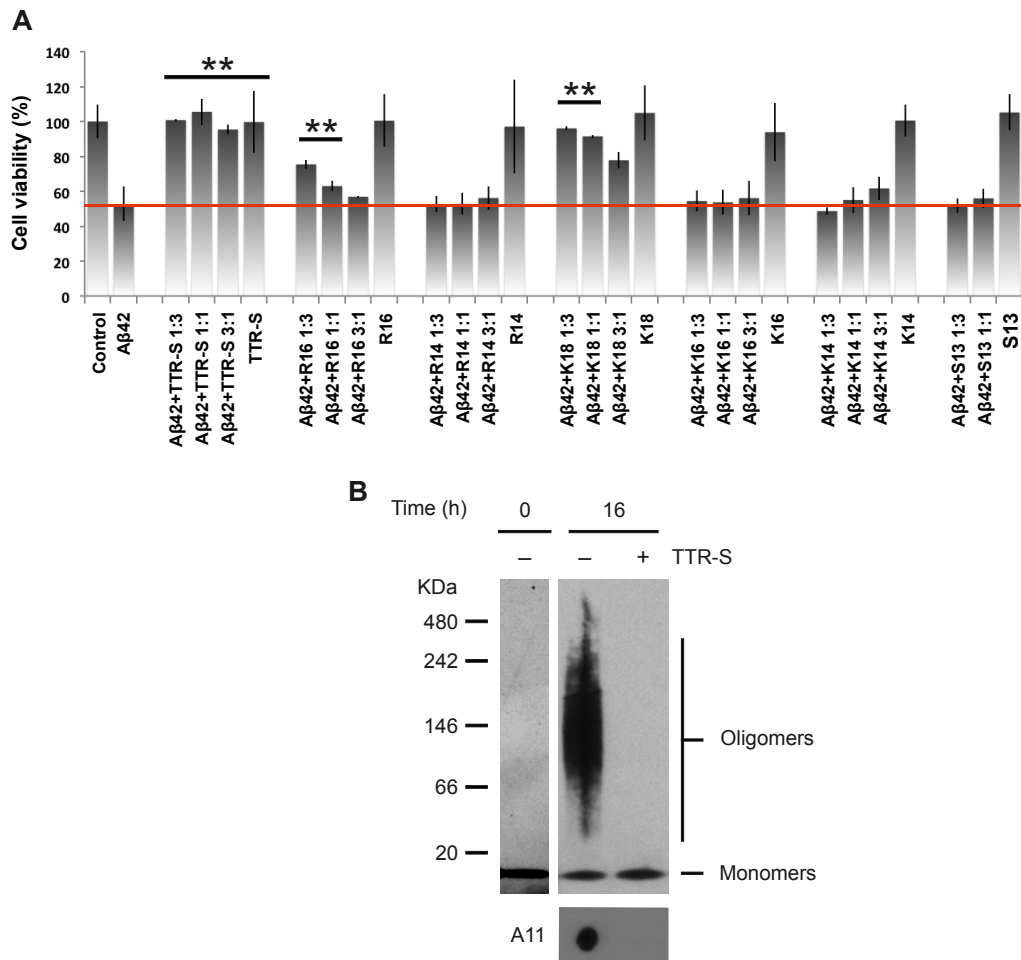

**Figure 1. The inhibition of Aβ42 cytotoxicity by TTR depends on the aggregation propensity of each TTR variant. (A)** Aggregation assay of three TTR variants followed by immunodot blot of insoluble fractions collected prior incubation, or after 1, 2, and 4 days of incubation at 37° C, as labeled. **(B)** Electron micrographs of aggregated TTR variants after 4 days of incubation. Scale bar, 200 nm. **(C)** Size exclusion chromatography of soluble TTR variants at pH 7.4. **(D)** Cytotoxicity assay of Aβ42 in the presence of TTR variants at different stages of aggregation, followed by MTT reduction. A five-fold molar excess of soluble TTR, and aggregated samples collected after 1, 2 and 4 days of incubation was added to soluble 10 μM Aβ42 and incubated overnight. Samples were added to HeLa cells, and MTT reduction was measured after 24 hours. Buffer-treated cells were considered 100% viability and used for normalization. These results suggest that the dissociation of the tetrameric TTR structure precedes Aβ42 cytotoxicity protection, whereas aggregated TTR does not exert any effect.

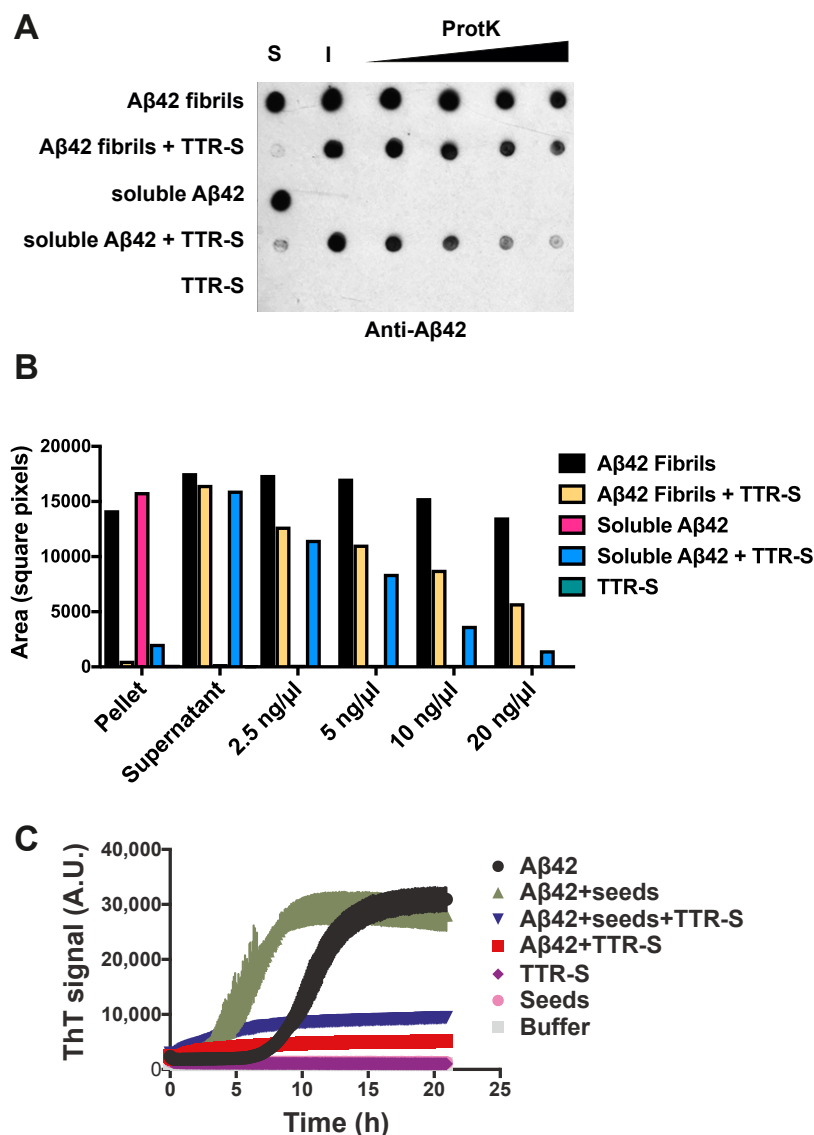

**Figure 2. Protein-protein docking of TTR monomer with three KLVFFA polymorphs.** Protein-protein docking was performed using monomeric TTR and three KLVFFA polymorphs identified previously (Colletier et al., 2011): 2y2a.pdb, 2y21.pdb and 3ow9.pdb. **(A)** Monomeric TTR obtained from chain A of the model 4TLT.pdb (Saelices et al., 2015) is shown in grey as secondary structure. On the left, view down the hydrophobic pocket. On the right, lateral view. **(B)** Fibrillar structures of KLVFFA from 2y2a.pdb (left), 2y21.pdb (middle), and 3ow9.pdb (right). Only one sheet of each KLVFFA polymer was included in the docking, shown in blue. The resulting docking models, shown in **(C)**, suggest that TTR may interact with A $\beta$ 42 through residues 105-117. Monomeric TTR is shown in grey with the segment TTR(105-117) in red. Top row, lateral view of interface. Bottom row, view down the binding interface. Residues involved in the interaction between monomeric TTR and KLVFFA are shown as sticks. Spheres represent the van der Waals radii of the side chain atoms of the tightly packed binding interface.

**Figure 3. Effect of TTR-S on both soluble and fibrillar Aβ42 (A)** Thioflavin T (ThT) fluorescence was measured from samples containing 10 μM Aβ42 in the presence and absence of a 3-fold molar excess of TTR-S. TTR-S was added before incubation (green), or after 18 minutes of incubation (red). TTR-S alone (purple) and buffer (not shown) were used as negative controls. For a complete assessment of Aβ42 inhibition by TTR-derived peptides, see Supplementary Fig. 4. **(B)** Electron micrographs of Aβ42 fibrils formed in the absence of inhibitor (up), Aβ42 amorphous aggregates formed when TTR-S was added after 18 minutes of incubation (middle), and Aβ42 amorphous aggregates formed when TTR-S was added prior to incubation (bottom). Scale bar, 400 nm. **(C)** Congo red staining of samples shown in **A** under bright field (left) and polarized light (right). **(D)** Circular dichroism traces of Aβ42 fibrils, Aβ42 fibrils after addition of TTR-S, and soluble Aβ42 after addition of TTR-S. Below, the table shows the calculated percentage of various structural conformations: helix, beta-stranded, and others (turns and unstructured). These analyses indicate that the TTR-derived peptide TTR-S inhibits Aβ42 aggregation and promotes the formation of non-amyloid amorphous aggregates.

**Figure 4. TTR-S inhibition of Aβ42 cytotoxicity. (A)** Cell viability assay followed by MTT reduction. HeLa cells were treated with 10 μM Aβ42 in the absence and the presence of increasing concentrations of peptides. Molar ratios of Aβ42 and peptides are labeled. As a negative control, cytotoxicity of peptides alone was also measured. Buffer-treated cells were considered 100% viability, and used for normalization. **(B)** Non-denaturing electrophoresis followed by immunoblot of Aβ42 after 16 hours of incubation at 37 °C without and with TTR-S. The same samples were analyzed by dot blot with the oligomer-specific A11 antibody (bottom). These results suggest that the inhibition of Aβ42 cytotoxicity by TTR-S results from the elimination of toxic oligomeric species.

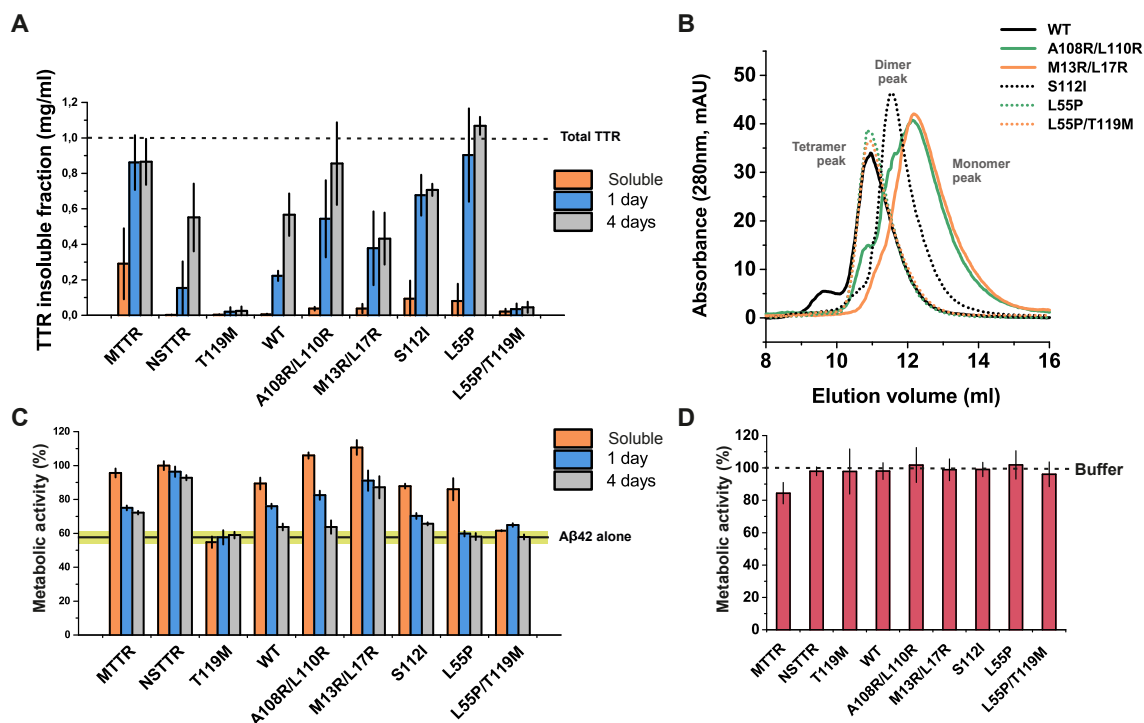

**Figure 5. Evaluation of the inhibitory effect of TTR-S by protease digestion and amyloid seeding.** (A) Anti-Aβ42 immuno-dot blot of Aβ42 aggregates after proteinase K digestion. Soluble Aβ42 and pre-formed fibrils were incubated with TTR-S. Half of the sample was subjected to centrifugation and soluble (S) and insoluble (I) fractions were collected. Increasing concentrations of proteinase K were added to the other half of the sample and incubated at 37° C for one hour. Samples were analyzed by dot blot using E610 specific anti-Aβ42 antibody. As negative control, we included a sample with TTR-S alone. The signal was quantified using ImageJ and plotted in (B). This assay shows that Aβ42 amorphous aggregates generated after the addition of TTR-S are degraded by proteinase K more readily than Aβ42 fibrils. (C) Amyloid seeding assay followed by ThT signal. Soluble Aβ42 was incubated with AD ex-vivo seeds in the presence or absence of TTR-S. Samples with only TTR-S, only AD seeds or buffer were included as negative control. Note that the addition of TTR-S results in inhibition of Aβ42 seeding.

Table 1. List of TTR variants evaluated in this study

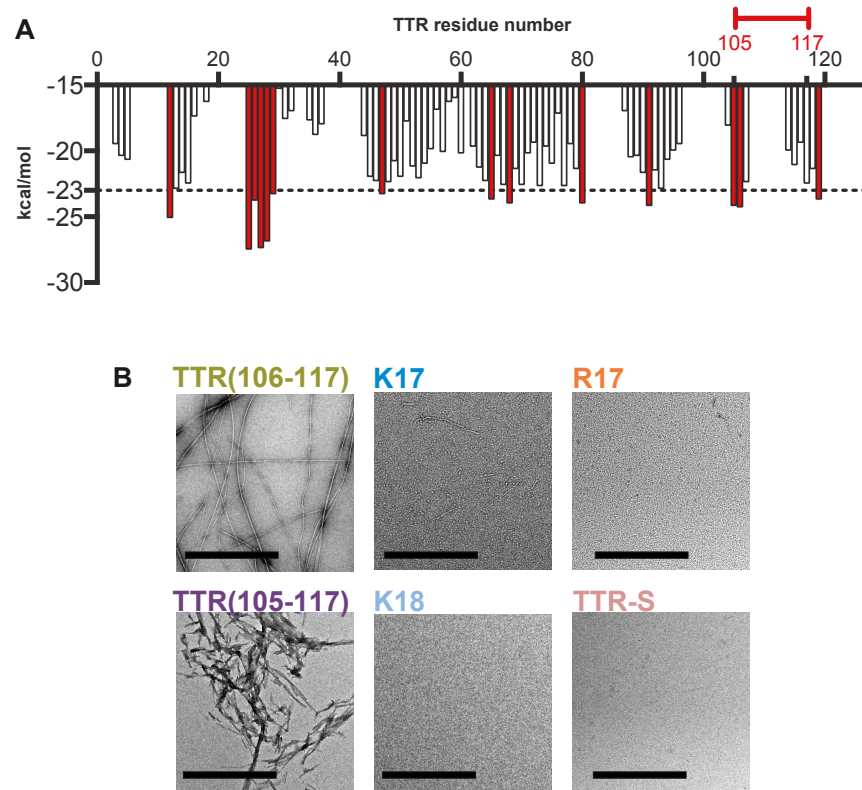

<b>TTR variant</b>	<b>Mutation</b>	<b>Oligomeric state in solution</b>
MTTR	F87M/L110M	Monomer
NSTTR	N99R/S100R	Tetramer
T119M	T119M	Tetramer
WT	None	Tetramer
A108R/L110R	A108R/L110R	Tetramer + Dimer + Monomer
M13R/L17R	M13R/L17R	Dimer + Monomer
S112I	S112I	Dimer
L55P	L55P	Tetramer
L55P/T119M	L55P/T119M	Tetramer

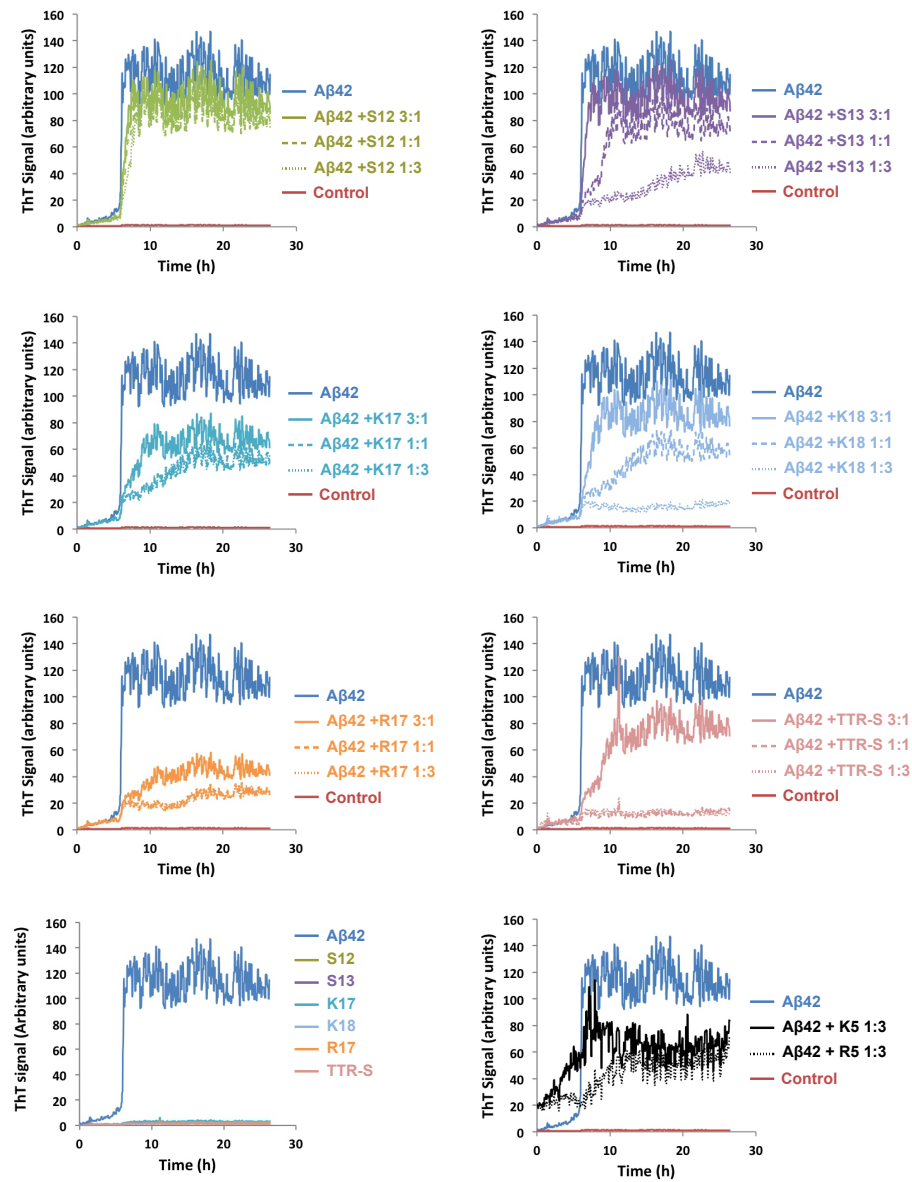

**Figure S1. Inhibition of Aβ42 cytotoxicity by TTR variants.** (A) Aggregation assay of TTR variants followed by protein concentration of insoluble fractions collected prior incubation, or after 1, and 4 days of incubation at 37° C, as labeled. (B) Size exclusion chromatography of soluble TTR variants at pH 7.4. (C) Cytotoxicity assay of Aβ42 in the presence of TTR variants at different stages of aggregation, followed by MTT reduction. A five-fold molar excess of soluble TTR, and aggregated samples collected after 1 and 4 days of incubation was added to soluble 10 μM Aβ42 and incubated over night. Samples were added to HeLa cells, and MTT reduction was measured after 24 hours. Buffer-treated cells were considered 100% viability, and used for normalization. (D) Cytotoxicity of TTR variants in the absence of Aβ42 measured by MTT reduction. TTR final concentration was kept the same as for (C), 50 μM.

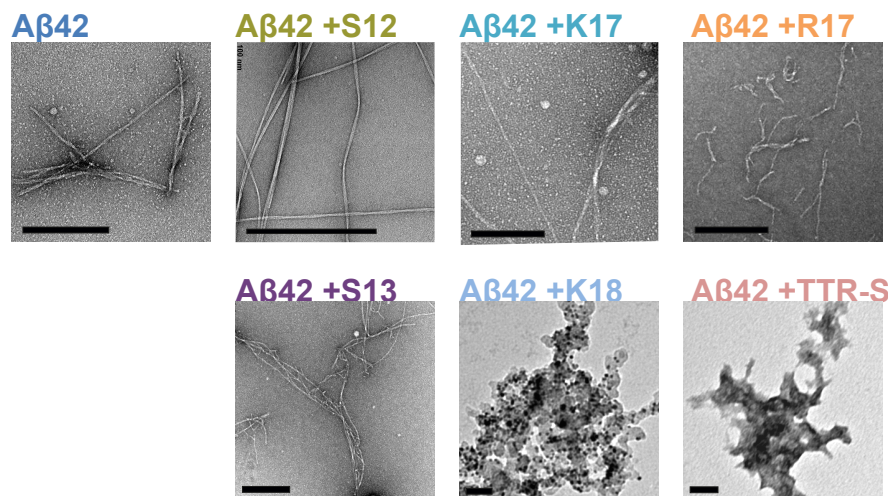

**Figure S2. Evaluation of TTR-derived peptides in the absence of A $\beta$ 42.** **(A)** Propensities of steric zipper formation of each 6-residue segment within the TTR sequence. Computationally predicted segments with steric zipper propensities are represented with *red bars*. The segment identified from docking modeling is marked with a red bracket. **(B)** Electron micrographs of TTR-derived peptides after 26 hours of incubation at 37°C. Scale bar, 200 nm.
