ABSTRACT

MicroRNA (miRNA)-based therapies are an emerging class of targeted therapeutics with many potential applications. Ewing Sarcoma patients could benefit dramatically from personalized miRNA therapy due to inter-patient heterogeneity and a lack of druggable (to this point) targets. However, because of the broad effects miRNAs may have on different cells and tissues, trials of miRNA therapies have struggled due to severe toxicity and unanticipated immune response. In order to overcome this hurdle, a network science-based approach is well-equipped to evaluate and identify miRNA candidates and combinations of candidates for the repression of key oncogenic targets while avoiding repression of essential housekeeping genes. We first characterized 6 Ewing sarcoma cell lines using mRNA sequencing. We then estimated a measure of tumor state, which we term network potential, based on both the mRNA gene expression and the underlying protein-protein interaction network in the tumor. Next, we ranked mRNA targets based on their contribution to network potential. We then identified miRNAs and combinations of miRNAs that preferentially act to repress mRNA targets with the greatest influence on network potential. Our analysis identified TRIM25, APP, ELAV1, RNF4, and HNRNPL as ideal mRNA targets for Ewing sarcoma therapy. Using predicted miRNA-mRNA target mappings, we identified miR-3613-3p, let-7a-3p, miR-300, miR-424-5p, and let-7b-3p as candidate optimal miRNAs for preferential repression of these targets. Ultimately, our work, as exemplified in the case of Ewing sarcoma, describes a novel pipeline by which personalized miRNA cocktails can be designed to maximally perturb gene networks contributing to cancer progression.

Conflict of Interest Statement: The authors have no conflicts of interest to disclose.

Introduction

Ewing sarcoma is a rare malignancy arising from a gene fusion secondary to rearrangements involving the EWS gene1. There are 200-300 reported cases each year in the United States, disproportionately affecting children2. High levels of inter-tumor heterogeneity are observed among Ewing sarcoma patients despite a shared EWS gene fusion initiating event3. Ewing sarcoma is also extremely prone to developing resistance to available chemotherapeutics4. These features make it an ideal system to develop personalized therapies for resistant tumors or to avoid the development of resistance altogether.

MicroRNA (miRNA)-based therapeutics, including anti-sense oligonucleotides, are an emerging class of cancer therapy5. Recent work has highlighted the critical importance of miRNAs in the development and maintenance of the cancer phenotype5-6. MiRNA dysregulation has been implicated in the development of each of the hallmark features of cancer7, and restoration of expression of some of these critical downregulated miRNAs has been studied as a potential treatment for several different cancers8,9. In particular, in the past decade, anti-sense oligonucleotide inhibitors of the STAT3 transcription factor have shown promise in the settings of lymphoma10,11 and neuroblastoma12. MiR-34 has shown to be effective in pre-clinical studies for treatment of both lung cancer13-15 and prostate cancer16. Finally, miR-34 and let-7 combination therapy has been shown to be effective in pre-clinical studies of lung cancer15.

MiRNAs have been recognized as potential high-value therapeutics in part due to their ability to cause widespread changes in a cell-signaling network5. A single miRNA molecule can bind to and repress multiple mRNA transcripts6,17-19, a property...
that can be exploited when designing therapy to maximally disrupt a cancer cell signaling network. This promiscuity of miRNA binding may also increase the risk of off-target effects and toxicity (Figure 1). For example, miR-34 was effective in pre-clinical studies for the treatment of a variety of solid tumors, only to fail in a phase I clinical trial due to “immune-related serious adverse events”. To capitalize on the promise of miRNA-based cancer therapy while limiting potential toxicity, we developed a systematic, network-based approach to evaluate miRNA cocktails. We focused on miRNA cocktails rather than single miRNA therapeutics due to the potential for miRNA cocktails to minimize toxicity compared to single miRNA regimens (Figure 1).

In this work, we build on previous studies applying thermodynamic measures to cell signaling networks in the field of cancer biology, as well as works that describe a method to use gene homology to map miRNAs to the mRNA transcripts they likely repress. Reitman et al. previously described a metric of cell state analogous to Gibbs free energy that can be calculated using the protein-protein interaction network of human cells and corresponding transcriptomic data. Gibbs free energy has been correlated with a number of cancer-specific outcomes, including cancer grade and patient survival. Additionally, Reitman et al. leveraged Gibbs and other network measures to identify personalized protein targets for therapy in a dataset of low-grade glioma patients from The Cancer Genome Atlas (TCGA). Previous work has also highlighted the critical importance of miRNAs to maintenance and development of the oncogenic phenotype, and demonstrated the utility of applying miRNA-mRNA mappings. In this work, we developed and applied a computational pipeline that leverages these network principles to identify miRNA cocktails for the treatment of Ewing sarcoma.

## 1 Methods

### 1.1 Overview

We characterized six previously described Ewing sarcoma cell lines in triplicate – A673, ES2, EWS502, TC252, TC32, and TC71 – using mRNA sequencing. By evaluating 6 distinct cell lines, we aimed to assess the heterogeneity inherent to Ewing sarcoma. We then defined a measure of tumor state, which we term network potential (Equation 1), based on both mRNA gene expression and the underlying protein-protein interaction (PPI) network. Next, we ranked mRNA targets based on their contribution to network potential of each cell line, aiming to approximate the relative importance of each mRNA to network stability. Relative importance of each mRNA to network stability was determined by calculating the change in network potential of each network before and after in silico repression of each mRNA (ΔG, described in Section 1.5). After identifying these mRNA targets, we then identified miRNA and miRNA cocktails that preferentially acted to repress the most influential of the ranked mRNA targets, with the aim of defining synthetic miRNA-based therapy for down-regulation of these targets. Our computational pipeline is schematized in Figure 2.

### 1.2 Data sources

We utilized two data sources to develop our Ewing sarcoma cell signaling networks: the BioGRID protein-protein interaction database and mRNA expression data from 6 Ewing sarcoma cell lines, which are available on GEO (accession GSE98787). BioGRID The BioGRID interaction database contains curated data detailing known interactions between proteins for a variety of different species, including Homo sapiens. The data were generated by manual curation of the biomedical literature to identify documented interactions between proteins. To assist in manual curation, the BioGRID project uses a natural language
We defined a measure of tumor state, which we term network potential (Equation 1), based on both mRNA gene expression and the underlying protein-protein interaction (PPI) network. Next, we ranked mRNA targets based on their contribution to network potential of each cell line, aiming to approximate the relative importance of each mRNA to network stability. After identifying these mRNA targets, we then identified miRNA and miRNA cocktails that preferentially acted to repress the most influential of the ranked mRNA targets, with the aim of defining synthetic miRNA-based therapy for down-regulation of these targets.

Second, we utilized mRNA expression data from in vitro experiments conducted on six Ewing sarcoma cell lines (3 biological replicates per cell line). RNA/miRNA extraction was performed with a Qiagen kit with on-column DNase digestion. These mRNA and miRNA expression data were then normalized to account for between sample differences in data processing and further adjusted using a regularized log (Rlog) transformation. Notably, methods for calculating network potential from this type of data require protein concentrations rather than mRNA transcript concentrations. For the purposes of this analysis, we assumed that concentration of protein in an Ewing sarcoma tumor was equivalent to the concentration of the relevant mRNA transcript. A large body of work suggests that mRNA levels are the primary driver of protein levels in a cell under steady state conditions (i.e. not undergoing proliferation, response to stress, differentiation etc). However, recent work in a 375 cancer cell lines has shown that mRNA expression may not be predictive of protein expression in the setting of malignancy. For this reason, we included the protein-mRNA correlations from their experiments.
alongside some of our key findings to provide needed context.

1.3 Network development
We first developed a generic network to represent human cell signaling networks using the BioGRID interaction database\(^{25}\). The BioGRID protein-protein interaction network can be downloaded as a non-linear data structure containing ordered pairs of proteins and all the other proteins with which they interact. This data structure can be represented as an undirected graph, with vertex set \(V\), where each vertex represents a protein, and edge set \((E)\) describes the interactions between proteins.

Using RNA sequencing data from 6 Ewing sarcoma cell lines in triplicate, we then ascribed mRNA transcript concentration for each gene as an attribute to represent the protein concentration for each node in the graph. Through this process, we developed networks specific to each cell line and replicate in our study (18 total samples).

1.4 Network potential calculation
Using the cell signaling network with attached cell line and replicate number specific normalized mRNA expression data, we defined a measure of tumor state following Reitman et al.\(^{21}\), which we term network potential. We first calculate the network potential of the \(i\)-th node in the graph:

\[
G_i = C_i \ln \left[ \frac{C_i}{\sum_j C_j + C_i} \right],
\]

where \(G_i\) is equal to the network potential of an individual node of the graph, \(C_i\) is equal to the concentration of protein corresponding to node \(G_i\), and \(C_j\) is the concentration of protein of the \(j\)-th neighbor of \(G_i\). Total network potential \((G)\) of the network can then be calculated as the sum over all nodes:

\[
G = \sum_i G_i.
\]

where \(G\) is equal to the total network potential for each biological replicate of a given cell line. We then compared total network potential across cell lines and biological replicates.

1.5 Ranking of protein targets
After calculating network potential for each node and the full network, we simulated "repression" of every node in each network by reducing their expression (computationally) to zero, individually\(^{33}\). Clinically, this would be akin to the application of a drug that perfectly inhibited the protein/mRNA of interest. Next, we re-calculated network potential for the full network and calculated the change in network potential \((\Delta G)\) by subtracting the new network potential value for the network potential value of the "unrepressed" network. We then ranked each node in the network according to the change in network potential for further analysis. Our pipeline was designed to make use of parallel computing on the high-performance cluster (HPC) at Case Western Reserve University in order to complete these analyses.

1.6 Identification of miRNA cocktails
To generate miRNA-mRNA mappings, we implemented a protocol described previously\(^{34}\). Briefly, we identified all predicted miRNA targets for each miRNA in our dataset using the miRNAAtap database in R, version 1.18.0, as implemented through the Bioconductor targetscan org.Hs.es.db package, version 3.8.2\(^{17}\). We used all five possible databases (default settings): DIANA version 5.061\(^{19}\), Miranda 2010 release\(^{62}\), PicTar 2005 release\(^{63}\), TargetScan 7.164\(^{37}\) and miRDB 5.065\(^{18}\), with a minimum source number of 2, and the union of all targets found was taken as the set of targets for a given miRNA. Through this mapping, we identified a list of mRNA transcripts that are predicted to be repressed by a given miRNA. Our code and processed data files are available on Github at: https://github.com/DavisWeaver/MiR_Combo_Targeting/.

Using this mapping, as well as our ranked list of promising gene candidates for repression from our network analysis, we were able to identify a list of miRNA that we predict would maximally disrupt the Ewing sarcoma cell signaling network when introduced synthetically. To rank miRNA targets, we first identified all the genes on the full target list that a given miRNA was predicted to repress (described in Section 1.5). Next, we summed the predicted \(\Delta G\) when each of these genes was repressed \textit{in silico} to generate the maximum potential disruption that could be achieved if a given miRNA were introduced synthetically into an Ewing sarcoma tumor. We then ranked miRNA candidates in descending order of the maximum predicted network disruption (Figure 6).

Given the documented cases of systemic toxicities associated with miRNA-based therapies, the miRNA that inhibits the most targets might not necessarily be the best drug target. We therefore sought to identify combinations of miRNAs that
individually repressed key drug targets, while avoiding repression of housekeeping genes that may lead to toxicity. We defined housekeeping genes using a previously described gene set. In this study, housekeeping genes were identified by evaluating RNA sequencing data from a large number of normal tissue samples. Genes that are consistently expressed in all or nearly all tissue types were assumed to be so-called housekeeping genes. Our hypothesis is that by giving a cocktail of miRNAs with predicted activity against one or multiple identified drug targets, each individual miRNA could be given at a low dose such that only the mRNA transcripts that are targeted by multiple miRNAs in the cocktail are affected (Figure 1).

We first transformed the projected change in network potential for each gene such that housekeeping genes exerted a positive change in network potential and the top 10 predicted targets exerted a negative change in network potential. We then ranked 3-miRNA combinations according to their projected effect on network potential, where more negative changes in network potential were interpreted as more effective for maximizing on-target effects while minimizing off-target effects. As a further constraint, a gene had to be targeted by 2 or more miRNAs in a given cocktail to be considered repressed. Each miRNA was assumed to downregulate a given gene by 20%, such that genes targeted by 2 miRs were assumed to have their expression decreased by 40%, and genes targeted by 3 miRs were assumed to have their expression decreased by 60%. We repeated our analysis, varying between 10% and 50% repression to assess the impact of this assumption on our predicted miRNA cocktails. Rather than evaluate every potential 3-miRNA combination, we limited our analysis to miRNA that target at least 2 of our 10 target genes. We repeated this analysis to identify cocktails that target larger or smaller groups of mRNA (the top 5 or 15 mRNA targets) in order to assess the stability of the predicted cocktail to changing conditions.

2 Results

2.1 Network Overview

We calculated the network potential, a unitless measure of cell state, for each protein in the cell signaling networks for each of the six Ewing sarcoma cell lines in our experiment. An overview of the total network potential for each cell line and evolutionary replicate compared to total mRNA expression is presented in Figure 3. The histograms of network potential and mRNA expression demonstrate markedly different distributions (Figure 3A and Figure 3B), indicating that network potential describes different features of a cell signaling network compared to mRNA expression alone. Notably, network potential and mRNA expression for these cell lines are stable across different biological replicates, as demonstrated by the low interquartile range (Figure 3C and 3D). There were larger differences in both mean expression and network potential across cell lines (Figure 3C and 3D) when compared to between-replicate differences. The global average network potential across all samples was $-3.4 \times 10^5$ with a standard deviation of 1605.

2.2 Identification of Protein Targets

We identified TRIM25, APP, ELAV1, RNF4, and HNRNNPL as top 5 targets for therapy for each of the 6 cell lines based on the degree of network disruption induced following in silico repression of each gene. There was a high degree of concordance between cell lines among the top predicted targets, indicating that these targets may be conserved across Ewing sarcoma (Table S1). Of the top ten predicted targets, all 10 targets are conserved for all 6 cell lines. The top 50 protein targets are presented in Figure 4. Some of these identified genes may be essential housekeeping genes highly expressed in all or most cells in the body, making them inappropriate drug targets. TRIM25, and ELAV1, for example, are involved in protein modification and RNA binding, respectively. We therefore repeated this analysis, limiting our search to gene targets that have been causally implicated in cancer. With this limitation in place, we identified XPO1, LMNA, EWSR1, HSP90AA1, and CUL3 as the top 5 targets for therapy when $\Delta G$ was averaged for all cell lines. The top 10 cancer-related targets for each cell line can be found in (Table S2). The top 50 protein targets (limited to those causally implicated in cancer) can be found in Figure S1.

We also conducted gene set enrichment analysis for the all the genes represented in our cell signaling network (averaged across all samples). We ranked genes by network potential (averaged across all samples) and compared our gene set to the “hallmarks” pathways set, downloaded from the Molecular Signatures Database (MSigDB). This analysis was conducted using the gSEA package in R, which uses the Benjamini - Hochberg procedure to correct the false discovery rate. Our gene set was enriched (adjusted p-value < 0.05) in 24 of the 50 pathways included in the hallmarks set; including apoptosis, DNA repair, mTOR signaling, MYC signaling, and WNT $\beta$-catenin signaling. Our gene set was also highly enriched (normalized enrichment score = 1.73) in the miRNA bio-genesis pathway. The full results are presented in Table S3.

2.3 Identification of miRNA Cocktails

We identified several miRNAs that were predicted to dramatically disrupt the Ewing sarcoma cell signaling network (Figure 6). When averaging all cell lines, we identified miR-3613-3p, let-7a-3p, miR-300, miR-424-5p, and let-7b-3p as the ideal miRs for preferential repression of proteins predicted to be important for Ewing sarcoma signaling network stability. miR-3613-3p, let-7a-3p, miR-300, miR-424-5p, and let-7b-3p were predicted to cause an average network network potential increase (driving the system less negative) of 17382, 13034, 12746, 12364 and 12280, respectively (see Figure 6). It should also be noted that we
Figure 3. Network potential describes different features of a cell signaling network compared to mRNA expression alone. 

Panel A: Histogram of mRNA expression for each gene (averaged across all samples). Panel B: Histogram of the network potential for each gene (averaged across all samples) mRNA transcripts with an expression level of zero were excluded from both histograms to better visualize the distribution of genes that are expressed. Panel C: Box plot showing the total mRNA expression for each cell line. Panel D: Box plot showing the total network potential for each cell line.

were able to identify a substantial number of miRNAs with potential activity against the Ewing sarcoma cell signaling network. We identified 27 miRNAs with an average predicted network potential disruption of greater than 10,000. For comparison, the largest network change in network potential that could be achieved with a single gene repression across all cell lines was just 2064 (TRIM25).

These individual miRNAs target large numbers of transcripts in the cell and therefore may be difficult to administer as single-agents due to extreme toxicity. For example, the top miR candidate, miR-3613-3p, was predicted to repress 144 distinct mRNA transcripts in the full target set. We therefore sought to identify cocktails of miRNA that could cooperatively down-regulate key non-housekeeping genes while avoiding cooperative down-regulation of housekeeping genes that may be associated with toxicity. When targeting the top 10 predicted proteins from our in silico repression experiments, a 3 miRNA cocktail of miR-483-3p, miR-379-3p, and miR-345-5p was predicted to be the most optimal across all cell lines (Figure 5A and Figure 5B). Under the same conditions, a 3-miR cocktail of miR-300, let-7b-3p, and let-7a-3p was predicted to be the least optimal among 16,215 tested combinations (Figure 5C and Figure 5D). Notably, the most and least optimal miRNA combinations had similar activity against the 10 targets (Figure 5A and Figure 5C). The worst cocktail was defined by high levels of cooperative downregulation of housekeeping genes rather than lack of efficacy against putative targets (Figure 5C and Figure 5D). Let-7b-3p and let-7a-3p were heavily represented in the least optimal cocktails tested, appearing in 10 of the 10 worst 3 miRNA cocktails (Figure 5E). These highly promiscuous miRNA target large numbers of housekeeping genes, limiting their therapeutic utility alone or in combination (Figure 6B).

Notably, many of the most promising miRNA when considering only their total predicted network disruption tend to appear
in the least optimal cocktails (Figure 6). This likely occurs because these miRNA tend to target large numbers of housekeeping genes and large numbers of genes overall. In contrast, the best miRNA cocktails tend to be composed of miRNA that target relatively few genes overall but exhibit some degree of target specificity. Put another way, they target the desired target genes while repressing relatively few essential housekeeping genes. An extreme example of this is the case of miR-345-5p. MiR-345-3p is in the bottom 50% of all miRNA when ranked by predicted network disruption, and is only predicted to repress 10 different transcripts. However, because it selectively targets several of our targets of interest, this relative small total projected network disruption is actually an attractive feature that makes it easy to build effective cocktails that include miR-345-3p. As a result, miR-345-3p appears in 8 of the top 10 predicted 3 miRNA cocktails. To assess the stability of our results, we repeated this analysis, focusing on the top 5 or top 15 predicted protein targets. We also repeated this analysis, assuming 10% and 50% repression per miRNA that target a given mRNA. The top and bottom predicted cocktails were similar across these conditions and across all six cell lines. We have included the full ranked list of all miRNA cocktails tested across all conditions on Github.

3 Discussion

In this work, we described a novel methodology for the identification of potential miRNA cocktails for Ewing sarcoma therapy. First, we performed mRNA sequencing on six Ewing sarcoma cell lines (GEO accession GSE98787). We then defined a metric of cell state, network potential, based on mRNA expression and signaling network topology. Using in silico repression and change in network potential, we identified the most important proteins in the cell signaling network for each of the 6 cell lines. Notably, this set of proteins was enriched in 24 of the 50 pathways included in the “halmarks” gene set. The ranked protein set was also enriched for genes involved in the canonical miRNA biogenesis pathway. We then evaluated more than 16000 3-miRNA cocktails (per cell line) based on predicted ability to disrupt key proteins in the Ewing Sarcoma cell signaling network while avoiding cooperative down-regulation of essential housekeeping genes. We ranked these 3-miRNA cocktails to identify promising miRNA combinations for therapy of Ewing Sarcoma.

The protein targets and miRNA candidates we identified in our dataset are consistent with the literature on Ewing sarcoma and cancer cell signaling, suggesting biological plausibility of our methodology. Of the top 50 protein targets that we identified, Figure 4. TRIM25, APP, ELAVL1, AND RNF4, and XPO1 are the top protein targets ranked by predicted disruption following in silico repression. Panel A: Box and whisker plot describing the change in network potential following in silico repression for each of the top 50 proteins. It is notable that EWSR1, the kinase associated with Ewing sarcoma development, is considered highly influential in the cell signaling network by this method. Genes that have previously been causally implicated in cancer according to the Cosmic database are highlighted in red. Essential housekeeping genes (excluding those that are causally implicated in cancer) are highlighted in blue. The heatmap on the x-axis corresponds to the protein-mRNA correlation of each gene in the Cancer Cell Line Encyclopedia. Panel B: Histogram depicting the distribution of Pearson correlation between mRNA expression and protein expression from the Cancer Cell Line Encyclopedia for all nodes included in our final Ewing sarcoma cell signaling networks. Proteins that were ranked particularly highly in panel A were labeled in panel B.
15 were previously causally implicated in cancer\textsuperscript{40}, including EWSR1, the proposed driver of Ewing sarcoma development. In addition, our network-based approach suggests that known oncogenic hub genes such as KRAS and MYC are prime targets for disruption in cancer cells.

In addition, many of the miRNA we identified as potential therapeutic candidates have been previously studied due to their association with cancer outcomes, including members of the let-7 family, miR-300, miR-424-5p, miR-4282, miR-15a-5p, and miR-590-3p. Loss of expression of the let-7 family of miRNA has been widely implicated in cancer development\textsuperscript{45–48}. In Ewing sarcoma specifically, low levels of let-7 family miRNA have been correlated with disease progression or recurrence\textsuperscript{45}. The let-7 family of miRNA have also been studied as treatment for non-small cell lung cancer in the pre-clinical setting\textsuperscript{15}. Loss of miR-300 has been previously correlated with development and aggressiveness of hepatocellular carcinoma\textsuperscript{49} as well as in oncogenesis of pituitary tumors\textsuperscript{50}. Reduced expression of miR-424-5p and miR-4282 have each been implicated in the development of basal-like breast cancer\textsuperscript{51,52}. MiR-15a-5p has been shown to have anti-melanoma activity\textsuperscript{53}. In addition, miR-590-3p has been shown to suppress proliferation of both breast cancer\textsuperscript{54}, and hepatocellular carcinoma\textsuperscript{55}. The broad literature linking many of our proposed miRNA candidates for Ewing sarcoma treatment to the development and maintenance of cancer highlights the ability of our computational pipeline to identify potentially promising therapeutic candidates in this setting. Prior to application of these findings for treatment of Ewing sarcoma or any other disease, specific \textit{in vitro} and \textit{in vivo} validation is needed.

The process by which putative miRNA targets were selected was based on sequence homology rather than direct experimental validation. As a result, it is possible that we included false positive miRNA targets in our analysis. For this study we relied on a protein-protein interaction network presumably curated from analyzing normal human cells. It is possible that the derangements observed in cancer cells could change the underlying interaction network of a tumor cell. In the future, it may be possible to utilize protein-protein interaction networks specific to cancer or even specific to the cancer type under study. We also used mRNA concentration as a surrogate for protein concentration in designing our cell signaling network. While this is not true in all cases, it is likely a reasonable approximation under steady state conditions\textsuperscript{28–31} (see Section 1.2 for more details). In addition, protein-mRNA correlations in the cancer cell line atlas for the top proteins identified by our pipeline were fairly good, ranging from 0.07 to 0.8 for the top 50 identified protein targets\textsuperscript{32} (Fig S1).

Despite these limitations, our findings may facilitate the development of novel therapies for patients suffering from Ewing Sarcoma. To this point, severe toxicity has limited the translation of miRNA-based cancer therapies to the clinical setting. Our pipeline may enable the development of better miRNA therapies that clear this hurdle and open up this promising avenue of therapy for patients suffering from cancer. In addition, this novel method can facilitate the rapid identification of key proteins in any cancer cell signaling network for which mRNA sequencing data is available. This may facilitate more rapid drug discovery and assist in the discovery of proteins and miRNA that play a significant role in the cancer disease process.

3.1 Additional Analyses
As described in the main text, we ranked proteins according to their contribution to network stability by calculating the change in network potential following complete in silico repression of each protein. In the main text, we limited our analysis to proteins that had been causally implicated in cancer according to the cosmic database. Here, we present the top 50 proteins (when network potential for all 6 cell lines was averaged) ranked by contribution to network stability, not limited to proteins that were causally implicated in cancer (Figure 4).

Figure S1. Protein targets ranked by contribution to network stability. When averaging across cell lines, XPO1, LMNA, EWSR1, HSP90AA1, and CUL3 were identified as the most important proteins in the Ewing sarcoma cell signaling network (when limiting our analysis to proteins causally implicated in cancer). When each protein was simulated as completely repressed in silico, network potential was increased by 654, 456, 429, 425, and 399, respectively. The heatmap at the bottom of the plot describes the protein-mRNA correlation for each gene in the cancer cell line atlas. Grey indicates no data was available. It is reassuring that EWSR1, the kinase associated with Ewing sarcoma development, is identified as highly influential in the cell signaling network by this method.

We also analyzed each cell line individually to identify the top protein targets for each cell line. In the main text, we limited this analysis to proteins that had been causally implicated in cancer. Here, we present the top protein targets for each cell line, not limited to those proteins that had previously been causally implicated in cancer (Table S1).

Gene set enrichment analysis We conducted gene set enrichment analysis, using all genes in our Ewing sarcoma cell signaling network as the gene set. We ranked this set of genes by change in network potential and used the “hallmarks” pathways set from the Molecular Signatures Database as the genomic background. We also included a gene set corresponding to the miRNA biogenesis pathway. We used the “fgsea” R package version 1.8.0 to conduct the analysis using the following settings: nperm = 500, minSize = 1, maxSize = ∞, nproc = 0, gseaParam = 1, BPPARAM = NULL. We found our gene set to be significantly enriched in several pathways related to oncogenesis, including DNA repair, apoptosis, and MTOR signaling (Table S3). These results indicate that network potential can identify a cancer-specific signal from mRNA expression data.
Table S1. Top protein targets for each cell line. We ranked potential targets by predicted change in network potential when each protein was modeled as repressed.

**Table S3.** Genes ranked by network potential are enriched for several biological pathways related to cancer as well as the miRNA bio-genesis pathway. Pathways with an adjusted p-value < 0.05 are shown above. “ES” refers to enrichment score and “NES” refers to the normalized enrichment score. “nMoreExtreme” refers to the number of random gene sets (out of 500) that were more enriched than the test set. Size refers to the number of genes in the pathway that were also present in our mRNA expression dataset.
