#### 15 Abstract

16 Organisms that live in deserts offer the opportunity to investigate how species adapt to environmental 17 conditions that are lethal to most plants and animals. In the hot deserts of North America, high temperatures and lack of water are conspicuous challenges for organisms living there. The cactus mouse 18 19 (*Peromyscus eremicus*) displays several adaptations to these conditions, including low metabolic rate, 20 heat tolerance, and the ability to maintain homeostasis under extreme dehydration. To investigate the 21 genomic basis of desert adaptation in cactus mice, we built a chromosome-level genome assembly and 22 resequenced 26 additional cactus mouse genomes from two locations in southern California (USA). Using 23 these data, we integrated comparative, population, and functional genomic approaches. We identified 16 24 gene families exhibiting significant contractions or expansions in the cactus mouse compared to 17 other 25 Myodontine rodent genomes, and found 232 sites across the genome associated with selective sweeps. 26 Functional annotations of candidate gene families and selective sweeps revealed a pervasive signature of 27 selection at genes involved in the synthesis and degradation of proteins, consistent with the evolution of 28 cellular mechanisms to cope with protein denaturation caused by thermal and hyperosmotic stress. Other 29 strong candidate genes included receptors for bitter taste, suggesting a dietary shift towards chemically 30 defended desert plants and insects, and a growth factor involved in lipid metabolism, potentially involved in prevention of dehydration. Understanding how species adapted to the recent emergence of deserts in 31 North America will provide an important foundation for predicting future evolutionary responses to 32 33 increasing temperatures, droughts and desertification in the cactus mouse and other species.

### 34 Introduction

35 For decades, researchers have been intrigued by adaptation, or the process by which organisms become 36 better fitted to their environments. To this end, scientists have devoted substantial efforts to this issue and 37 have successfully elucidated how natural selection has shaped organismal phenotypes in response to 38 environmental pressures (Berner and Salzburger, 2015; Cooke et al., 2013; Linnen et al., 2009; Nachman 39 et al., 2003; Savolainen et al., 2013). Given their influence on metabolism, water availability and ambient 40 temperature are environmental factors relevant to all organisms and are also of growing concern within 41 the context of anthropogenically-induced global climate change and increasing desertification (IPCC, 42 2018). Studying how animals that are currently living in hot and dry environments have adapted to those 43 conditions is one approach for helping to predict the potential impacts of increasing temperatures and 44 aridity (Hoelzel, 2010; Somero, 2010). 45 Despite the challenging conditions, a wide variety of organisms have evolved adaptations to live in hot deserts. These adaptations include changes in behavior to avoid dehydration, excessive solar 46 47 radiation, and heat (e.g., nocturnal life and sheltering in burrows) and a suite of anatomical modifications 48 to dissipate heat (e.g., long body parts and pale colors). Some of the most striking adaptations are at the 49 physiological level and help to either minimize water loss through efficient excretion and reabsorption of water (Schmidt-Nielsen, 1964; Schmidt-Nielsen and Schmidt-Nielsen, 1952) or compensate for lack of 50 51 environmental water via enhanced production of metabolic water from nutrient oxidation (Takei et al., 52 2012; Walsberg, 2000). While these adaptations to desert life have been described in several species (for a 53 review on small mammals see Walsberg, 2000) and are important under current climate predictions 54 (IPCC, 2018), the genetic underpinnings of these traits are less well known. Genomic studies on camels (*Camelus bactrianus*) have provided substantial evidence related to 55 the genomic basis of adaptation to deserts. For example, analysis of the camel genome showed an 56

57 enrichment of fast-evolving genes involved in lipid and carbohydrate metabolism, potentially linked to

58	energy production and storage in a food-scarce environment (Bactrian Camels Genome Sequencing and
59	Analysis Consortium et al., 2012; Wu et al., 2014). Transcriptome analysis of renal cortex and medulla in
60	control and water-restricted camels showed a strong response to dehydration in genes involved in water
61	reabsorption and glucose metabolism (Wu et al., 2014). Overall, genes in the arachidonic acid pathway
62	seem to play a role in desert adaptation in both camels and desert sheep (Bactrian Camels Genome
63	Sequencing and Analysis Consortium et al., 2012; Yang et al., 2016). This pathway regulates water
64	retention and reabsorption in the kidney, primarily through changes in reno-vascular tone. Aquaporins,
65	transmembrane water channel proteins, are also involved in water reabsorption and urine concentration,
66	and changes in their expression levels have been associated with dry environments in kangaroo rats
67	(Marra et al., 2014, 2012) and the Patagonian olive mouse (Giorello et al., 2018).
68	The cactus mouse (Peromyscus eremicus) is native to the deserts of southwestern North America
69	and displays a suite of adaptations to this extreme environment. Cactus mice have behavioral and
70	anatomical adaptations for heat avoidance and dissipation, such as a nocturnal lifestyle, larger ears, and
71	aestivation (Macmillen, 1965). They have also evolved lower metabolic rates, which result in a reduction
72	in water loss, and resistance to heat stress compared to other generalist Peromyscus spp. (Murie, 1961).
73	For example, while several desert rodents produce concentrated urine (Schmidt-Nielsen, 1964;
74	Schmidt-Nielsen and Schmidt-Nielsen, 1952), the cactus mouse is essentially anuric (Kordonowy et al.,
75	2017), which indicates its extreme efficiency of renal water reabsorption. Kordonowy et al. (2017)
76	showed through experimental manipulation of water availability that captive cactus mice were
77	behaviorally and physiologically intact after three days of severe acute dehydration. Gene expression
78	profiling of kidneys highlighted a starvation-like response at the cellular level in dehydrated mice, despite
79	access to food, and strong differential expression of Cyp4 genes, which are part of the arachidonic acid
80	metabolism pathway (MacManes, 2017). Although these results indicate some degree of convergent
81	evolution with other desert-adapted mammals (Bactrian Camels Genome Sequencing and Analysis

Consortium et al., 2012; Takei et al., 2012; Yang et al., 2016), they are limited to expressed genes under
particular experimental conditions and in one tissue type only.

84 Deserts in southwest North America formed relatively recently, only after the retreat of the Pleistocene ice sheets that covered most of the continent during the Last Glacial Maximum approximately 85 86 10,000 years ago (Pavlik, 2008). Because the ability to detect genomic signatures of selection depends on 87 coalescent time and effective population size (Nielsen et al., 2005), and given the recent emergence of 88 North American deserts, the footprint of these recent adaptations should continue to be evident in 89 contemporary cactus mouse genomes. Whole genome analyses allow us to detect signatures of selection 90 associated with life in the desert across the complete set of cactus mouse genes, regardless of expression 91 patterns. Further, they allow for analysis of intergenic areas, and for characterization of genomic features 92 that may promote or hinder adaptive evolution, such as the distribution of standing genetic variation and 93 repetitive elements.

94 To identify genes associated with desert adaptation and to investigate the factors affecting 95 adaptation using the cactus mouse as a model, we first generated a chromosome-level genome assembly 96 and then integrated comparative, population, and functional genomics approaches. As dehydration is a 97 primary challenge desert animals face, we expected to identify signatures of selection associated with metabolism and sodium-water balance (i.e. adaptations that either enhance production of metabolic water 98 or prevent fluid loss via excretion) in line with previous studies in the cactus mouse and other 99 100 desert-adapted species (Bactrian Camels Genome Sequencing and Analysis Consortium et al., 2012; 101 Giorello et al., 2018; Marra et al., 2014; Takei et al., 2012; Wu et al., 2014; Yang et al., 2016). Our 102 analyses of gene family evolution and selective sweeps point instead to regulation of protein synthesis 103 and degradation as the main target of selection. While we find strong support for an evolutionary response 104 in perception of bitter taste and lipid metabolism, we do not identify an extensive signal of selection at 105 genes linked to water-sodium balance at the whole-genome level.

#### 106 **Results**

#### 107 *Genome assembly and annotation*

- 108 Illumina and PacBio reads yielded a draft genome assembly of 2.7 Gb and an N50 of 1.3 Mb. Scaffolding
- 109 with Hi-C data increased contiguity 100-fold and yielded 24 chromosome-sized scaffolds for a total
- assembly size of 2.5 Gb, plus 173 Mb of unplaced scaffolds. The final assembly contained 92.9%
- 111 complete BUSCOs, with 1.2% of the genes duplicated and 3.7% missing. Together these statistics
- indicate that the cactus mouse genome assembly is highly contiguous, complete and non-redundant (Table
- 113

2).

- 114 Whole genome alignment to the *P. maniculatus* genome revealed the presence of several
- intrachromosomal differences between the two species, but no large inversions, translocations, or
- 116 interchromosomal rearrangements were evident at the resolution granted by *mummer4* (Supplementary
- 117 Figure 1). This, in combination with a conserved number of chromosomes supported by both karyotype
- characterization (Smalec et al., 2019) and genome assemblies, indicates that genome structure is highly
- 119 conserved between these *Peromyscus* species.
- 120 We annotated 18,111 protein-coding genes. *Repeatmasker* masked 35% of the genome as
- repetitive. LINE1 and LTR elements alone constituted 21% of the repeats. Total proportion of repeats and
- 122 relative proportion of different repeats classes were similar across eight *Peromyscus* species

123 (Supplementary Table 2).

124

### 125 *Genomic differentiation across space and time*

Our PCA showed that the first two principal components (PCs) explained 13.32% of the variation present across 26 cactus mice. Both the PCA (Supplementary Figure 2) and the MDS (Figure 1A) clearly separated individuals from Motte and Deep Canyon Reserve. Within the Deep Canyon Reserve, no differentiation at the temporal or microspatial scale was observed (Supplementary Figure 2, Figure 1A).

130	One individual from Motte appeared distinct from other individuals included in the analysis. As we could
131	not ascertain the reason for such behavior, e.g., technical artifact, taxonomic misidentification,
132	hybridization, etc., this individual was excluded from further analyses.
133	Differentiation between Motte and Deep Canyon Reserve populations was high, with an average
134	$F_{st}$ value of 0.19 and 0.14 across the 23 autosomes and the X chromosome, respectively. $F_{st}$ calculated in
135	50 kb windows ranged from 0.06 to 0.46 with 95% of the windows ranging from 0.12 and 0.28 (Figure
136	1B).
137	
138	Sequence and structural standing genetic variation
139	A total of 1,875,915,109 variant and invariant sites, representing 75% of the genome, were included in
140	our analyses. We identified 43,695,428 SNPs with high-confidence (one every 43 bp $-2.3\%$ of all sites).
141	Global genome-wide $\pi$ was $6x10^{-3}$ . $\pi$ was lowest on the X chromosome and seemed to increase from
142	chromosome 1 to 23 (Figure 1C). In fact, chromosome length was a strong negative predictor of
143	nucleotide diversity at each autosome ( $R^2 = 0.65$ , $F_{(1,21)} = 39.58$ , p < 0.001; Figure 2).
144	A large area of elevated nucleotide diversity (~17 Mb long) was evident at the beginning of
145	chromosome 1. Conserved synteny with other Peromyscus species and unequivocal support from the
146	Hi-C contact map strongly indicated that the assembly was correct for chromosome 1. To begin to
147	understand the genome-level processes that may have generated this pattern, we calculated depth of
148	coverage in chromosomes 1 and 2 - a reference chromosome that did not show similar large regions of
149	elevated $\pi$ - using a subset of the shotgun data and the number and proportion of repetitive elements in 50
150	kb windows (Supplementary Figure 3). Depth of sequencing in this unusual area of chromosome 1 was
151	higher than in the rest of chromosome 1 (up to 7x higher) and compared to chromosome 2 (10% higher
152	overall), and showed a similar peak as the one shown for nucleotide diversity (Supplementary Figure 3).
153	The number and proportion of repetitive elements were both higher in this area relative to other parts of

154	chromosome 1, and all of chromosome 2 (Supplementary Figure 3). Together, these analyses suggest that
155	this area is highly repetitive, rather than containing a misassembled large duplication.
156	Analysis of the 10x Genomics data using LongRanger resulted in an estimated mean DNA
157	molecule length of only 13,620 bp (ideal is $>$ 40,000 bp), and the number of linked reads per molecule
158	was six, much lower than the ideal threshold of 13. As short molecules can negatively impact the
159	detection of large structural variants and generate many false positives, we adopted a conservative
160	approach by reporting only short indels (41-29,527 bp). We identified a total of 87,640 indels between the
161	reference and an individual from the same population. Indels affected 101 Mb of the total genome
162	assembly, which represents 4% of the total sequence. Number of indels per chromosome was strongly
163	positively correlated with chromosome size ( $R^2 = 0.95$ , $F_{(1,21)} = 438.7$ , p < 0.001; Figure 2).
164	
165	Gene family evolution
166	Orthofinder2 grouped protein sequences from 18 Myodontine rodents into a total of 23,020 orthogroups.
167	After removing orthogroups with either high or no variation in the number of genes across species, the
168	dataset was reduced to 21,347 orthogroups. On average, all species included in our analysis showed gene
169	family contraction, albeit of varying magnitude. Mus musculus had the highest number of significant
170	changes (p < 0.01) in gene family size (92 orthogroups), while <i>Dipodomys ordii</i> had no significant
171	changes (Figure 3). The number of gene families with significant contractions or expansions varied
172	between 16 and 24 among Peromyscus species, with more expansions than contractions except in the
173	cactus mouse, which exhibited four gene family expansions and 12 contractions (Figure 3). Four of these
174	gene families contained genes associated with sperm motility, four included ribosomal proteins, three
175	were associated with immune response, and two included genes in the ubiquitin-like (ubl) conjugation
176	pathway. Other functions included pheromone reception, cytoskeletal protein binding, and prohibitin (one
177	gene family each).

178

### 179 *Identification of selective sweeps*

180 Analysis of the signatures of selective sweeps yielded a total of 232 sites under selection. Of these, 119 181 clustered in 44 larger regions that included two or more adjacent CLR outliers (Supplementary Figure 4). 182 By retrieving the genes closest to each peak (one in both up- and down-stream directions), we compiled a 183 list of 186 genes associated with selective sweeps (Supplementary Table 3). Fourteen of these genes, 184 including many putative olfactory and vomeronasal receptors, were not matched with a corresponding GO 185 term. Ribosomes were overrepresented among 'cellular components', with eight GO terms pointing to 186 this organelle (p < 0.001, after Bonferroni correction). In addition to this, 279 biological processes and 89 187 molecular functions were significantly overrepresented (before correction for multiple tests; full list in 188 Supplementary Table 4 and 5, respectively). GO terms clustering in *REVIGO* showed that terms with the 189 lowest p-values under 'biological processes' included 'membrane organization', 'cellular amide 190 metabolism process', 'translation', 'ribosome assembly', and 'detection of chemical stimulus involved in 191 sensory perception of bitter taste' (Figure 4, Supplementary Table 3); while under 'molecular functions' 192 they included 'structural constituent of ribosome', 'binding', 'olfactory receptor binding', and 'mRNA 193 binding' (Figure 4, Supplementary Table 4). Contrary to predictions, mean  $\pi$  and Tajima's D were significantly higher across the candidate 194 195 areas for selective sweeps when compared to genome-wide means (Wilcoxon test, p < 0.001 for both  $\pi$ 

and Tajima's D; Figure 5). Among the candidate genes from previous studies, 8 (all *Cvp4* genes, *SLC8A1*,

and *aqp4*, *aqp5*, *aqp8*, and *aqp12*) and 6 genes (the *Cyp4a* gene cluster, *Cyp4v2*, *SLC8A1*, and *aqp5*,

198 *aqp9*, and *aqp12*) showed significant deviations from genome-wide average in  $\pi$  and Tajima's D,

- respectively (p < 0.05 after Benjamini-Yekutieli correction for multiple testing), but not always in the
- 200 predicted direction (Supplementary Figure 5). Among the *Cyp4* genes, *Cyp4f* showed a modest decrease

201	in $\pi$ ; among aquaporins, <i>aqp8</i> showed a decrease in $\pi$ , and <i>aqp9</i> showed a decrease in Tajima's D; and
202	<i>SLC8a1</i> showed the greatest reduction in $\pi$ and Tajima's D overall (Supplementary Figure 5).
203	Number of sweeps in each chromosome did not correlate with mean $\pi$ (p > 0.05). A correlation
204	with either chromosome size or number of indels ( $p < 0.01$ ) was entirely driven by the outlier behaviour
205	of chromosome 1, and it did not hold when chromosome 1 was removed from the dataset ( $p > 0.05$ ).
206	
207	Discussion
208	A chromosome-level assembly for the cactus mouse
209	A high-quality chromosome-level assembly of the cactus mouse genome allowed us to investigate
210	genomic patterns of variation, differentiation, and other genomic features (i.e. genes, repetitive elements,
211	number and size of chromosomes), and to identify regions of the genome that may be associated with
212	desert adaptations. As the number of publicly available Peromyscus genome assemblies increases (Colella
213	et al., 2019), the cactus mouse genome will provide additional insights into adaptation, speciation and
214	genome evolution when analyzed in a comparative framework. For example, our comparison of the cactus
215	mouse and the deer mouse genomes revealed higher than expected genome stability considering the
216	divergence time between the two species (~9 MYA), and their large effective population sizes and short
217	generation times (Bromham, 2009; Charlesworth, 2009). Our synteny analysis confirms at the sequence
218	level what is reported from karyotype analyses of several Peromyscus spp. (Smalec et al., 2019), i.e. that
219	between P. eremicus and P. maniculatus there is no variation in chromosome number and no
220	interchromosomal rearrangements but abundant intrachromosomal variation. The genome stability among
221	Peromyscus species (Long et al., 2019) is in sharp contrast to the Muridae family (Order Rodentia) among
222	Mus species and the brown rat (Rattus norvegicus), where the number of chromosomes varies
223	dramatically, even within the Mus genus, and large chromosomal rearrangements are abundant (Thybert et
224	al., 2018).

#### 225 High genetic diversity and differentiation

226 Our results indicate that population differentiation between cactus mouse populations inhabiting the 227 Motte and Deep Canyon Reserves in Southern California is high despite being separated by only 90 km. 228 Patterns of differentiation across the genome were high without distinguishable  $F_{sT}$  peaks (Figure 1B). 229 The distribution of allele frequency changes is suggestive of prolonged geographical isolation, which is 230 consistent with the Peninsular Ranges mountains acting as a dispersal barrier. Although this is not 231 surprising given the limited dispersal ability of cactus mice, the close proximity of these two sampling 232 locations suggests that population structure across the species range, which spans more than 2500 km 233 from Nevada (USA) to San Luis Potosì (Mexico), is likely to be strong. Previous analyses based on a 234 single mitochondrial marker split the *P. eremicus* species complex into three species – *P. eva*, *P.* 235 fraterculus and P. merriami – plus West and East P. eremicus clades (Riddle et al., 2000). Our whole 236 genome analyses suggest that population structure could be pronounced even within each *P. eremicus* 237 clade, which warrants further investigation to elucidate the taxonomic status of these species and to reveal 238 potential differences in adaptation to local desert conditions.

239 As standing genetic variation is the main source of adaptive genetic variation (Barrett and 240 Schluter, 2008), characterizing levels and distribution of sequence and structural variation can help understand how and where in the genome adaptations evolve. With more than 43 million high-quality 241 242 SNPs and  $\sim 87,000$  indels, the cactus mouse exhibits high levels of standing genetic variation, which is 243 consistent with large effective population sizes and comparable to what has been reported for the 244 congeneric white-footed mouse (P. leucopus; 42 million SNPs across 26 wild-caught individuals; (Long et 245 al., 2019). While SNPs are the main, and most often the only, type of variation screened in genomic 246 studies of adaptation (Wellenreuther et al., 2019), here we show that small- to mid-sized indels, a type of 247 structural variant, are common and cover  $\sim 4\%$  of the genome. Given that our analysis of structural 248 variation leveraged sequence data from only one individual, the level of standing structural variation in

249 the population is likely much higher. Pezer et al. (2015) found that indels covered  $\sim 2\%$  of an individual 250 wild house mouse (*M. musculus domesticus*) genome compared to a reference genome, likely an 251 underestimation considering that the analysis was based on variation of read depth only. The full 252 characterization of standing genetic variation in a wild fish showed that levels of structural variation were 253 threefold the levels of sequence variation (SNPs) across 12 individuals sequenced at high coverage 254 (Catanach et al., 2019). To this end, while the inclusion of our high coverage 10X Genomics dataset 255 allowed us to characterize structural variation in a single individual, future work conducted at the 256 population level will allow us to integrate more deeply the role of structural variation in the evolution of 257 desert adaptation in the cactus mouse. 258 Nucleotide variation and number of indels were significantly correlated with chromosome size in

259 the cactus mouse. With increasing chromosome length, sequence variation decreased while the number of 260 indels increased. While a positive, linear relationship between chromosome size and number of indels is expected, a negative correlation between chromosome size and nucleotide diversity may be explained by 261 262 recombination rate, which is higher in shorter chromosomes (Kaback et al., 1992). Chromosome 1 was an 263 outlier compared to the rest of the autosomes in that it was the largest (203 Mb), with the greatest 264 difference from the next largest autosome (26.6 Mb, range 26.6 Mb - 561 Kb), and it had higher nucleotide diversity than expected based on size (i.e. similar to what is expected for much smaller 265 266 chromosomes). The outlier behavior of chromosome 1 could be due to an ancient fusion of two smaller 267 chromosomes demonstrated by syntenic analysis of *Peromyscus leucopus* and *Mus musculus* (Long et al., 268 2019).

Sex chromosomes generally harbor lower nucleotide diversity (Wilson Sayres, 2018) and higher differentiation (Presgraves, 2018) when compared to autosomes due to their reduced effective population size, different mode of inheritance, and their role in the evolution of reproductive barriers. We did observe lower  $\pi$  in comparison to autosomes (45-71% of mean  $\pi$  for each autosome), slightly lower than neutral

273 expectations assuming equal sex ratio (75%). Demographic processes and/or selection could be 274 implicated in this additional reduction, but their relative roles were not tested here. However, contrary to 275 our expectations, analysis of genomic differentiation based on  $F_{sT}$  showed that the X chromosome was less differentiated than the autosomes in the interpopulation comparison. In fact, sex chromosomes are 276 277 more differentiated than autosomes in 95% of the studies for which this information is available 278 (Presgraves, 2018). In two cases regarding mammals, domestic pigs and wild cats, lower differentiation 279 on the X chromosomes was ascribed to hybridization and introgression (Ai et al., 2015; Li et al., 2016). 280 Hybridization has been reported among several *Peromyscus* species (Barko and Feldhamer, 2002; Leo 281 and Millien, 2017), and it represents a viable hypothesis given that the cactus mouse is sympatric with the 282 canyon mouse (Peromyscus crinitus) and numerous other Peromyscus species throughout much of its 283 range. Population genomic data from additional Peromyscus species are necessary to assess how common 284 this pattern is within and across species, to test the hybridization hypothesis, to identify potential donor 285 and recipient species, and to test the potential role of hybridization and introgression in desert adaptation. 286 Neither sequence nor structural variation at the chromosome level was a strong predictor of the 287 number of selective sweeps in a chromosome. However, mean  $\pi$  and Tajima's D were significantly higher 288 in the areas affected by selective sweeps than across the whole genome. Theory predicts that a selective sweep should remove variation from the adaptive site and its surroundings, thus resulting in a localized 289 290 reduction in  $\pi$  and lower Tajima's D relative to the ancestral level of variation (Kim and Stephan, 2002; 291 Smith and Haigh, 1974). However, the signature of a selective sweep, and the ability to detect it, depends 292 on the strength of selection, the recombination rate around the selected site, and whether the sweep is 293 hard, soft, or incomplete (i.e. whether a single or multiple haplotype carries the beneficial allele, or the 294 allele hasn't reached fixation yet; Messer and Neher, 2012). Sweepfinder2 is best suited to detect hard 295 selective sweeps and has limited power to identify soft or incomplete sweeps (DeGiorgio et al., 2016; 296 Huber et al., 2016; Nielsen et al., 2005). Therefore, if we do not observe a general reduction of diversity

297 compared to the genome-wide average around adaptive sites, it could be for one or a combination of the 298 following reasons. a) High recombination rates due to a large effective population size may break up 299 linkage among neighboring sites, thus reducing the size of the typical, diagnostic dip in diversity to a 300 point of non-detectability. b) Due to computational limitations (*Sweepfinder2* is not able to parallelize, 301 leading to long run times) we estimated the CLR of a site every 10 kb, which may not be dense enough to 302 pinpoint the exact location of the sweep and reveal narrow reductions in  $\pi$ . c) If soft sweeps are 303 indistinguishable from hard sweeps when selection is strong (Harris et al., 2018), selective sweeps may 304 preferentially occur in areas of high standing genetic variation. Finally, d) even if a reduction in diversity 305 occurs relative to ancestral levels,  $\pi$  may still not drop under the genome-wide average, especially if 306 diversity was originally high. On chromosome 9, for example, where three consecutive outlier regions 307 extend over 440 kb, the reduction of  $\pi$  and Tajima's D was drastic, suggesting that coarse resolution may 308 prevent the detection of diversity dips around selected sites if the genomic area affected is small. 309

Lost in translation: pervasive signature of selection in genes associated with protein synthesis and
 degradation

312 Together, the analyses of gene family evolution and selective sweeps strongly indicate that traits 313 associated with the synthesis and degradation of proteins have evolved under the influence of natural 314 selection. Four ribosomal protein families are either expanded or contracted, and gene ontology analysis 315 demonstrated an enrichment of terms associated with ribosomes (e.g., ribosome assembly and translation, 316 structural constituents of ribosomes, mRNA binding, and unfolded protein binding). We also report a 317 significant contraction of a gene family associated with the ubl conjugation pathway, which was similarly 318 identified in an analysis of selective sweeps. Ubiquitin and ubl-proteins function either as a tag on 319 damaged proteins to be lysed or as regulators of interactions among proteins (Hochstrasser, 2009). Cactus 320 mice face many stressors including high temperatures and lack of water. Heat causes cellular stress

321 directly, via thermal stress, and indirectly, by exacerbating the negative effects of dehydration due to lack 322 of water and rapid water loss (e.g., respiratory water loss, evaporative cooling). Thermal and 323 hyperosmotic stress can suppress the transcription and translation machinery, increase DNA breaks and 324 protein oxidation, and cause cell cycle arrest, and eventually apoptosis and cell death (Burg et al., 2007; 325 Kampinga, 1993). However, the strongest and most immediate effect of thermal and hyperosmotic stress 326 is protein denaturation (Burg et al., 2007; Kampinga, 1993; Lamitina et al., 2006). Our results are 327 consistent with the expected cellular response to both thermal and hyperosmotic stress, which have 328 similar physiological effects even though the underlying mechanisms may differ. A meta-analysis of 329 genomics and transcriptomics studies investigating the evolutionary response to different thermal 330 environments in metazoans, including invertebrates to mammals, highlighted 'translation', 'structural 331 constituents of ribosomes', and 'ribosome' as the gene ontology terms most commonly enriched (Porcelli 332 et al., 2015), in line with our results. Similarly, many genes mediating the cellular response to 333 hyperosmotic stress are involved in the regulation of protein translation and the elimination of denatured 334 proteins in *Caenorhabditis elegans* (Lamitina et al., 2006). These analyses suggest that selection has acted 335 strongly on genes responsible for protection against thermal and/or hyperosmotic stress or for efficiently 336 removing damaged proteins and resuming translation after acute stress (Kampinga, 1993). Additionally, 337 as the volume of dehydrated cells decreases causing rearrangements in the cytoskeleton (Burg et al., 338 2007), the significant contraction of a cytoskeletal protein gene family could also point to additional 339 adaptations to hyperosmotic stress in the cactus mouse. Acute dehydration experiments on captive cactus 340 mice also found limited tissue damage and apoptosis in the kidneys of dehydrated individuals 341 (MacManes, 2017), consistent with our hypothesis. Negative regulation of cell death was one of the most 342 significant GO terms, suggesting that these genes may be under selection to avoid tissue necrosis during 343 acute or chronic stress.

344

#### 345 *Life in the desert involves dietary and metabolic adaptations*

346 The GO analysis of genes associated with selective sweeps indicated an enrichment for bitter taste 347 receptors. The perception of bitter taste has evolved to allow organisms to avoid toxic compounds found 348 in many plants and insects (Garcia and Hankins, 1975; Glendinning, 1994). Although herbivorous and 349 insectivorous animals generally have a larger repertoire of bitter taste receptors compared to their 350 carnivorous counterparts (Li and Zhang, 2014; Wang and Zhao, 2015), they are also less sensitive to 351 bitterness (Glendinning, 1994). The cactus mouse is omnivorous, with a diet predominantly based on 352 seeds, insects, and green vegetation with proportions varying according to seasonal availability (Bradley 353 and Mauer, 1973; Meserve, 1976). We hypothesize that repeated signal of selective sweeps at bitter taste 354 receptor genes may have increased the frequency of alleles that decrease bitter sensitivity, thus making a 355 greater variety of food palatable to the cactus mouse in an environment that is characterized by scarcity of 356 resources and an abundance of bitter-tasting plants and insects.

357 Chromosome 9 showed the largest and strongest selective sweep in the genome (Supplementary 358 Figure 4). This area was associated with *Gdf10* (growth/differentiation factor 10), the only annotated gene 359 of known function in the region, which is involved in osteogenesis and adipogenesis. Overexpression of 360 *Gdf10* in the adipose tissues of mice prevents weight gain under a high-fat diet and affects their metabolic homeostasis, including oxygen consumption and energy expenditure (Hino et al., 2017). The drastic loss 361 362 of weight and the starvation-like response reported in experimentally dehydrated cactus mice suggests 363 that lipid metabolism has a role in the adaptive response to dehydration (MacManes, 2017). Experimental 364 water deprivation induced higher food consumption and loss of body fat in the spinifex hopping mouse 365 (Notomys alexis), a desert-specialist rodent (Takei et al., 2012). In camels, accelerated evolution of genes associated with lipid metabolism was associated with food scarcity in the desert (Wu et al., 2014). The 366 367 strong signature of selection around Gdf10 in the cactus mouse therefore warrants further investigation, as 368 adaptive changes in lipid metabolism may be pivotal for survival in the desert.

369	Among the candidate genes we selected from previous studies, only SLC8a1 - the sodium carrier
370	gene – show significant reduction in both $\pi$ and Tajima's D, consistent with a selective sweep. However,
371	Cyp4v2 – one of the genes in the arachidonic acid pathway – was in proximity of a selective sweep on
372	chromosome 17. This gene shows similar catalytic properties to other Cyp4 genes in the arachidonic acid
373	pathway and is commonly expressed in retinal, kidney, lung, and liver of humans (Nakano et al., 2009).
374	Known to be strongly associated with ocular disease, its role, however, has not been investigated in the
375	context of water-sodium balance in the kidneys. The discrepancy between the strong changes in gene
376	expression in Cyp4 genes between hydrated and dehydrated mice (MacManes, 2017) and the results
377	presented here suggest that these genes affect kidney physiology predominantly via gene expression and
378	potentially through changes in regulatory regions that we have not targeted explicitly. Future comparative
379	analyses of sequences from additional rodents, including other desert-adapted species, will help us
380	understand the relative role of gene expression regulation versus coding changes in adaptation to desert
381	environments.

382 Comparisons with studies on other desert-adapted mammals highlight a combination of 383 convergent and idiosyncratic adaptations to life in the desert. Although the arachidonic acid pathway 384 showed signatures of selection in camels, sheep, and the cactus mouse (Bactrian Camels Genome 385 Sequencing and Analysis Consortium et al., 2012; MacManes, 2017; Yang et al., 2016), the specific genes 386 involved differed among species and between the mechanisms by which they putatively affected adaptive 387 phenotypes: gene family contractions and expansions in camel, selective sweeps in desert sheep, and 388 changes in gene expression under acute dehydration in the cactus mouse. In addition to the stress imposed 389 by heat and lack of water, comparative genomics analyses suggest that camels have unique adaptations to 390 avoid the deleterious effects of dust ingestion and intense solar radiation (Wu et al., 2014). The cactus 391 mouse avoids solar radiation altogether with a nocturnal lifestyle and shows strong signatures of selection 392 at receptors for bitter taste, consistent with adaptation to a diet based on bitter-tasting desert plants and

393	insects. Desert woodrats (Neotoma lepida) are highly specialized to bitter and toxic plants, such as juniper
394	(Juniperus monosperma) and creosote bush (Larrea tridentata), and have evolved several adaptations to
395	consume them, including detoxifying gut microbiomes (Kohl et al., 2014) and hepatic enzymes (Skopec
396	and Dearing, 2011). Although the repertoire of bitter taste receptors, or their sensitivities to bitter taste,
397	has not been investigated in desert rodents, nor our genomic analyses of cactus mice highlighted
398	detoxification genes, it is evident that many desert species have evolved different strategies to cope with
399	bitter, toxic plants in the absence of more palatable options.
400	

401 Signatures of selection potentially involved in reproductive isolation

402 We reported significant evolutionary changes linked to genes for sperm motility, spermatogenesis, and 403 pheromone reception that may lend support to a role of sexual selection in the evolution of the cactus 404 mouse genome. The comparison of sperm morphology and behaviour in *Peromyscus* species has revealed 405 a link between sperm traits and reproductive strategies. Sperm of the promiseuous *P. maniculatus*, for 406 example, can aggregate on the basis of relatedness, thus increasing motility and providing a competitive 407 advantage against other males, whereas sperm of the monogamous P. polionotus lacks these adaptations 408 (Fisher et al., 2014; Fisher and Hoekstra, 2010). The four gene families associated with sperm motility 409 showed a conspicuous contraction in the cactus mouse when compared to other *Peromyscus* species (9) 410 versus 26, 17 and 21 in *P. leucopus*, *P. maniculatus*, and *P. polionotus*, respectively). Although these 411 results may suggest a correlation between reduction in the number of sperm motility genes and a 412 monogamous reproductive strategy, P. maniculatus also has fewer genes than P. polionotus in these gene 413 families (17 versus 21 in total). Nonetheless, these candidate genes represent interesting targets for future 414 studies on sperm competition within the cactus mouse and among *Peromyscus*. 415

#### 417 *Conclusions*

418 The high-quality assembly of the cactus mouse genome and the candidate genes identified in this study 419 build on the growing body of genomic resources available to further understand the genomic and 420 physiological basis of desert adaptation in the cactus mouse and other species. Taken together, our results 421 indicate that the strongest signatures of selection in the cactus mouse genome are consistent with 422 adaptations to life in the desert, which are mostly, but not solely, associated with high temperatures and 423 dehydration. Contrary to expectations, we did not find a pervasive signature of selection at genes involved 424 in water-sodium balance in the kidneys. However, this does not necessarily minimize the relative role of 425 these organs under thermal and hyperosmotic stress, as we have not yet tested when and where in the 426 body the expression of these candidate genes is beneficial. Our analyses also show that signatures of 427 selection are widespread across the cactus mouse genome, with all autosomes showing selective sweeps, 428 and that they are not affected by chromosome-level patterns of standing genetic variation, sequence or 429 structural. Sweeps seem to be associated with high local  $\pi$ , instead. Dynamic gene families and 430 enrichment of several GO terms associated with selective sweeps indicate that the genetic basis of at least some desert-adapted traits may be highly polygenic. In the future, evolutionary and physiological 431 432 genomics work stemming from these results will allow us to better characterize the phenotypes and genotypes associated with desert adaptations in the cactus mouse, and to understand how they evolved. 433 434

#### 435 Methods

#### 436 *Ethics Statement*

All sample collection procedures were approved by the Animal Care and Use Committee located at the
University of California, Berkeley (2009 samples, protocol number R224) and University of New
Hampshire (2018 samples, protocol number 130902) as well as the California Department of Fish and
Wildlife (permit number SC-008135) and followed guidelines established by the American Society of

Mammalogy for the use of wild animals in research (Sikes and Animal Care and Use Committee of the
American Society of Mammalogists, 2016).

443

444 *Genome assembly and annotation* 

445 We extracted DNA from the liver of a female cactus mouse (ENA sample ID: SAMEA5799953) captured 446 near Palm Desert, CA, USA using a Qiagen Genomic Tip kit (Qiagen, Hilden, Germany). We built two 447 short-insert Illumina libraries (300 bp and 500 bp inserts) using an Illumina Genomic DNA TruSeq kit, 448 following manufacturer recommendations. For scaffolding, we added four mate pair libraries (3 kb, 5 kb, 449 7 kb, 8 kb) prepared using a Nextera Mate Pair Library Prep kit (Illumina, San Diego, CA, USA). Each 450 library was sequenced on an Illumina HiSeq 2500 sequencer by Novogene (Sacramento, CA, USA) at a 451 depth of approximately 30x for each short-insert library, and 5x for each mate pair library. After adapter 452 trimming, libraries were assembled using the program ALLPATHS (Butler et al., 2008). The resulting 453 assembly was gap-filled using a PacBio library (Pacific Biosciences of California, Inc., Menlo Park, CA, 454 USA), constructed from the same DNA extraction and sequenced at ~5x coverage, using *PBJelly* (English 455 et al., 2012). We error-corrected the resulting assembly with short-insert Illumina data and the *Pilon* 456 software package (Walker et al., 2014).

To improve the draft assembly, we used proximity-ligation data (Hi-C) to further order and orient 457 draft scaffolds. We prepared a Hi-C library using the Proximo Hi-C kit from Phase Genomics (Seattle, 458 459 WA, USA). We used  $\sim 200 \ \mu g$  of liver from a second wild-caught animal and proceeded with library 460 preparation following the protocol for animal tissues. The Hi-C library was sequenced at Novogene using 461 one lane of 150 bp paired-end reads on an Illumina HiSeq 4000 platform. To arrange the draft scaffolds in chromosomes we used the program Juicer in an iterative fashion (Durand et al., 2016b). Following each 462 run, we loaded the *.map* and *.assembly* files generated by *Juicer* into *Juicebox* (Durand et al., 2016a), the 463 464 accompanying software developed to visualize crosslinks, and corrected misassemblies manually. We ran

- 465 *Juicer* until no well-supported improvements in the assembly were observed. We thus obtained 24
- 466 chromosome-sized scaffolds plus 6,785 unplaced short scaffolds. We calculated assembly statistics with

467 the *assemblathon\_stats.pl* script from the Korf Lab

- 468 (https://github.com/KorfLab/Assemblathon/blob/master/assemblathon\_stats.pl) and assessed assembly
- 469 completeness with *BUSCO v3* (Simão et al., 2015) and the Mammal gene set.
- 470 To standardize chromosome naming and enable future comparative analyses, we used the genome
- 471 assembly of the deer mouse (*Peromyscus maniculatus bairdii*; NCBI Bioproject PRJNA494228) to name
- 472 and orient the cactus mouse chromosomes. We used *mummer4* (Marçais et al., 2018) to align the cactus
- 473 mouse genome to the deer mouse genome with the function *nucmer* and the options *--maxgap 2000* and
- 474 *—minclust 1000.* We filtered alignments smaller than 10 kb with *delta-filter* and plotted the alignment
- using *mummerplot*. These genome alignments also allowed us to test for synteny between the two species,
- 476 diverged ~9 million years ago (timetree.com), and to assess the degree of structural divergence between
- 477 the two genomes.

We identified transposable elements and other repetitive elements using *RepeatMasker v.4.0*(Smit et al., 2015) and the Rodentia dataset. The masked genome was annotated using *Maker v.2.3.1*(Cantarel et al., 2008) and the *Mus musculus* reference protein dataset.

481

482 *Whole genome resequencing* 

We sequenced the genomes of an additional 26 cactus mice collected from two locations in Southern
California: Motte Rimrock and Boyd Deep Canyon Reserves (both belonging to the University of
California Natural Reserve System; Table 1). The Motte Rimrock Reserve (Motte hereafter) sits on a
broad, rocky plateau and supports both coastal and desert habitats as it is located equidistant between the
Pacific coast and the Colorado Desert. We captured cactus mice in xeric areas characterized by rocky
outcrops, which constitutes their typical habitat. The Boyd Deep Canyon Reserve (Deep Canyon

489 hereafter) is a large natural reserve extending from low to high elevation (290-2657 m). We sampled at 490 two locations in the lower elevation part of the Deep Canyon Reserve: Deep Canyon (290 m a.s.l.), the 491 driest and hottest location, with average monthly temperatures between 10-40 °C and mean annual 492 rainfall of 15 cm, and Agave Hill (820 m a.s.l.), with average monthly temperatures between 9-35 °C and 493 mean annual rainfall of 18 cm. Samples from Deep Canyon were collected in 2009 and 2018 (Table 1). 494 Genomic libraries were prepared at the Biotechnology Resource Center at Cornell University 495 (Ithaca, NY, USA) using the Illumina Nextera Library Preparation kit and a modified protocol for 496 low-coverage whole genome resequencing ('skim-seq'). Individually barcoded libraries were sequenced 497 at Novogene using 150 bp paired-end reads from one lane on the Illumina NovaSeq S4 platform. We 498 conducted an analysis of sequencing read quality and trimmed adapters from raw sequencing data with 499 fastp (Chen et al., 2018). We mapped sequences from each of the 26 individuals the cactus mouse 500 reference genome using *bwa mem* (Li and Durbin, 2009) and removed duplicates with *Samblaster* (Faust 501 and Hall, 2014). The resulting BAM files were sorted and indexed using *Samtools* (Li et al., 2009). 502 As sequencing depth was variable among individuals (raw coverage between  $\sim 2-17X$ ), we called 503 variants in ANGSD (Korneliussen et al., 2014) as its algorithm takes into account genotype uncertainty 504 associated with low-coverage data. To identify a list of high-confidence variable sites, we ran a global variant calling analysis including all 26 individuals. To be included in our analyses, a site had to satisfy 505 the following criteria: p-value below  $10^{-6}$ , minimum sequencing and mapping qualities above 20, 506 507 minimum depth and number of individuals equal to half of the number of individuals included in the 508 analysis (13 out of 26), and a minor allele frequency (MAF) above 1%. 509

510 *Genomic differentiation across space and time* 

511 To estimate the effects of temporal and spatial distance on levels of genomic differentiation among

512 individuals, we first ran an Analysis of Principal Components (PCA) of genetic data using the *ngsCovar* 

513 program from ngsTools (Fumagalli et al., 2014). We used all high-quality SNPs (defined above) called at 514 the species level and ran the PCA using genotype posterior probabilities, rather than called genotypes, as 515 input. To estimate genetic distance between individuals controlling for the effect of varying depth of sequencing across individuals, we downsampled to a single base for each site included in the high-quality 516 517 SNPs list and performed multidimensional scaling analysis (MDS) in ANGSD. Preliminary analysis 518 revealed the presence of an individual from Motte that grouped with neither population. This individual 519 was subsequently removed and variants were re-called. 520 After outlier exclusion, we reran ANGSD to estimate allele frequencies in Motte and Deep 521 Canyon separately. We provided a list of high-confidence SNPs for use in downstream analyses and 522 applied the same filters as in the global SNP calling, excluding SNP p-value and MAF thresholds, with 523 the major allele fixed across runs. We used the sample allele frequencies (.mafs file) from each population 524 to calculate the 2D Site Frequency Spectrum (SFS), which we also used as prior for estimating F<sub>ST</sub>, a 525 measure of genetic differentiation. We calculated average  $F_{ST}$  across autosomes and across the X 526 chromosome separately, and investigated patterns of differentiation across the genome in 50 kb sliding 527 windows. 528

#### 529 *Sequence and structural standing genetic variation*

To estimate levels and patterns of standing genetic variation within the cactus mouse, we analyzed samples from both populations together. We calculated the overall proportion of polymorphic sites and nucleotide diversity ( $\pi$ ) in 50 kb sliding windows. Estimates of  $\pi$  for each polymorphic site were based on the maximum likelihood of the SFS calculated with *realSFS* in *ANGSD*. To obtain accurate estimates of diversity, we corrected global and window estimates of  $\pi$  by the number of variant and invariant sites covered by data. We estimated genome coverage, total and per window, by rerunning *ANGSD* (including all 25 samples) using the same filtering parameters we used for the global calling variant but without the

537 SNP p-value and the MAF filters. We then divided the sum of per-site  $\pi$  by the number of variant and 538 invariant sites in a given window.

539 To investigate the distribution of structural variation in the cactus mouse genome, we sequenced the genome of an additional individual from the Deep Canyon site within the Deep Canyon Reserve 540 541 (sampled in 2009) using 10X Genomics (Pleasanton, CA, USA). This method is based on linked-reads 542 technology and enables phasing and characterization of structural variation using synthetic long-range 543 information. We used the program Long Ranger v.2.2.2 from 10X Genomics and ran it in whole genome 544 mode with *longranger wgs* using *Freebayes* (Garrison and Marth, 2012) as variant caller. Finally, we 545 tested whether chromosome size was a predictor of either sequence or structural standing variation using 546 linear models in *R* (R Core Team 2019). 547 548 *Gene family evolution in the cactus mouse* 549 To investigate gene family contractions and expansions in the cactus mouse, we analyzed the genomes of 550 25 additional species (Supplementary Table 1) within the Myodonta clade (Order: Rodentia), which 551 includes rats, mice, and jerboas, for which genome assemblies were publicly available from NCBI in June 552 2019. To avoid potential biases due to different gene annotation strategies, we re-annotated all 25 genomes with the same strategy used for the cactus mouse (see above). Genome quality was evaluated 553 554 using BUSCO. We identified groups of orthologous sequences (orthogroups) in all species using the 555 package Orthofinder2 (Emms and Kelly, 2018) with Diamond as protein aligner (Buchfink et al., 2015). 556 In a preliminary run, we observed that fewer orthogroups and fewer genes per orthogroup were identified

in species with lower genome assembly quality. Therefore, we filtered assemblies that had less than 70%

- 558 complete benchmarking universal single-copy orthologs (BUSCOs) and thus retained 18 species
- 559 (Supplementary Table 1).

560	We analyzed changes in gene family size accounting for phylogenetic history with the program
561	CAFE v4.2.1 (De Bie et al., 2006). We filtered both invariant orthogroups and those that varied across
562	species by more than 25 genes. We used the rooted species tree inferred by Orthofinder2 and ran the
563	analysis using a single value for the death-birth parameter ( $\lambda$ ) estimated in <i>CAFE</i> for the whole tree.
564	Finally, we summarized the results with the python script <i>cafetutorial_report_analysis.py</i> from the <i>CAFE</i>
565	developers (https://hahnlab.github.io/CAFE/manual.html).
566	
567	Detection of signatures of selection
568	We used an integrative approach to detect signatures of selection from the population genomics data.
569	First, we used Sweepfinder2 (DeGiorgio et al., 2016; Nielsen et al., 2005) to detect recent selective
570	sweeps. We ran these analyses using all 25 individuals, based on the rationale that potential differences
571	between the two populations (Deep Canyon and Motte) due to local adaptation or demography would be
572	swamped by signatures common in the species across populations. As recommended by Huber et al.
573	(2016), we included both variant and invariant sites, but we could not reconstruct the ancestral state of
574	these sites due to lack of data from closely related species. The X chromosome was excluded from this
575	analysis. We converted allele frequencies estimated in ANGSD to allele counts, and estimated the SFS
576	from the autosomes only in SweepFinder2. We then tested for sweeps using SweepFinder2 with the -l
577	setting, i.e. using the pre-computed SFS, and calculated the composite likelihood ratio (CLR) and $\alpha$ every
578	10,000 sites. Only the peaks with CLR values above the 99.9th percentile of the empirical distribution of
579	CLR values were considered under selection. We functionally annotated the closest genes to these outlier
580	peaks and ran a Gene Ontology (GO) enrichment analyses to test whether genes under putative selection
581	were enriched for a particular function or pathway. We performed this analysis on the geneonotology.org

webpage using the program *Panther* (Mi et al., 2017) and the *Mus musculus* gene set as reference. As GO terms are hierarchical, we summarized these results with the software package *REVIGO* (Supek et al.,

2011), which uses a clustering algorithm based on semantic similarities, setting the similarity threshold at0.5.

586	Finally, we generated a list of <i>a priori</i> candidate genes potentially involved in desert adaptation.
587	These included the genes that were most differentially expressed in response to experimental
588	dehydration, including 11 Cyp4 genes from the arachidonic acid metabolism pathway, and the sodium
589	carrier gene Slc8a1 (MacManes, 2017). We also included the 9 aquaporins, which are important in water
590	reabsorption in the kidney but were not differentially expressed in hydrated versus dehydrated cactus
591	mice (MacManes, 2017). We integrated this list of candidate genes with the genomic areas showing
592	strong signatures of selective sweeps in the <i>Sweepfinder2</i> analysis. As decreases in $\pi$ and Tajima's D can
593	also be indicative of selective sweeps, we calculated these two statistics in 1 kb windows across these
594	candidate regions, plus an additional 10 kb flanking on each side.
595	

#### 597 **Data availability**

598	All read data for the genome assembly are housed on ENA under project ID PRJEB33593. Specifically,
599	genome assembly (ERZ1195825), 300 bp PE (ERR3445708), 500 bp PE (ERR3446161), 8 kb mate pair
600	(ERR3446162), 5 kb mate pair (ERR3446317), 3 kb mate pair (ERR3446318), 7 kb mate pair
601	(ERR3446319), Hi-C (ERR3446437), 10X Genomics (ERR3447855). Whole genome resequencing data
602	for 26 cactus mice are housed on ENA under project ID PRJEB35488. Scripts for the genome assembly
603	and all other analyses can be found at https://github.com/atigano/Peromyscus_eremicus_genome/
604	

#### 605 Acknowledgements

We would like to thank Christopher Tracy for access to the Boyd Deep Canyon Reserve, Adam Stuckert

and Douglas Kelt for help with field sampling, the Biotechnology Resource Center at Cornell University

608 for preparation of the whole genome resequencing libraries, the MacManes Lab and the Evolutionary

609 Genomics Journal Group at the University of New Hampshire (UNH) for useful comments on earlier

610 versions of the manuscript. All analyses were performed on the UNH Premise Cluster. This work was

funded by the National Institute of Health National Institute of General Medical Sciences to MDM

612 (1R35GM128843)

613

## 614 Author contributions

AT and MDM conceived the study, collected the data, assembled the cactus mouse genome and

616 performed analyses. JPC provided input on the interpretation of results. AT wrote the first version of the

617 paper and AT, JPC and MDM reviewed and edited the paper.

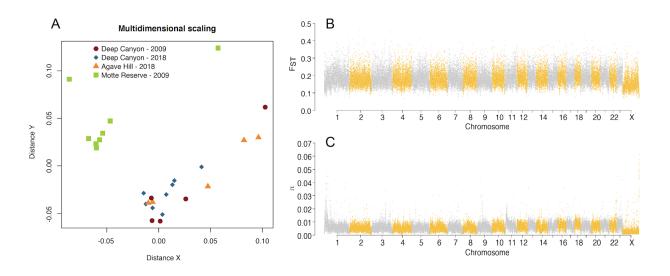

Figure 1. Diversity and differentiation in the cactus mouse. a) MDS plot showing relative distance among individuals based on downsampling to a single base at 43.7 million variable sites. Note outlier from Motte on the far left side of the plot. b) Manhattan plot showing patterns of differentiation based on  $F_{sT}$  between Motte and Deep Canyon Reserves (after outlier removal). c) Manhattan plot showing patterns of nucleotide diversity  $\pi$  from all samples combined (after outlier removal).

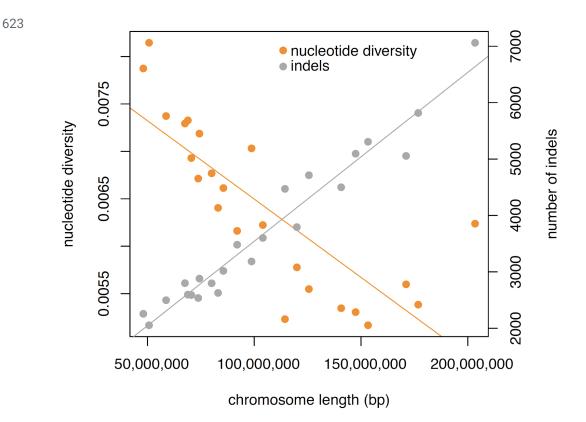

Figure 2. Plot showing mean nucleotide diversity and number of indels as a function of chromosome

length (p < 0.001 in both cases, albeit with opposite trends).

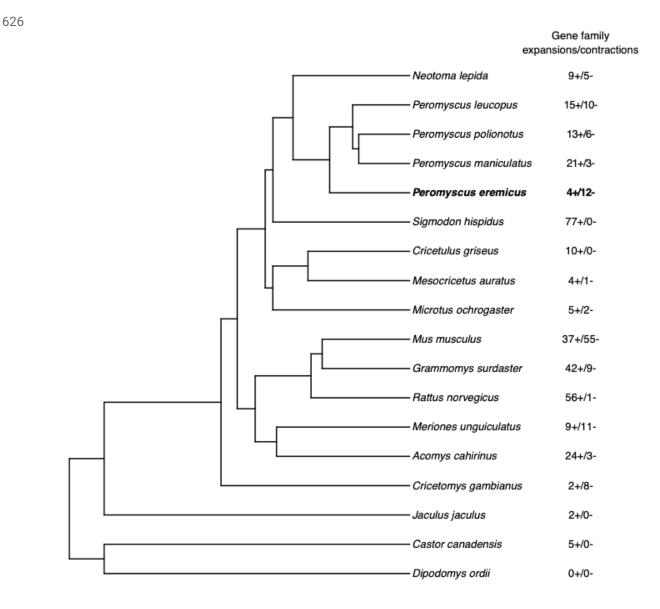

Figure 3. Species tree built in *Orthofinder2* from protein sequences of 18 species in the Myodonta clade (Order: Rodentia). Beside each species name are the number of gene families that underwent significant (p < 0.05) expansions (+) or contractions (-).

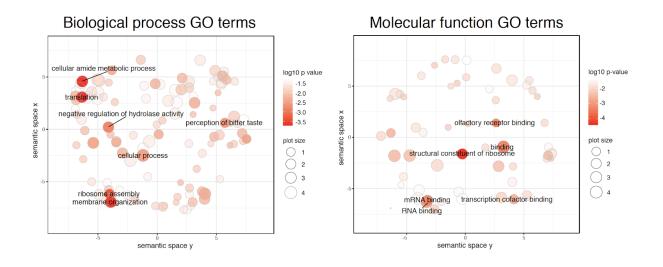

Figure 4. Scatterplot showing clusters representative of enriched GO terms after semantic reduction in *REVIGO* for biological process GO terms (left) and molecular function GO terms (right). Only the names of GO clusters with a p-value  $< 10^{-2.5}$  are shown for visual clarity. The full list of genes and reduced GO terms in *REVIGO* can be found in Supplementary Tables 3, 4 and 5).

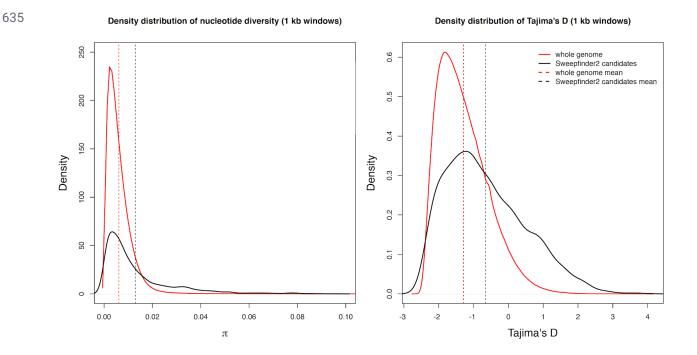

Figure 5. Density plots comparing distribution of  $\pi$  (left) and Tajima's D (right) across the genome (in red) and across *Sweepfinder2* candidate regions only (in black). Values are calculated in 1 kb non-overlapping windows along the genome. Dashed vertical lines show the means across the genome in red and across *Sweepfinder2* candidate regions only in black. Means across the genome and across

640 *Sweepfinder2* candidate regions only are highly significant in both cases (p < 0.001).
