13 **ABSTRACT**

14 A central issue in affective science is whether the brain represents the emotional expressions of
15 faces, bodies and voices as abstract categories in which auditory and visual information converge
16 in higher order conceptual and amodal representations. This study explores an alternative theory
17 based on the hypothesis that under naturalistic conditions where affective signals are acted upon
18 that rather than reflected upon, major emotion signals (face, body, voice) have sensory specific
19 brain representations. During fMRI recordings, participants were presented naturalistic dynamic
20 stimuli of emotions expressed in videos of either the face or the whole body, or voice fragments.
21 To focus on automatic emotion processing and bypass explicit emotion cognition relying on
22 conceptual processes, participants performed an unrelated target detection task presented in a
23 different modality than the stimulus. Using multivariate analysis to assess neural activity patterns
24 in response to emotion expressions in the different stimuli types, we show a distributed brain
25 organization of affective signals in which distinct emotion signals are closely tied to the sensory
26 origin. Our findings are consistent with the notion that under ecological conditions the various
27 sensory emotion expressions have different functional roles, even when from an abstract
28 conceptual vantage point they all exemplify the same emotion category.

29

30 INTRODUCTION

31 In the course of daily social interactions, emotion signals from the face, voice and body
32 are recognized effortlessly and responded to spontaneously when rapid adaptive actions are
33 required. The specifics of the subjective experience in the natural environment determine which
34 affective signal dominates and triggers the adaptive behavior. Rarely are the face, the whole
35 body and the voice equally salient. That is, the actual conditions under which we react to an
36 angry face may be different from those of hearing an angry voice or viewing whole body
37 movements. For example, we see faces from close by and therefore personal familiarity may play
38 a role in how we react to the angry face. This is less so for the voice or the whole body, both of
39 which already prompt reactions when seen or heard from a distance while information about
40 personal identity is not yet available or needed for action preparation. Thus, the angry body
41 expression viewed from a distance and the angry face expression seen from closeby may each
42 trigger a different reaction as behavior needs to be adapted to the concrete context. Therefore, a
43 representation of affective meaning that is sensitive to the spatiotemporal parameters may seem
44 desirable rather than an abstract system of higher order concepts as traditionally envisaged by
45 emotion theorists (Ekman P and D Cordaro 2011); but see (Lindquist KA et al. 2012).

46 Research on the brain correlates of emotion has favored the traditional notion of abstract
47 neural representations of basic emotions and this has also been the dominant rationale for
48 multisensory research. Studies comparing how not just the face but also the voice and the whole
49 body convey emotions have followed this overall basic emotion perspective and asked where in
50 the brain affective information from different sensory systems converges (Peelen MV et al. 2010;
51 Klasen M et al. 2011). Such representations were found in high-level brain areas known for their
52 role in categorization of mental states (Peelen MV *et al.* 2010). Specifically, medial prefrontal
53 cortex (MPFC) and superior temporal cortex (STS) represent emotions perceived in the face,
54 voice or body at a modality-independent level. Furthermore, these supramodal or abstract
55 emotion representations presumably play an important role in multisensory integration by
56 driving and sustaining convergence of the sensory inputs towards the amodal emotion
57 representation (Gerdes AB et al. 2014).

58 The present study explores a different perspective, complementary or compatible with
59 that of high level abstract emotion representations yet motivated by the natural variability of

60 daily emotion perception conditions that do not routinely involve conscious use of verbal labels.
61 Emotion perception in naturalistic conditions is often driven by a specific context relative to a
62 behavioral goal, as opposed to the conditions in the lab, where tasks often use explicit evaluation
63 of emotional expressions. Under natural conditions, each sensory modality may have its own
64 functionality such that e.g. fear is more effectively conveyed by the face, anger by the body and
65 happiness by the voice. If so, brain responses would be characterized by specific emotion-
66 modality combinations.

67 Additionally, the notion that supramodal representations of basic emotions are the pillars
68 of emotion processing in the brain and allow for smooth convergence between the different
69 sensory modalities is not fully supported by the literature. First, since the original proposal by
70 Ekman (Ekman P 1992) and the constructivist alternative argued by Russell (Russell JA 2003)
71 and most recently Feldman Barrett (Lewis M et al. 2010; Barrett LF 2017), the notion of a set of
72 basic emotions with discrete brain correlates continues to generate controversy (Kragel PA and
73 KS LaBar 2016; Saarimaki H et al. 2016). Second, detailed meta-analyses of crossmodal and
74 multisensory studies, whether they are reviewing the findings about each separate modality or
75 the results of crossmodal studies (Dricu M and S Fruhholz 2016; Schirmer A and R Adolphs
76 2017), provide a mixed picture. Furthermore, these meta-analyses also show that a number of
77 methodological obstacles stand in the way of valid comparisons across studies. That is, taking
78 into account the role of task (incidental perception, passive perception, and explicit evaluation of
79 emotional expression) and the use of appropriate control stimuli reduces the number of studies
80 that can validly be compared. Third, findings from studies that pay attention to individual
81 differences and to clinical aspects reveal individual differences in sensory salience and
82 dominance in clinical populations, for example in autism and schizophrenia. For example, (Karle
83 KN et al. 2018) report an alteration in the balance of cerebral voice and face processing systems
84 in the form of an attenuated face-vs-voice bias in emotionally competent individuals. This is
85 reflected in cortical activity differences as well as in higher voice-sensitivity in the left
86 amygdala. Finally, even granting the existence of abstract supramodal representations – probably
87 in higher cognitive brain regions - it is unclear how they relate to early stages of affective
88 processing where the voice, the face and the body information are processed by different sensory
89 systems comprising distinct cortical and subcortical structures.

90
91 Here we used naturalistic dynamic stimuli to investigate whether the brain represents
92 different sensory emotion expressions as modality specific or modality-invariant, using fMRI
93 with dynamic stimuli expressing affect with either the body, the face or the voice. Importantly,
94 we investigate these processes independently of the explicit evaluation of emotion to study
95 whether the brain still differentiates between emotional expressions even when they are not in
96 the direct focus of attention. We perform multivariate pattern analysis to identify cortical regions
97 containing representations of emotion independently of the explicit evaluation of emotion.

98 For the sake of clarity, we contrast the implications of the centralist view and the
99 distributed modality view for the neural representation of emotions. Following the first, there
100 should be localized representations (here multi voxel patterns) for specific emotions that are
101 independent of modality. These region(s) would show the following behavior: (1) respond to all
102 stimuli above some threshold (i.e. be activated by all emotions/modalities); (2) have no
103 discernable activation pattern between modalities, that is, modality cannot be decoded from the
104 voxel activation patterns; (3) exhibit distinct voxel activation patterns for each emotion (emotion
105 is decodable from the regions). This would provide strong evidence for a cross-modal or
106 modality independent emotion representation and correspond to the classical notion of basic
107 emotions in the literature. The alternative, distributed theory postulates that emotions are
108 represented in the brain in a modality-emotion specific way. For example, some specific
109 emotion-modality combination like a fearful body will elicit activation patterns that are different
110 from fear from the voice or the face. Likewise, hearing a happy voice (laughing) can elicit
111 different brain responses from seeing a happy expression from the face or body. In terms of
112 testing this hypothesis, we would expect to find brain regions where emotion can be decoded but
113 only within a specific modality, not across modalities. That pattern would provide clear evidence
114 that the decoding will be driven by specific responses to emotion-modality combination.

115

116 **METHODS**

117 *Participants*

118 Thirteen healthy participants (mean age = 25.3; age range = 21-30; two males) took part in the
119 study. Participants reported no neurological or hearing disorders. Ethical approval was provided
120 by the Ethical Committee of the Faculty of Psychology and Neuroscience at Maastricht
121 University. Written consent was obtained from all participants. The experiment was carried out
122 in accordance with the Declaration of Helsinki. Participants either received credit points or were
123 reimbursed with monetary reward after their participation in the scan session.

124 *Stimuli*

125 Stimuli consisted of color video and audio clips of four male actors expressing three different
126 emotional reactions to specific events (e.g. fear in a car accident or happiness at a party). Images
127 were shown to the actors during recordings with the goal of triggering spontaneous and natural
128 reactions of anger, fear, happiness and an additional neutral reaction. A full description of the
129 recording procedure, the validation and the video selection is given in (Kret ME, S Pichon, J
130 Grezes, et al. 2011). In total there were 16 video clips of facial expressions, 16 video clips of
131 body expressions, and 32 audio clips of vocal expressions, half of which were recorded in
132 combination with the facial expressions and half of which were recorded in combination with the
133 body expressions (i.e. two audio clips per emotional expression per actor). All actors were
134 dressed in black and filmed against a green background under controlled lighting conditions.

135 Video clips were computer-edited using Ulead, After Effects, and Lightworks (EditShare). For
136 the body stimuli, faces of actors were blurred with a Gaussian mask such that only the
137 information of the body was available. The validity of the emotional expressions in the video
138 clips was measured with a separate emotion recognition experiment (emotion recognition
139 accuracy > 80%). For more information regarding the recording and validation of these stimuli,
140 see (Kret ME, S Pichon, J Grezes, *et al.* 2011; Kret ME, S Pichon, J Grèzes, et al. 2011).

141 *Experimental design and behavioral task*

142 In a slow-event related design, participants viewed series of 1 second video clips on a projector
143 screen or listened to series of 1 second audio clips through MR-compatible ear buds
144 (Sensimetrics S14) equipped with sound attenuating circumaural earbuds (attenuation > 29 dB).
145 The experiment consisted of 12 runs divided over 2 scan sessions. Six runs consisted of blocks of
146 face and voice stimuli, followed by six runs consisting of body and voice stimuli. Blocks were

147 either *auditory* (consisting of 18 audio clips) or *visual* (consisting of 18 video clips). These 18
148 trials within each block comprised 16 regular trials, and two catch trials requiring a response.
149 Catch trials were included to determine that attention was diverted from explicit recognition or
150 evaluation of the emotional expression by focusing attention on the other modality. That is,
151 during visual blocks, participants were instructed to detect auditory catch trials, and during
152 auditory blocks, participants were instructed to detect visual catch trials. For the auditory catch
153 trial task, a frequency modulated tone was presented and participants had to respond whether the
154 direction of frequency modulation was up or down. For the visual distractor task, participants
155 indicated whether the fixation cross turned lighter or darker during the trial. A separate localizer
156 session was also performed where participants passively viewed stimuli of faces, bodies, houses,
157 tools and words in blocks; see (Zhan M et al. 2018) for details.

158 *Data acquisition*

159 We measured blood-oxygen level-dependent (BOLD) signals with a 3 Tesla Siemens Trio whole
160 body MRI scanner at the Scannexus MRI scanning facilities at Maastricht University
161 (Scannexus, Maastricht). Functional images of the whole brain were obtained using T2*-
162 weighted 2D echo-planar imaging (EPI) sequences [number of slices per volume = 50, 2 mm in-
163 plane isotropic resolution, repetition time (TR) = 3000 ms, echo time (TE) = 30 ms, flip angle
164 (FA) = 90°, field of view (FoV) = 800 x 800 mm², matrix size = 100 x 100, multi-band
165 acceleration factor = 2, number of volumes per run = 160, total scan time per run = 8 min]. A
166 three-dimensional (3D) T1-weighted (MPRAGE) imaging sequence was used to acquire high
167 resolution structural images for each of the participants [1-mm isotropic resolution, TR = 2250
168 ms, TE = 2.21 ms, FA = 9°, matrix size = 256 x 256, total scan time = 7 min approx.]. The
169 functional localizer scan also used a T2*-weighted 2D EPI sequence [number of slices per
170 volume = 64, 2 mm in-plane isotropic resolution, TR = 2000 ms, TE = 30 ms, FA = 77, FoV =
171 800 x 800 mm², matrix size = 100 x 100, multi-band acceleration factor = 2, number of volumes
172 per run = 432, total scan time per run = 14 min approx.].

173 *Analysis*

174 *Pre-processing:* Data were preprocessed and analyzed with BrainVoyager QX (Brain
175 Innovation, Maastricht, Netherlands) and custom Matlab code (Mathworks, USA) (Hausfeld L et

176 al. 2012; Hausfeld L et al. 2014). Preprocessing of functional data consisted of 3D motion
177 correction (trilinear/sync interpolation using the first volume of the first run as reference),
178 temporal high pass filtering (thresholded at five cycles per run), and slice time correction. We
179 co-registered functional images to the anatomical T1-weighted image obtained during the first
180 scan session and transformed anatomical and functional data to the default Talairach template.

181 *Univariate analysis:* We estimated a random-effects General Linear Model (RFX GLM) with a
182 predictor for each stimulus condition of interest (12 conditions in total): four emotion conditions
183 times three modalities (face, body, voice). We note that modality is used here in a broader sense
184 than just the physical nature of the stimuli (sound versus visual). Additionally, we included
185 predictors for the trials indicating the start of a new block and the catch trials. Predictors were
186 created by convolving stimulus predictors with the canonical hemodynamic function. Finally, we
187 included six motion parameters resulting from the motion correction as predictors of no interest.
188 For this analysis, data was spatially smoothed with a 6mm full-width half-maximum (FWMH)
189 Gaussian kernel. To assess where in the brain the two different experimental factors had an
190 influence, an ANOVA was run with either modality or emotion as a factor. Additionally the
191 ANOVA with the emotion factor was run for each modality separately. As effect sizes were
192 generally low, the final group statistical maps were liberally thresholded at $p < 0.001$ uncorrected.
193 For visualization purposes, the group volume maps were mapped to the cortical surface. As this
194 operation involves resampling the data (during which the original statistical values get lost),
195 surface maps are displayed with discrete label values instead of continuous statistical values. As
196 such, we do not include a colorbar in the surface map figures.

197 *Multivariate analysis:* We first estimated beta parameters for each stimulus trial with custom
198 MATLAB code by fitting an HRF function with a GLM to each trial in the time series. These
199 beta values were then used as input for a searchlight multivariate pattern analysis (MVPA) with a
200 Gaussian Naïve Bayes classifier (Ontivero-Ortega M et al. 2017). The searchlight was a sphere
201 with a radius of 5 voxels. The Gaussian Naïve Bayes classifier is an inherently multi-class
202 probabilistic classifier that performs similar to the much-used Support Vector Machine classifier
203 in most scenarios, but is computationally more efficient. The classifier was trained to decode (1)
204 stimulus modality (visual or auditory) (2) stimulus type (i.e. body, face or voice); (3) stimulus
205 emotion (e.g. fear in all stimulus types vs angry in all stimulus types); (4) within-modality

206 emotion (e.g. body angry vs. body fear) (5) cross-modal emotion (e.g. classify emotion by
207 training on body stimuli and testing on the voice stimuli from the body session). Classification
208 accuracy was computed by averaging the decoding accuracy of all folds of a leave one-run out
209 cross-validation procedure. We tested the significance of the observed decoding accuracies at the
210 group level with a one-sample t-test against chance (50% for modality, 33% for stimulus types,
211 25% for emotion). We also tested the emotion effect with an additional analysis where the
212 neutral condition was excluded. As in the univariate analyses, these maps were transformed to
213 the cortical surface for display purposes. The cross-modal decoding revealed several subcortical
214 structures that are not visualized well on the cortical surface and therefor are displayed on a
215 volume map ($p < 0.01$, uncorrected).

216 To evaluate the relative contribution of either stimulus type or of emotion in terms of
217 information content that can be decoded, we performed an analysis where all stimuli for a
218 specific combination of two emotions (e.g. anger and happy from the same session) were
219 extracted and a decoder was trained to either classify the two different emotions or the two
220 different stimulus types (body/voice or face/voice). The resulting accuracy maps were first
221 thresholded such that regions where both the stimulus type and emotion decoder accuracy were
222 below chance at the group level were excluded. Next we contrasted the two accuracy maps at the
223 group level i.e. accuracy for emotion $>$ accuracy for stimulus type and displayed these as a
224 volume map at $p < 0.001$ uncorrected.

225 *ROI analysis:* Lastly, to gain more insight into details of the responses in some of the regions
226 identified by the previously mentioned analyses, as well as regions known to be important for
227 emotion or multi-modal integration (Peelen MV *et al.* 2010), we extracted beta values from these
228 ROIs and made several plots that (1) display the decoding accuracy of the selected voxels for
229 stimulus type and emotion, (2) display the mean beta values for each of the 12 conditions, (3)
230 display the multivoxel representational dissimilarity matrix (Kriegeskorte N *et al.* 2008) and (4)
231 warp the multivoxel patterns to a 2-dimensional space with multidimensional scaling and display
232 the relative distance between the conditions with graphical indicators for the stimulus type (icon)
233 and emotion (line color)

234 **RESULTS**

235 *Univariate analysis*

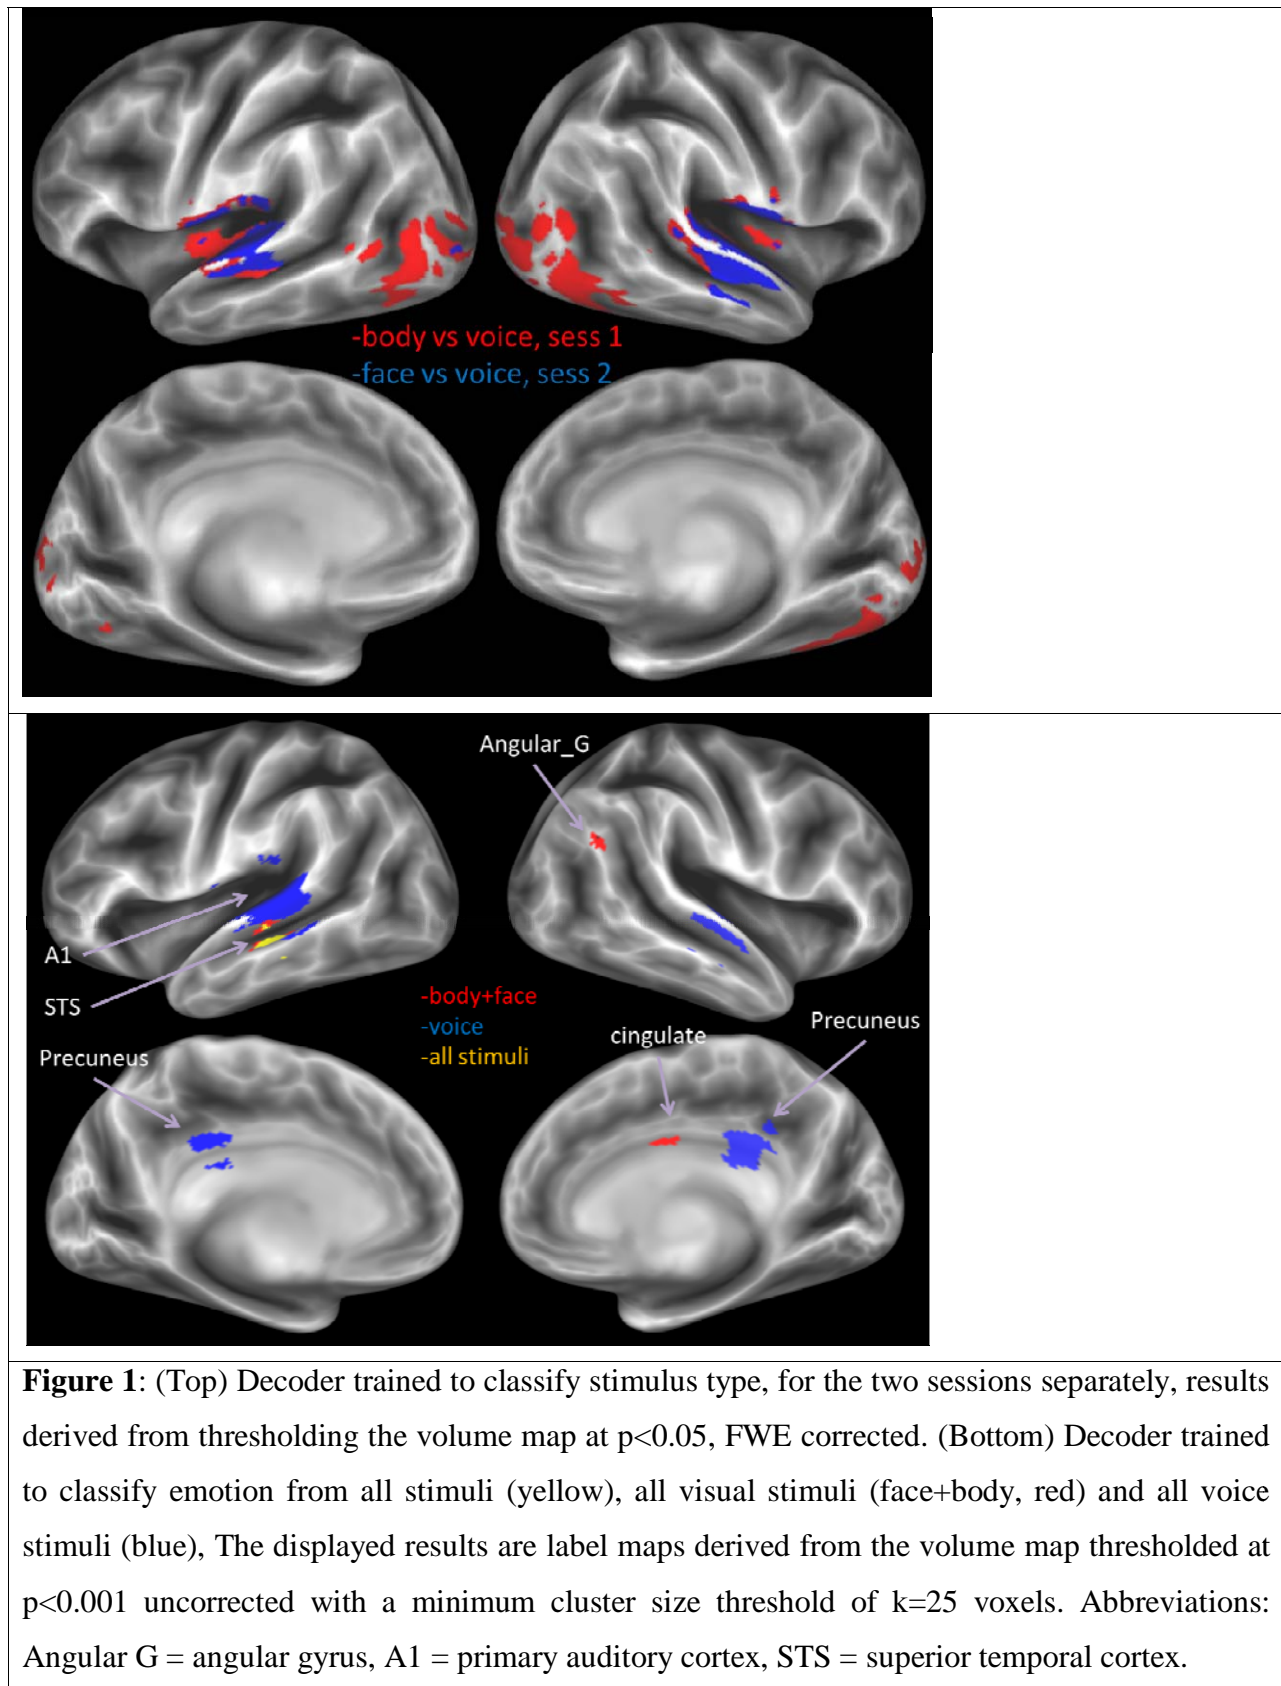

236 We ran an ANOVA with factors ‘stimulus type’ and ‘emotion’ on the beta values estimated with
237 an RFX GLM on the entire data set, as well as separate ANOVAs with factor ‘emotion’ on the
238 data of each stimulus type (i.e. faces, bodies, and voices). As expected, the F-map for stimulus
239 type (see Fig. S1) revealed significant clusters with differential mean activation across stimulus
240 types in primary and higher-order auditory and visual regions, as well as in motor, pre-motor and
241 dorsal/superior parietal cortex. The univariate analyses did not reveal cortical regions showing a
242 significant effect for emotion. Although the F-maps of these emotion analyses showed some
243 small clusters at lenient thresholds ($p < 0.001$, uncorrected), none of these survived correction for
244 multiple comparisons. See Supplementary results for details.

245 *Multivariate analysis with the GNB decoder*

246 We aimed to decode stimulus type by training the classifier separately for the two sessions to
247 decode visual vs. auditory stimuli: body vs. voice (session 1) and face vs. voice (session2). As
248 expected, stimulus type could be decoded significantly above chance level (50%, $p < 0.05$ FWE
249 corrected) in auditory, visual and fusiform cortex, and large part of the lateral occipital and
250 temporo-occipital cortex, presumably including the extrastriatal body area (EBA; see Fig. 1 top
251 panel).

252 Decoding of emotion resulted in qualitatively lower accuracies and smaller clusters compared to
253 the decoding of modality. Above chance accuracies (33%) for decoding emotion from all
254 stimulus types together were observed in STS (Fig. 1, bottom panel). Next, we trained and tested
255 the classifier to decode emotions within a specific stimulus modality, that is, considering either
256 the combined face and body stimuli (i.e. visual), or the voice stimuli (i.e. auditory). For body and
257 face this revealed STS, cingulate gyrus and angular gyrus. Emotion could be decoded for voice
258 stimuli in primary and secondary auditory regions (including the superior temporal gyrus
259 [STG]), and the precuneus (see Fig 1 bottom panel). See Table 1 for details of these results.

260 We also trained and tested the classifier to decode emotions within each visual category, that is,
261 considering either the face or the body. This did not reveal any clusters where emotion could be
262 decoded accurately (suprathreshold at $p < 0.05$ FWE corrected), although additional results were
263 obtained at more lenient thresholds (see Fig. S4).

265 **Table 1: Results for the decoding of emotion**

	<i>cluster size</i>	<i>clusgter p(unc)</i>	<i>peak T</i>	<i>peak p(unc)</i>	<i>x</i>	<i>y</i>	<i>z</i>
All stimuli							
STS	38	0.0536	5.8422	0.0000	-3	21	-7
Voice stimuli only							
planum temporale	749	0.001	6.462	0.000	-58	-34	6
posterior cingulate gyrus / precuneus	187	0.058	5.654	0.000	8	-34	30
planum temporale	210	0.046	5.206	0.000	62	-18	2
Face and body stimuli							
STS	59	0.0200	6.8069	0.0000	-52	-26	-12
right caudate	92	0.0052	6.5513	0.0000	16	-12	20
angular gyrus	27	0.0979	6.4339	0.0000	60	-50	34

266

267 **ROI Analysis**

268 In addition to the whole-brain searchlight analysis, we performed a more sensitive region-of-
 269 interest (ROI) analysis. Specifically, we used data of an independent localizer (see *Methods*) to
 270 identify early auditory cortex, early visual cortex, rEBA, and rFFA. We furthermore included
 271 two multisensory regions, pSTS and mPFC that were previously identified as regions holding
 272 supramodal representations of emotion (Peelen MV *et al.* 2010). We used an anatomical
 273 definition of these areas, defined by a spherical ROI with a radius of 5 voxels centered on the
 274 reported cluster peak locations. Finally, we included the amygdala given its important role in
 275 previous studies, most recently in the study by (Whitehead JC and JL Armony 2019) using the
 276 univariate contrast face fear > face neutral ($p < 0.01$ uncorrected).

277 In all ROIs, stimulus type could be decoded above chance level (one sample t-test against chance
 278 level, all $p < 0.0001$). Furthermore, when the classifier operated on all stimuli together (that is,
 279 face, body, and voice), emotion could be successfully decoded in the EBA, auditory cortex, and
 280 left amygdala (all $p < 0.02$). That is, in line with the results of the searchlight analysis, when the
 281 classifier operated on the data of each modality in isolation, decoding accuracies for emotion
 282 were above chance level in early visual cortex for face stimuli ($p < 0.03$), and in auditory cortex
 283 for voice stimuli ($p < 0.002$). Emotion could not be decoded above chance level in the supramodal

284 regions (mPFC and pSTS). Taken together, these results demonstrate that these regions could not
285 be identified as supramodal as the responses were not invariant to stimulus type (see Fig. 2).
286 Qualitatively, the RDM and MDS plots in Figure 2 show that in all tested ROIs there is a strong
287 effect of stimulus type (blocks on diagonal for the RDM and a large distance between types in
288 the MDS). Notable, this effect is not always clearly present in just the beta magnitudes (response
289 levels) and is at least partially caused by the multi-voxel pattern dissimilarities.

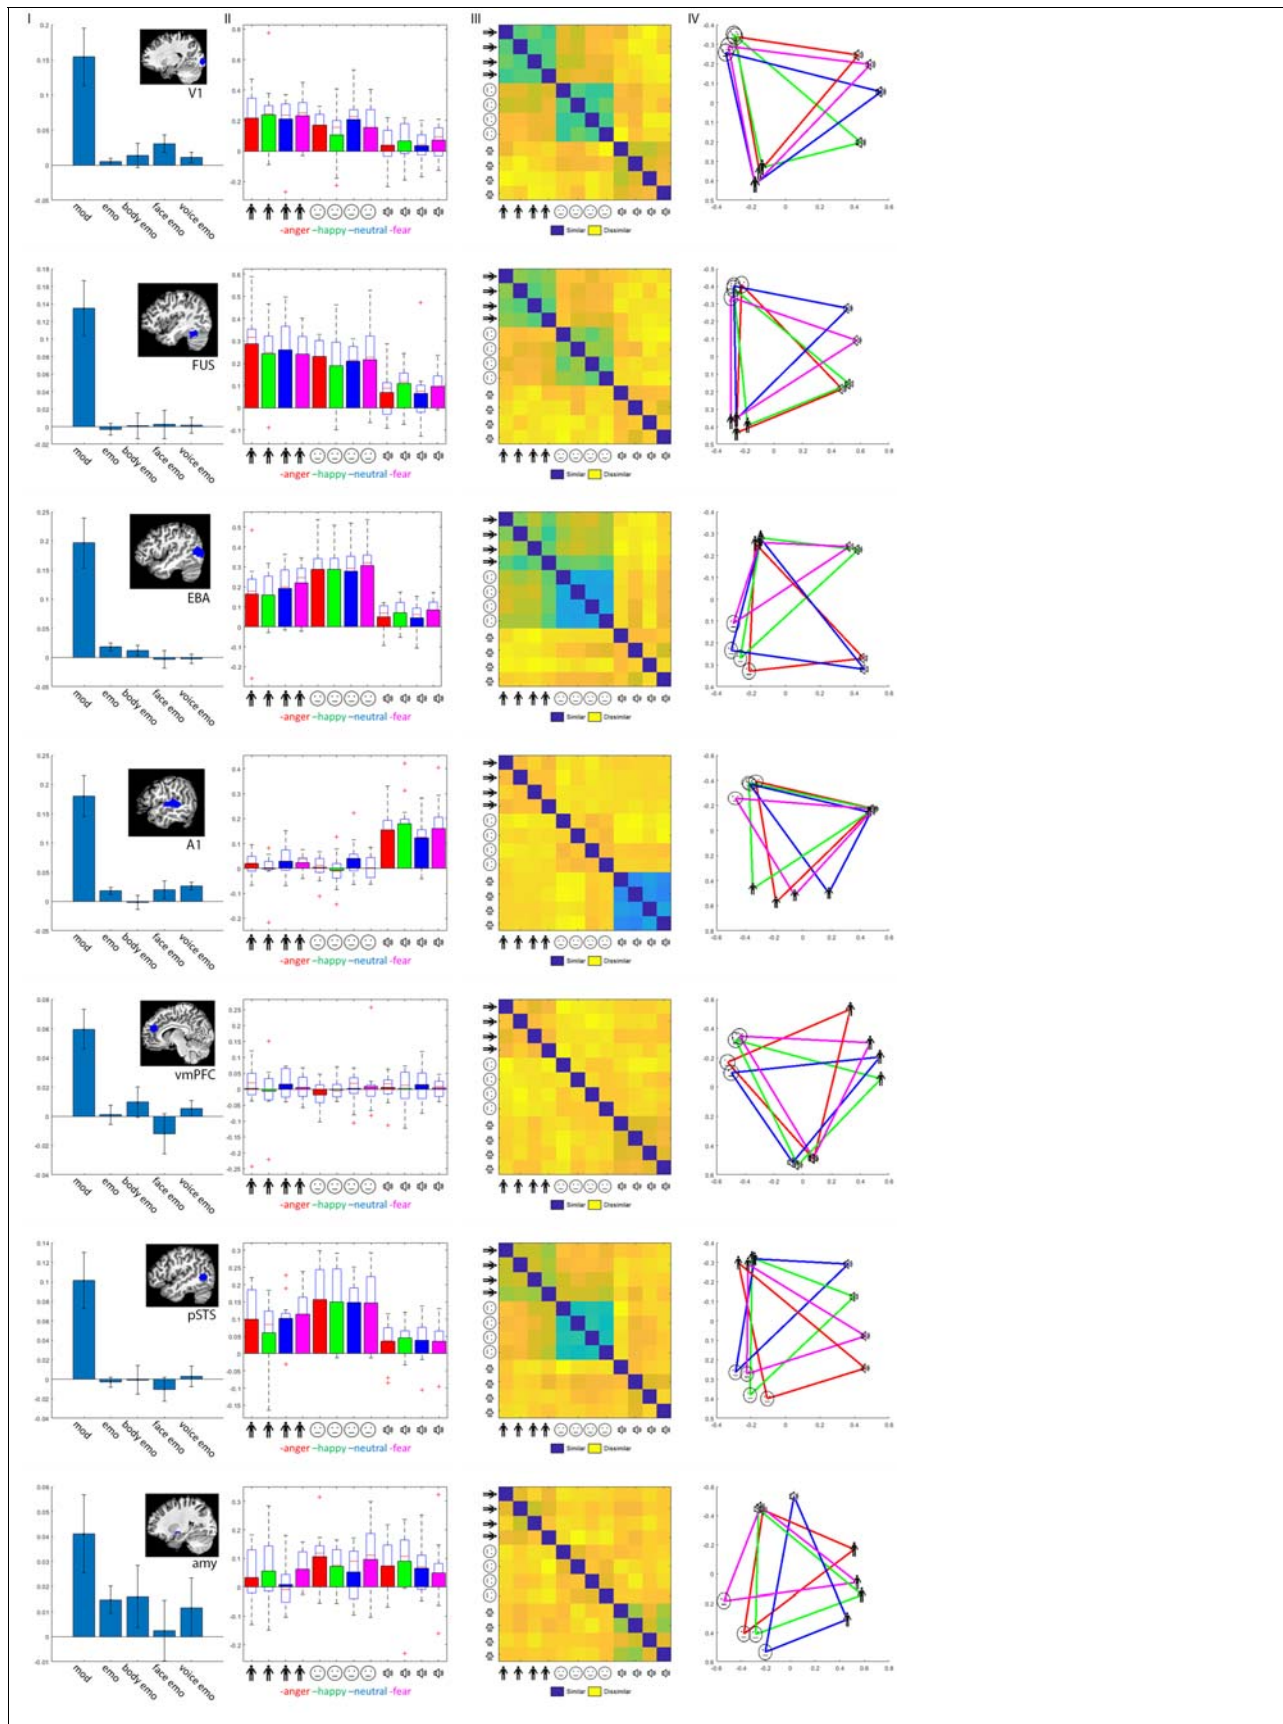

Figure 2: I) Location of the ROI and graphs indicating decoding accuracy for stimulus type and emotion and emotion for each stimulus type in the ROI. II) Trial-wise beta values for all 12 conditions (3x modality and 4x emotion) averaged over the ROI and group. Error bars indicate SE. III) Representational dissimilarity matrix for the ROI. IV) Multidimensional scaling plot of the group averaged trial-wise beta values. Line colors indicate same emotion, icons display modality. Distance in the plot is related to similarity of the ROI voxel activation patterns. Colors as in the beta plot for emotion.

290

291 *Cross-modal decoding*

292 We performed an additional analysis to gain insight into where in the brain supramodal emotion
293 regions might be found by training a classifier to decode emotion across stimulus modalities.
294 Being able to predict emotion by training on one modality and testing on another modality would
295 be a strong indication of supramodal emotion encoding in the brain. Therefore, the cross-modal
296 classifier was trained (or tested) on either the body or face stimuli and tested (or trained) on the
297 voice stimuli from the body or face session, respectively. Thus, four classifiers were trained in
298 total (training on body and testing on voice, training on voice and testing body, training on face
299 and testing on voice, training on voice and testing on face). In contrast to the successful decoding
300 of modality and emotion within modality, none of these cross-modal classifiers resulted in
301 accurate decoding of emotion ($p < 0.001$, see Supplementary Fig. S5).

302 *Contrasting accuracies for emotion and modality*

303 There was little overlap in regions identified by the within stimulus type classifier (see Fig. 2 and
304 S4). Specifically, regions where emotion was decoded successfully from body stimuli did not
305 converge with regions where emotion was decoded successfully from the face and/or voice.
306 Therefore, to identify regions that have a purely supramodal representation of emotion, we
307 contrasted the accuracy map for modality versus emotion directly. Here, finding regions having
308 higher decoder accuracy for emotion compared to modality would be a strong indication for
309 supramodal emotion encoding. This analysis revealed in general that, as expected, modality
310 could be decoded with greater accuracy than emotion in primary auditory and visual regions, as
311 well as in parietal and pre-motor regions. We could not clearly identify any regions where binary

312 combination of two specific emotions could be decoded with higher accuracy than the modality.
313 Only for fear and neutral in the face-voice session did we find a region in the medial motor
314 cortex and for happy and neutral in the body-voice session in the white matter (at $p < 0.001$
315 uncorrected, see Fig. S6).

316 **DISCUSSION**

317 Our results indicate that the brain regions involved in emotion processing are modality specific.
318 That is, in the regions where emotion can be decoded, it could only be decoded within modality
319 but not across modalities, indicating that the decoding is driven by a specific response to a
320 specific emotion-modality combination. In a departure from the few previous studies using a
321 partially comparable approach we found evidence for sensory specific rather than abstract
322 supramodal representations that sustain perception of various affective signals as a function of
323 the modality (visual or auditory) and the stimulus category (face, voice or body). Because of the
324 three stimulus categories used, the different emotions studied, the task conditions, and the
325 converging results from different analysis techniques, our study presents a novel approach to
326 understanding the specific contribution and the neural basis of emotional signals provided by
327 different sensory modalities.

328 To understand our findings against the background of the literature, some specific aspects
329 of our study must be highlighted. We used dynamic realistic face and body stimuli instead of
330 point light displays or static images. The latter are also known to complicate comparisons with
331 dynamic auditory stimuli (Campanella S and P Belin 2007). Next, our stimuli do not present
332 prototypical emotion representations obtained by asking actors to portray emotions but present
333 spontaneous whole body reactions to images of familiar events. The images we used may
334 therefore be more spontaneous and trigger more sensorimotor processes in the viewer than posed
335 expressions. Third, many previous studies used explicit emotion recognition (Lee KH and GJ
336 Siegle 2012), passive viewing (Winston JS et al. 2003), implicit tasks like gender categorization
337 (Dricu M and S Fruhholz 2016) or oddball tasks presented in the same modality as the stimulus.
338 In contrast, our modality specific oddball task is presented in the alternate modality of the
339 stimulus presentation thereby diverting attention not only from the emotion content but also from
340 the perceptual modality in which the target stimuli of that block are shown. This task was
341 intended to approximate the naturalistic experience of emotional signals, where often one is

342 engaged in one activity (visual perception) when another event intrudes (an auditory event). We
343 discuss separately the findings on the major research questions.

344

345 *Univariate analysis*

346 Although our goal was to characterize neural responses with MVPA techniques, for the
347 sake of comparisons with the literature, we also briefly discuss our univariate results. How do
348 these results compare to findings and meta-analyses in the literature? As a matter of fact, there
349 are no previous studies that used comparable materials (four emotion categories, three stimulus
350 types, two modalities) and an other modality centered task like the present. The studies that did
351 include bodies used only neutral actions, not whole body emotion expressions (Dricu M and S
352 Fruhholz 2016) except for one study comparing face and body expression videos by (Kret ME, S
353 Pichon, J Grezes, *et al.* 2011). Only the study by Peelen *et al.* used faces, bodies, and voices, but
354 with a very different task as we discuss below (Peelen MV *et al.* 2010).

355 Compared to the literature, the findings of the univariate analysis present
356 correspondences as well as differences. A previous study (Kret ME, S Pichon, J Grezes, *et al.*
357 2011) with face and body videos used only neutral, fear and anger expression and a visual
358 oddball task. They reported that EBA and STS show increased activity to threatening body
359 expressions and FG responds equally to emotional faces and bodies. For the latter, higher activity
360 was found in cuneus, fusiform gyrus, EBA, tempo-parietal junction, superior parietal lobe, as
361 well in as the thalamus while the amygdala was more active for facial than for bodily
362 expressions, but independently of the facial emotion. Here we replicate that result for faces and
363 bodies and found highly significant clusters with differential mean activation across stimulus
364 types in primary and higher-order auditory and visual regions, as well as in motor, pre-motor and
365 dorsal/superior parietal cortex (Fig. S1).

366

367 Regions sensitive to stimulus category were not only found in primary visual and auditory cortex
368 as expected but also in motor, pre-motor and dorsal/superior parietal cortex consistent with the
369 findings in Kret *et al.* 2011. In view of the literature on perception of emotion expressions in
370 either the face, voice or body it is not surprising that dorsal parietal cortex, pre- motor cortex and
371 anterior insula (Fig. S2) differentially respond to emotions as different emotions trigger different
372 adaptive actions (de Gelder B 2006; Grezes J *et al.* 2007; Pichon S *et al.* 2008; Whitehead JC and

373 JL Armony 2019). Interestingly, the interaction effect between modality and emotion also
374 revealed the retrosplenial cortex (Fig. S3). Retrosplenial cortex receives input from areas known
375 to play a role in processing salient information (prefrontal cortex, superior temporal sulcus,
376 precuneus, thalamus, and claustrum (Maddock RJ 1999). The retrosplenial cortex is associated
377 with navigation and memory functions and may be part of a network that conveys predatory
378 threat information to the cerebral cortex (de Lima MAX et al. 2019). A similar functionality may
379 be reflected in this activity here. Activity in this area is also consistent with the recent findings
380 that the retrosplenial cortex contributed to the accurate classification of fear stimuli. (Caruana F
381 et al. 2018).

382 To summarize, this univariate analysis including three stimulus modalities and four
383 emotion categories replicates some main findings about brain areas involved respectively in face,
384 body and voice expressions while also revealing parietal and motor area activity but does not
385 provide evidence for overlap in brain activity neither for modality nor emotion category.

386 387 *Multivariate analysis*

388 The goal of our multivariate approach was to reveal the areas that contribute most
389 strongly to an accurate distinction between the modalities and the stimulus emotion. Our results
390 of the MVPA searchlight show that modality type can be decoded from the sensory cortex and
391 that emotion can be decoded in STG for voice stimuli and in STS for face and body stimuli. We
392 found no overlap in brain regions that contribute to the classification of emotion when using
393 either the face, the body or the voice decoder (Fig. S4). Thus the brain areas that are involved in
394 discriminating between face, voice or body expressions irrespective of the emotion are different
395 from each other. Nor did we find evidence for neural activity overlap the other way around when
396 using a cross-modal emotion decoder and looking for possible brain areas common to the
397 modalities (Fig. S5). Lastly, we could not clearly identify regions where emotion could be
398 decoded with higher accuracy than modality (Fig. S6). To put it negatively, we could not clearly
399 identify supramodal emotion regions, defined by voxel patterns where emotion could be decoded
400 and that would show very similar voxel patterns for the same emotion in the different modalities.
401 This clearly indicated that the brain responds to facial, body and vocal emotion expression in a
402 unique fashion. Thus the overall direction pointed to by our results seems to be that that being
403 exposed to emotional stimuli (that are not task relevant and while performing a task requiring

404 attention to the other modality than that in which the stimulus is presented) is associated with
405 brain activity that shows both an emotion specific and a modality specific pattern.

406

407 ***ROI analysis***

408 To follow up on the whole-brain analysis we performed a detailed and specific analysis
409 of a number of ROIs. For the ROIs based on the localizer scans (early visual, auditory areas as
410 well as FFA and EBA) stimulus type could be decoded and these results are consistent with the
411 MVPA searchlight analysis. We also defined ROIs based on the literature with the goal of
412 comparing our results to findings about higher order areas that had been identified as
413 supramodal areas, mPFC and pSTS. This analysis revealed accurate decoding of stimulus type
414 but no evidence of supramodal representations.

415 Two previous MVPA studies addressed similar issues investigated in this study using
416 faces, bodies and voices (Peelen MV *et al.* 2010) or bodies and voices (Whitehead JC and JL
417 Armony 2019). The first study reported medial prefrontal cortex (MPFC) and posterior superior
418 temporal cortex as the two areas hosting supramodal emotion representations. These two areas
419 do not emerge in our MVPA searchlight analysis. To understand this very different result it is
420 important to remember that in their study participants were encouraged to actively evaluate the
421 perceived emotional states. The motivation was that explicit judgments would increase activity
422 in brain regions involved in social cognition and mental state attribution (Peelen MV *et al.*
423 2010). In contrast, the motivation of the present study was to approximate naturalistic perception
424 conditions. Our design and task were intended to promote spontaneous non-focused processes of
425 the target stimuli and did not promote amodal conceptual processing of the emotion content. It is
426 likely that using an explicit recognition task would have activated higher level representations
427 e.g. posterior STS, prefrontal cortex and posterior cingulate cortex that would then feedback to
428 lower level representations and modulate these towards more abstract representations (Schirmer
429 A and R Adolphs 2017). Note that no amygdala activity was reported in that study. The second
430 study using passive listening or viewing of still bodies and comparing fear and neutral
431 expressions also concludes about a distributed network of cortical and subcortical regions
432 responsive to fear in the two stimulus types they used (Whitehead JC and JL Armony 2019). Of
433 interest is their finding concerning the amygdalae and fear processing. While in their study this is
434 found across stimulus type for body and voice, the classification accuracy when restricted to the

435 amygdalae was not significantly above chance. They concluded that fear processing by the
436 amygdalae heavily relies on contribution of a distributed network of cortical and subcortical
437 structures.

438 Our findings suggest a different and a novel perspective on the role of the different
439 sensory systems and the different stimulus categories that convey affective signals in daily life
440 and fits with the role of emotions as seen from an evolutionary perspective. Our results are
441 compatible with an ecological and context sensitive approach to brain organization (Cisek P and
442 JF Kalaska 2010; Mobbs D et al. 2018) rather than with an exclusive focus on high order
443 representation of emotion categories grounded in concepts and verbal labels. For comparison, a
444 similar approach not to emotion concepts but to cognitive concepts was argued by Barsalou et al.
445 (Barsalou LW et al. 2003). This type of distributed organization or emotion representation may
446 be more akin to what is at stake in the daily experience of affective signals and how they are
447 flexibly processed for the benefit of ongoing action and interaction in a broader perspective of
448 emotions as states of action readiness (Frijda NH 2004).

449 Our results are relevant for two longstanding debates in the literature, one on the nature
450 and existence of abstract emotion representations and basic categories and the other on processes
451 of multisensory integration. Concerning the first one, our results have implications for the debate
452 on the existence of basic emotions (Ekman P 2016). Interestingly, modality specificity has rarely
453 been considered as part of the issue as the basic emotion debate largely focusses on facial
454 expressions. The present results might be viewed as evidence in favor of the view that basic
455 emotions traditionally understood as specific representations of a small number of emotions with
456 an identifiable brain correlate (Ekman P 2016) simply do not exist but that these are cognitive-
457 linguistic constructions (Russell JA 2003). On the one hand, our results are consistent with
458 critiques of basic emotions theories and meta-analysis (Lindquist KA *et al.* 2012) as we find no
459 evidence for representations of emotions in general or specific emotions within or across
460 modality and stimuli. Affective information processing thus appears not organized as
461 categorically, neither by conceptual emotion category nor by modality, as was long assumed.
462 Emotion representation, more so even than object representation, may possibly be sensory
463 specific or idiosyncratic (Peelen MV and PE Downing 2017) and neural representations may
464 reflect the circumstances under which specific types of signals are most useful or relevant rather
465 than abstract category membership. This pragmatic perspective is consistent with the notion that

466 emotions are closely linked to action and stresses the need for more detailed ethological behavior
467 investigations (de Gelder B 2016) .

468

469 While our study was not addressing issues of multisensory perception, our findings may
470 have implications for theories of multisensory integration. As has often been noted, human
471 emotion research by and far is still limited to the study of facial expressions. In line with the
472 dominant view studies extending the scope of facial expression based theories have primarily
473 been motivated to discover similarities across different modalities and stimulus types. Our group
474 has initiated studies that go beyond the facial expression and found rapid and automatic influence
475 of one type of expression on another (face and voice, (de Gelder B et al. 1999); face and body
476 (Meeren HK et al. 2005); face and scene (Righart R and B de Gelder 2008; Van den Stock J et al.
477 2013); body and scene, (Van den Stock J et al. 2014); auditory voice and tactile perception (de
478 Borst AW and B de Gelder 2017). These original studies and subsequent ones (Müller VI et al.
479 2012) investigated the impact of one modality on the other and targeted the area(s) where
480 different signals converge. For example, Müller et al. (Müller VI *et al.* 2012) report posterior
481 STS as the site of convergence of auditory and visual input systems and by implication, as the
482 site of multisensory integration. Note that here and in many other studies the amygdala and its
483 connectivity to face and voice areas emerges as a core structure involved in multisensory
484 integration. Current studies did not yet raise the question of sensory specificity of the
485 representations at stake in such cross-modal effects. Our findings stress the importance of
486 sensory specific representation and indicate that aside from loci of integration based presumably
487 on amodal representations, multisensory perception and integration seems to respect stimulus
488 complementarity in the vertical plane rather than convergence between different emotion signals
489 onto an abstract supramodal representation.

490

491 The motivation to include three stimulus categories led to some limitations of the current
492 design because two separate scanning sessions were required to have the desired number of
493 stimulus repetitions. To avoid that the comparison of representations of stimuli from two
494 different sessions was biased by a scan session effect, we did not include any results that referred
495 to differences or commonalities of stimuli from different sessions (e.g. bodies vs faces). A
496 second limitation is that the voice stimuli were not controlled for low level acoustic features over

497 different emotions and therefore results from the decoding of emotion from the voice stimuli
498 may partly have reflected these differences.

499 *Conclusions*

500 Our results show that the brain correlates of observing emotional signals from the body,
501 the face of the voice are specific for the modality as well as for the specific signal within the
502 same modality. Our results underscore the importance of considering the specific contribution of
503 each modality and each type of affective signal rather than only their higher order amodal
504 similarity. We suggest that future research may look into the differences between the emotion
505 signals and how they are complementary and not only at amodal similarity.

613 **Supplementary results**

614 *Univariate*

615 The F-map for emotion showed regions with different activation levels across emotions in
616 insular cortex, the superior temporal sulcus (STS), retrosplenial cortex, angular gyrus, and
617 superior medial occipital cortex, see Fig. S2.

618 We ran separate ANOVAs with factor ‘emotion’ for each stimulus type condition (voices, faces,
619 bodies; see Fig. S2), to identify regions that respond differentially across emotions within a
620 specific stimulus type. For the face condition, this revealed clusters in STS and retrosplenial
621 cortex. For the body condition, we observed regions in inferior temporal cortex and the
622 intraparietal sulcus (IPS). Finally, the ANOVA for the voice condition (for session 1 and session
623 2 separately) revealed auditory cortex, premotor cortex, IPS and angular gyrus.

624 We then tested for an interaction effect between the factors stimulus type and emotion. This
625 revealed clusters in the retrosplenial cortex, the dorsolateral prefrontal cortex (dLPFC), auditory
626 cortex and insula, see Fig. S3.

637 **Supplementary Figure 5**

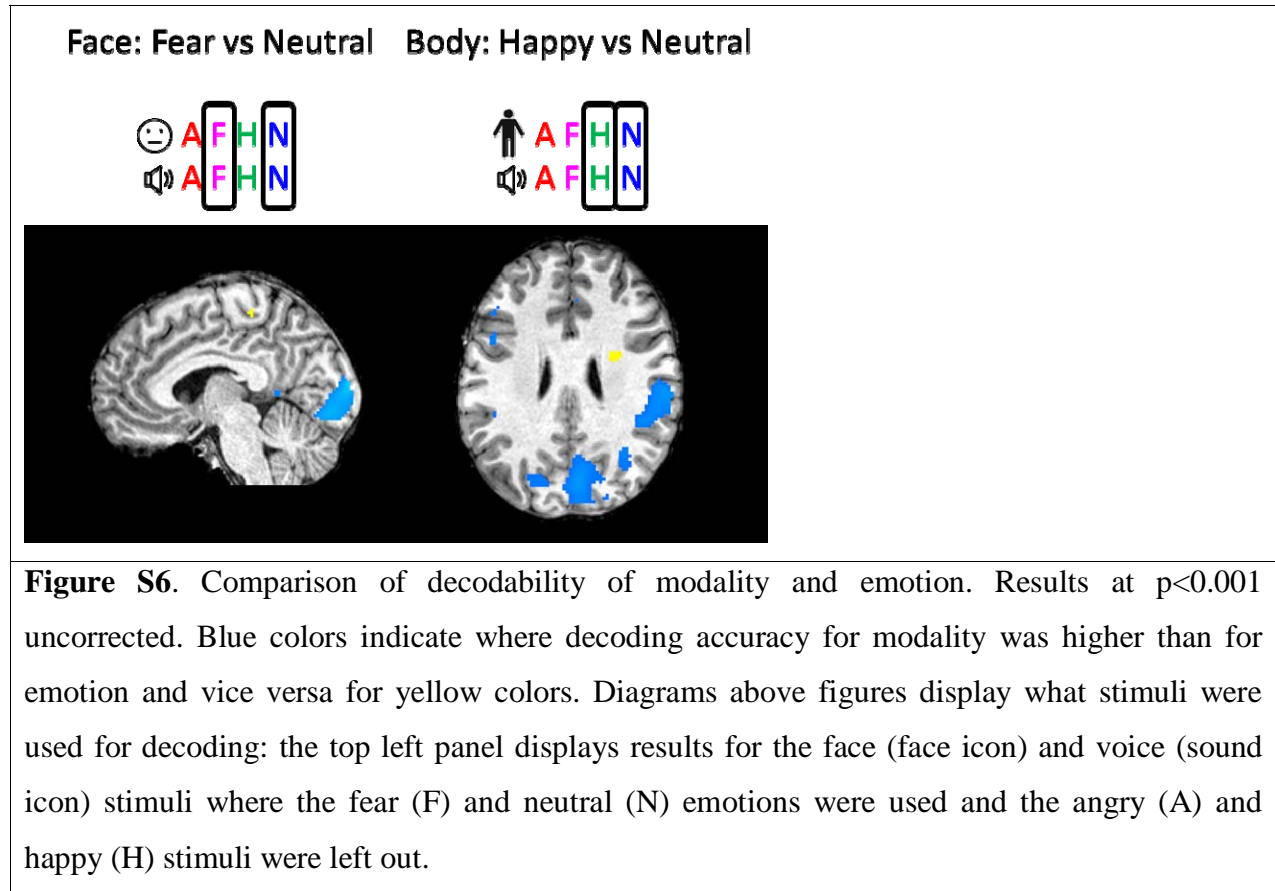

Figure S5. Crossmodal decoding of emotion. Red colors are for regions where emotion could be decoded from training on the body stimuli and tested on the voice stimuli from the body session. Green colors are for training on the voice stimuli from the body session and testing on the body stimuli. The same logic applies to stimuli from the face session (see top diagram). Results are at $t > 3.00$ ($p < 0.01$) uncorrected.
