- ABSTRACT

Shotgun metagenomics applied to archaeological feces (paleofeces) can bring new insights into the composition and functions of human and animal gut microbiota from the past. However, paleofeces often undergo physical distortions in archaeological sediments, making their source species difficult to identify on the basis of fecal morphology or microscopic features alone. Here we present a reproducible and scalable pipeline using both host and microbial DNA to infer the host source of fecal material. We apply this pipeline to newly sequenced archaeological specimens and show that we are able to distinguish morphologically similar human and canine paleofeces, as well as non-fecal sediments, from a range of archaeological contexts.

53 INTRODUCTION

The gut microbiome, located in the distal colon and primarily studied through the analysis of feces, 54 is the largest and arguably most influential microbial community within the body (Huttenhower et al., 55 2012). Recent investigations of the human microbiome have revealed that it plays diverse roles in 56 57 health and disease, and gut microbiome composition has been linked to a variety of human health states, including inflammatory bowel diseases, diabetes, and obesity (Kho and Lal, 2018). To investigate the gut 58 microbiome, metagenomic sequencing is typically used to reveal both the taxononomic composition (i.e., 59 which bacteria are there) and the functions the microbes are capable of performing (i.e., their potential 60 metabolic activities) (Sharpton, 2014). Given the importance of the gut microbiome in human health, there 61 is great interest in understanding its recent evolutionary and ecological history (Warinner and Lewis Jr, 62 2015; Davenport et al., 2017). 63

Paleofeces, either in an organic or partially mineralized (coprolite) state, present a unique opportunity 64 to directly investigate changes in the structure and function of the gut microbiome through time (Warinner 65 et al., 2015). Paleofeces are found in a wide variety of archaeological contexts around the world and are 66 generally associated with localized processes of dessication, freezing, or mineralization. Paleofeces can 67 range in size from whole, intact fecal pieces (Jiménez et al., 2012) to millimeter-sized sediment inclusions 68 identifiable by their high phosphate and fecal sterol content (Sistiaga et al., 2014). Although genetic 69 approaches have long been used to investigate dietary DNA found within human (Gilbert et al., 2008; 70 Poinar et al., 2001) and animal (Poinar et al., 1998; Hofreiter et al., 2000; Bon et al., 2012; Wood et al., 71 2016) paleofeces, it is only recently that improvements in metagenomic sequencing and bioinformatics 72 have enabled detailed characterization of their microbial communities (Tito et al., 2008, 2012; Warinner 73 et al., 2017). 74

However, before evolutionary studies of the gut microbiome can be conducted, it is first necessary 75 to confirm the host source of the paleofeces under study. Feces can be difficult to taxonomically assign 76 by morphology alone (Supplementary Note), and human and canine feces can be particularly difficult to 77 distinguish in archaeological contexts (Poinar et al., 2009). Since their initial domestication more than 78 12,000 years ago (Frantz et al., 2016), dogs have often lived in close association with humans, and it is not 79 uncommon for human and dog feces to co-occur at archaeological sites. Moreover, dogs often consume 80 diets similar to humans because of provisioning or refuse scavenging (Guiry, 2012), making their feces 81 difficult to distinguish based on dietary contents. Even well-preserved fecal material degrades over time, 82 83 changing in size, shape, and color (Figure 1). The combined analysis of host and microbial ancient DNA (aDNA) within paleofeces presents a potential solution to this problem. 84

Previously, paleofeces host source has been genetically inferred on the basis of PCR-amplified 85 mitochondrial DNA sequences alone (Hofreiter et al., 2000); however, this is problematic in the case of 86 dogs, which, in addition to being pets and working animals, were also eaten by many ancient cultures 87 (Clutton-Brock and Hammond, 1994; Rosenswig, 2007; Kirch and O'Day, 2003; Podberscek, 2009), and 88 thus trace amounts of dog DNA may be expected to be present in the feces of humans consuming dogs. 89 Additionally, dogs often scavenge on human refuse, including human excrement (Butler and Du Toit, 90 2002), and thus ancient dog feces could also contain trace amounts of human DNA, which could be 91 further inflated by PCR-based methods. 92

A metagenomics approach overcomes these issues by allowing a quantitative assessment of eukaryotic DNA at a genome-wide scale, including the identification and removal of modern human contaminant

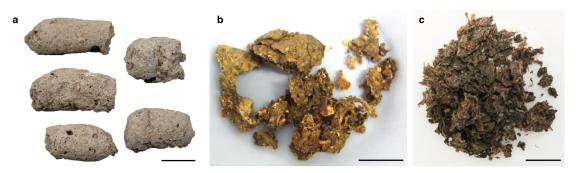

Figure 1. Examples of archaeological paleofeces analyzed in this study.

(a) H29-3, from Anhui Province, China, Neolithic period; (b) Zape 2, from Durango, Mexico, ca. 1300 BP; (c) Zape 28, from Durango, Mexico, ca. 1300 BP. Paleofeces ranged from slightly mineralized intact pieces (a) to more fragmentary organic states (b, c), and color ranged from pale gray (a) to dark brown (c). Each scale bar represents 2 cm.

DNA that could potentially arise during excavation or subsequent curation or storage. It also allows for the 95 microbial composition of the feces to be taken into account. Gut microbiome composition differs among 96 mammal species (Ley et al., 2008), and thus paleofeces microbial composition could be used to confirm and 97 authenticate host assignment. Available microbial tools, such as SourceTracker (Knights et al., 2011) and 98 FEAST (Shenhav et al., 2019), can be used to perform the source prediction of microbiome samples from 99 uncertain sources (sinks) using a reference dataset of source-labeled microbiome samples and, respectively, 100 Gibbs sampling or an Expectation-Maximization algorithm. However, although SourceTracker has been 101 widely used for modern microbiome studies and has even been applied to ancient gut microbiome data 102 (Tito et al., 2012) (Hagan et al., 2019), it was not designed to be a host species identification tool for 103 ancient microbiomes. 104

In this work we present a bioinformatics method to infer and authenticate the host source of paleofeces 105 from shotgun metagenomic DNA sequencing data: coproID (coprolite IDentification). coproID combines 106 the analysis of putative host ancient DNA with a machine learning prediction of the feces source based 107 on microbiome taxonomic composition. Ultimately, coproID predicts the host source of a paleofeces 108 specimen from the shotgun metagenomic data derived from it. We apply coproID to previously published 109 modern fecal datasets and show that it can be used to reliably predict their host. We then apply coproID to 110 a set of newly sequenced paleofeces specimens and non-fecal archaeological sediments and show that 111 it can discriminate between feces of human and canine origin, as well as between fecal and non-fecal 112 samples. 113

114 MATERIAL AND METHODS

115 Gut microbiome reference datasets

Previously published modern reference microbiomes were chosen to represent the diversity of potential paleofeces sources and their possible contaminants, namely human fecal microbiomes from Non-Westernized Human/Rural (NWHR), and Westernized Human/Urban (WHU) communities, dog fecal microbiomes, and soil samples (Table 1). Because the human datasets had been filtered to remove human genetic sequences prior to database deposition, we additionally generated new sequencing data from 118 fecal specimens from both NWHR and WHU populations (Table S5) in order to determine the average proportion and variance of host DNA in human feces.

Table 2. Archaeological samples

128 Sampling

Paleofeces specimens from Mexico were sampled in a dedicated aDNA cleanroom in the Laboratories 129 for Molecular Anthropology and Microbiome Research (LMAMR) at the University of Oklahoma, USA. 130 Specimens from China were sampled in a dedicated aDNA cleanroom at the Max Planck Institute for 131 the Science of Human History (MPI-SHH) in Jena, Germany. All other specimens were first sampled at 132 the Max Planck Institute for Evolutionary Anthropology (MPI-EVA) in Leipzig, Germany before being 133 transferred to the MPI-SHH for further processing. Sampling was performed using a sterile stainless 134 steel spatula or scalpel, followed by homogenization in a mortar and pestle, if necessary. Because the 135 specimens from Xiaosungang, China were very hard and dense, a rotary drill was used to section the 136 137 coprolite prior to sampling. Where possible, fecal material was sampled from the interior of the specimen rather than the surface. Specimens from Molphir and Leipzig were received suspended in a buffer of 138 trisodium phosphate, glycerol, and formyl following screening for parasite eggs using optical microscopy. 139 For each paleofeces specimen, a total of 50-200 mg was analyzed. 140

Modern feces were obtained under informed consent from Boston, USA (WHU) (Wibowo et al., 2019) from a long-term (>50 years) type 1 diabetes cohort, and from villages in Burkina Faso (NWHR) as part of broader studies on human gut microbiome biodiversity and health-associated microbial communities. Feces were collected fresh and stored frozen until analysis. A total of 250 mg was analyzed for each fecal specimen,

146 **DNA Extraction**

For paleofeces and sediment samples, DNA extractions were performed using a silica spin column 147 protocol (Dabney et al., 2013) with minor modifications in dedicated aDNA cleanrooms located at 148 LMAMR (Mexican paleofeces) and the MPI-SHH (all other paleofeces). At LMAMR, the modifications 149 followed those of protocol D described in (Hagan et al., 2019). DNA extractions at the MPI-SHH were 150 similar, but omitted the initial bead-beating step, and a single silica column was used per sample instead of 151 two. Additionally, to reduce centrifugation errors, DNA extractions performed at the MPI-SHH substituted 152 the column apparatus from the High Pure Viral Nucleic Acid Large Volume Kit (Roche, Switzerland) 153 in place of the custom assembled Zymo-reservoirs coupled to MinElute (Qiagen) columns described 154 in (Dabney et al., 2013). At both locations, non-template negative extraction controls were processed 155 alongside samples to identify and monitor potential contamination. 156 For modern feces, DNA was extracted from Burkina Faso fecal samples using the AllPrep PowerViral 157

¹⁵⁷ DNA/RNA Qiagen kit at Centre MURAZ Research Institute in Burkina Faso. DNA was extracted from ¹⁵⁸ the Boston fecal material using the ZymoBIOMICS DNA Miniprep Kit (D4303) at the Joslin Diabetes ¹⁶⁰ Center as described in (Wibowo et al., 2019).

161 Library preparation and Sequencing

For paleofeces and sediment samples, double-stranded, dual-indexed shotgun Illumina libraries were 162 constructed following (Meyer and Kircher, 2010) using either the NEBNext DNA Library Prep Master 163 Set (E6070) kit (Hagan et al., 2019; Mann et al., 2018) for the Mexican paleofeces or individually 164 purchased reagents (Mann et al., 2018) for all other samples. Following library amplification using a 165 Kapa HiFi Uracil+ polymerase or Agilent Pfu Turbo Cx Hotstart polymerase, the libraries were purified 166 using a Qiagen MinElute PCR Purification kit and quantified using either a BioAnalyzer 2100 with High 167 Sensitivity DNA reagents or an Agilent Tape Station D1000 Screen Tape kit. The Mexican libraries 168 were pooled in equimolar amounts and sequenced on an Illumina HiSeq 2000 using 2x100 bp paired-end 169 sequencing. All other libraries were pooled in equimolar amounts and sequenced on an Illumina HiSeq 170 4000 using 2x75 bp paired-end sequencing. 171

For modern NWHR feces, double-stranded, dual-indexed shotgun Illumina libraries were constructed 172 in a dedicated modern DNA facility at LMAMR. Briefly, after DNA quantification using a Qubit dsDNA 173 Broad Range Assay Kit, DNA was sheared using a QSonica Q800R in 1.5mL 4°C cold water at 50% 174 amplitude for 12 minutes to aim for a fragment size between 400 and 600 bp. Fragments shorter than 175 150 bp were removed using Sera-Mag SpeedBeads and a Alpaqua 96S Super Magnet Plate. End-repair 176 and A-tailing was performed using the Kapa HyperPrep EndRepair and A-Tailing Kit, and Illumina 177 sequencing adapters were added. After library quantification, libraries were dual-indexed in an indexing 178 179 PCR over four replicates, pooled, and purified using the SpeedBeads. Libraries were quantified using the Agilent Fragment Analyzer, pooled in equimolar ratios, and size-selected using the Pippin Prep to 180 a target size range of 400-600 bp. Libraries were sequenced on an Illumina NovaSeq S1 using 2x150 181

bp paired-end sequencing at the Oklahoma Medical Research Foundation Next-Generation Sequencing 182 Core facility. Modern WHU libraries were generated using the NEBNext DNA library preparation kit 183 following manufacturer's recommendations, after fragmentation by shearing for a target fragment size of 184 350 bp as described in (Wibowo et al., 2019). The libraries were then pooled and sequenced by Novogene

185

on a NovaSeq S4 using 2x150 bp paired-end sequencing. 186

Proportion of host DNA in gut microbiome 187

Because it is standard practice to remove human DNA sequences from metagenomics DNA sequence files 188 before data deposition into public repositories, we were unable to infer the proportion of human DNA 189 in human feces from publicly available data. To overcome this problem, we measured the proportion 190 of human DNA in two newly generated fecal metagenomics datasets from Burkina Faso (NWHR) and 191 Boston, U.S.A. (WHU) (Table S5). To measure the proportion of human DNA in each fecal dataset, 192 we used the Anonymap pipeline (Borry, 2019a) to perform a mapping with Bowtie 2 (Langmead and 193 Salzberg, 2012) with the parameters --very-sensitive -N 1 after adapter cleaning and reads 194 trimming for ambiguous and low-quality bases with a QScore below 20 by AdapterRemoval v2 (Schubert 195 et al., 2016). To preserve the anonymity of the donors, the sequences of mapped reads were then replaced 196 by Ns thus anonymizing the alignment files. We obtained the proportion of host DNA per sample by 197 dividing the number of mapped reads by the total number of reads in the sample. The proportion of host 198 DNA in dog feces was determined from the published dataset Coelho et al. (2018) as described above, but 199 without the anonymization step. 200

coproID pipeline 201

Data were processed using the coproID pipeline v1.0 (Figure 2) (DOI: 10.5281/zenodo.2653757) written 202 using Nextflow (Di Tommaso et al., 2017) and made available through nf-core (Ewels et al., 2019). 203 Nextflow is a Domain Specific Language designed to ensure reproducibility and scalability for scientific 204 pipelines, and nf-core is a community-developed set of guidelines and tools to promote standardization 205 and maximum usability of Nextflow pipelines. 206

coproID consists of 5 different steps: 207

Preprocessing 208

Fastq sequencing files are given as an input. After quality control analysis with FastQC (Andrews et al., 209

2010), raw sequencing reads are cleaned from sequencing adapters and trimmed from ambiguous and 210

low-quality bases with a QScore below 20, while reads shorter than 30 base pairs are discarded using 211

AdapterRemoval v2. By default, paired-end reads are merged on overlapping base pairs. 212

Mapping 213

The preprocessed reads are then aligned to each of the target species genomes (source species) by Bowtie2 214 with the --very-sensitive preset while allowing for a mismatch in the seed search (-N 1). 215

When running coproID with the ancient DNA mode (--adna), alignments are filtered by PMDtools 216 (Skoglund et al., 2014) to only retain reads showing post-mortem damages (PMD). PMDtools default 217 settings are used, with specified library type, and only reads with a PMDScore greater than three are kept. 218

Computing host DNA content 219

Next, filtered alignments are processed in Python using the Pysam library (pysam developers, 2018). 220 Reads matching above the identity threshold of 0.95 to multiple host genomes are flagged as common 221 reads reads commons whereas reads mapping above the identity threshold to a single host genome are 222

flagged as genome-specific host reads reads spec g to each genome g. Each source species host DNA is 223

normalized by genome size and gut microbiome host DNA content such as: 224

$$NormalizedHostDNA(source species) = \frac{\sum length(reads_{spec g})}{genome_{g \ length} \cdot endo_{g}}$$
(1)

where for each species of genome g, $\sum length(reads_{spec g})$ is the total length of all reads_{spec g}, 225 genome_{g length} is the size of the genome, and $endo_g$ is the host DNA proportion in the species gut 226 microbiome. 227

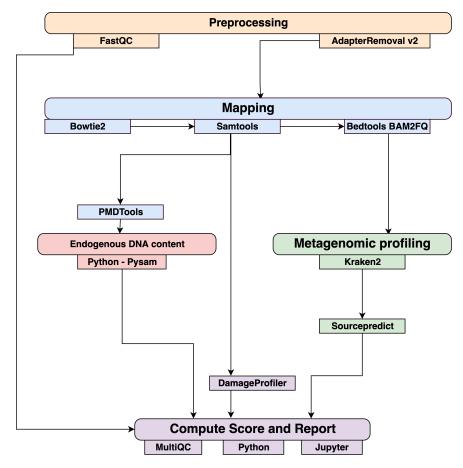

Figure 2. Workflow schematic of the coproID pipeline.

coproID consists of five steps: *Preprocessing* (orange), *Mapping* (blue), *Computing host DNA content for each metagenome* (red), *Metagenomic profiling* (green), and *Reporting* (violet). Individual programs (squared boxes) are colored by category(rounded boxes)

228

Afterwards, an host DNA ratio is computed for each source species such as:

$$NormalizedRatio(source species) = \frac{NormalizedHostDNA(source species)}{\sum NormalizedHost DNA (source species)}$$
(2)

where $\sum NormalizedHost DNA$ (source species) is the sum of all source species Normalized Host DNA.

231 Metagenomic profiling

Adapter clipped and trimmed reads are given as an input to Kraken 2 (Wood and Salzberg, 2014). Using 232 the MiniKraken2_v2_8GB database (2019/04/23 version), Kraken 2 performs the taxonomic classification 233 to output a taxon count per sample report file. All samples taxon count are pooled together in a taxon 234 counts matrix with samples in columns, and taxons in rows. Next, Sourcepredict (Borry, 2019b) is used to 235 predict the source based on each microbiome sample taxon composition. Using dimension reduction and 236 K-Nearest Neighbors (KNN) machine learning trained with reference modern gut microbiomes samples 237 (Table 1), Sourcepredict estimates a proportion *prop_{microbiome}*(source species) of each potential source 238 species, here Human or Dog, for each sample. 239

240 **Reporting**

For each filtered alignment file, the DNA damage patterns are estimated with DamageProfiler (Peltzer and Neukamm, 2019). The information from the host DNA content and the metagenomic profiling are

gathered for each source in each sample such as:

 $proportion(source \ species) = NormalizedRatio(source \ species) \cdot prop_{microbiome}(source \ species)$

Finally, a summary report is generated including the damage plots, a summary table of the coproID metrics, and the embedding of the samples in two dimensions by Sourcepredict. coproID is available on GitHub at the following address: **github.com/nf-core/coproid**.

244 **RESULTS**

We analyzed 21 archaeological samples with coproID v1.0 to estimate their source using both host DNA and microbiome composition.

247 Host DNA in reference gut microbiomes

Before analyzing the archaeological samples, we first tested whether there is a per-species difference in 248 host DNA content in modern reference human and dog feces. With Anonymap, we computed the amount 249 of host DNA in each reference gut microbiome (Table S1). We found that the median percentages of 250 host DNA in NWHR, WHU, and Dog (Figure 3) are significantly different at alpha = 0.05 (Kruskal-251 Wallis H-test = 117.40, p value < 0.0001). We confirmed that there is a significant difference of median 252 percentages of host DNA between dogs and NWHR, as well as dogs and WHU, with Mann-Whitney U 253 tests (Table 3) and therefore corrected each sample by the mean percentage of gut host DNA found in 254 each species, 1.24% for humans ($\mu_{NWHR} = 0.85$, $\sigma_{NWHR} = 2.33$, $\mu_{WHU} = 1.67$, $\sigma_{WHU} 0.81$), and 0.11% 255 for dogs ($\sigma_{dog} = 0.16$) (equation 1, table S1). This information was used to correct for the amount of host 256 DNA found in paleofeces. 257

Comparison	Mann-Whitney U test	p value
Dog vs NWHR	3327.0	< 0.0001
Dog vs WHU	41.0	< 0.0001
NWHR vs WHU	370.0	< 0.0001
Dog vs Human	3368.0	< 0.0001

Table 3. Statistical comparison of reference gut host DNA content. Mann–Whitney U test for independent observations . *H*0: the distributions of both populations are equal.

²⁵⁸ The effect of PMD filtering on host species prediction

Because aDNA accumulates damage over time (Briggs et al., 2007), we could use this characteristic to 259 filter for reads carrying these specific damage patterns using PMDtools, and therefore reduce modern 260 contamination in the dataset. We applied PMD filtering to our archaeological datasets, and for each, 261 compared the predicted host source before and afterwards. The predicted host sources did not change after 262 the DNA damage read filtering, but some became less certain (Figure 4). Most samples are confidently 263 assigned to one of the two target species, however some samples previously categorized as humans now lie 264 in the uncertainty zone. This suggests that PMDtools filtering lowered the modern human contamination 265 which might have originated from sample excavation and manipulation. 266

The trade-off of PMDtools filtering is that it reduces the assignment power by lowering the number of reads available for host DNA based source prediction by only keeping PMD-bearing reads. This loss is greater for well-preserved samples, which may have relatively few damaged reads (< 15% of total). Ultimately, applying damage filtering can make it more difficult to categorize samples on the sole basis of host DNA content, but it also makes source assignments more reliable by removing modern contamination.

273 Source microbiome prediction of reference samples by Sourcepredict

To help resolve ambiguities related to the host aDNA present within a sample, we also investigated gut

- ²⁷⁵ microbiome composition as an additional line of evidence to better predict paleofeces source. After ²⁷⁶ performing taxonomic classification using Kraken2, we computed a sample pairwise distance matrix from
- the species counts. With the t-SNE dimension reduction method, we embedded this distance matrix in

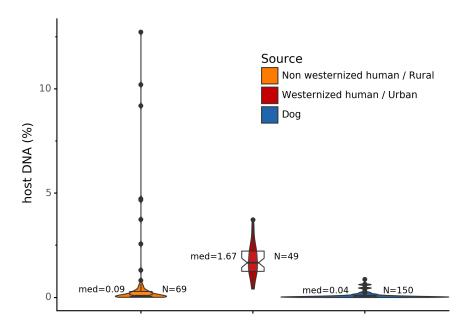

Figure 3. Gut microbiome host DNA content.

The median percentage of host DNA in the gut microbiome and the number of samples in each group are displayed besides each boxplot.

²⁷⁸ two dimensions to visualize the sample positions and sources (Figure 5a). We then used a KNN machine

²⁷⁹ learning classifier on this low dimension embedding to predict the source of gut microbiome samples.

²⁸⁰ This trained KNN model reached a test accuracy of 0.94 on previously unseen data (figure 5b).

281 Embedding of archaeological samples by Sourcepredict

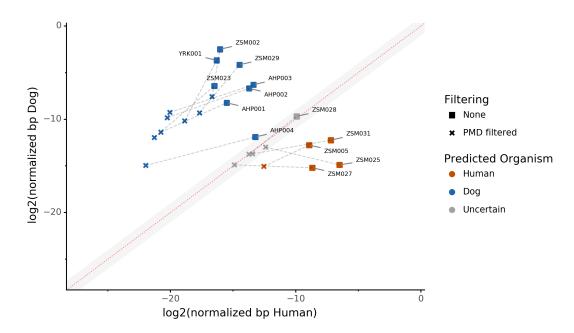

We used this trained KNN model to predict the sources of the 20 paleofeces and coprolite archaeological samples, after embedding them in a two-dimensional space (Figure 6). Based on their microbiome composition data, Sourcepredict predicted 2 paleofeces samples as dogs, 8 paleofeces samples as human,

²⁸⁵ 2 paleofeces samples and 4 archaeological sediments as soil, while the rest were predicted as unknown

286 (Table S2).

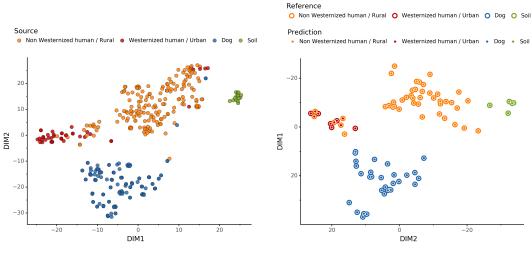

287 coproID prediction

Combining both PMD-filtered host DNA information and microbiome composition, coproID was able 288 to reliably categorize 7 of the 13 paleofeces samples, as 5 human paleofeces and 2 canine paleofeces, 289 whereas all of the non-fecal archaeological sediments were flagged as unknown. (Figure 8). This 290 confirms the original archaeological source hypothesis for five samples (ZSM005, ZSM025, ZSM027, 291 ZSM028, ZSM031) and specifies or rejects the original archaeological source hypothesis for the two 292 others (YRK001, AHP004). The 6 paleofeces samples not reliably identified by coproID have a conflicting 293 source proportion estimation between host DNA and microbiome composition (Figure 7a and 7b and 294 Table S3). Specifically, paleofeces AHP001, AHP002, and AHP003 show little predicted gut microbiome 295 preservation, and thus have likely been altered by taphonomic (decomposition) processes. Paleofeces 296 ZSM002, ZSM023, and ZSM029, by contrast, show good evidence of both host and microbiome 297 preservation, but have conflicting source predictions based on host and microbiome evidence. Given that 298 subsistence is associated with gut microbiome composition, this conflict may be related to insufficient gut 299 microbiome datasets available for non-Westernized dog populations (Hagan et al., 2019). 300

The \log_2 of the human *NormalizedHostDNA* is graphed against the \log_2 of the dog *NormalizedHostDNA*. Squares represent samples before filtering by PMD, whereas crosses represent samples after filtering by PMD. Dotted lines show the correspondence between samples. The red diagonal line marks the boundary between the two species, and the grey shaded area indicates a zone of species uncertainty ($\pm 1 \log_2 FC$) due to insufficient genetic information.

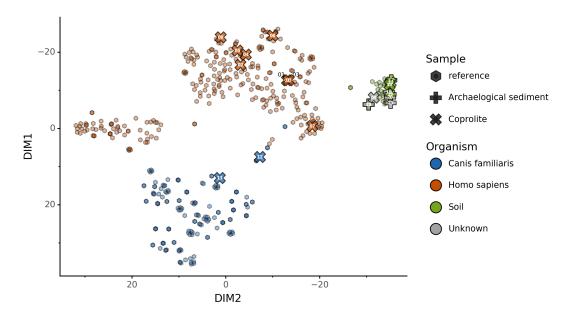

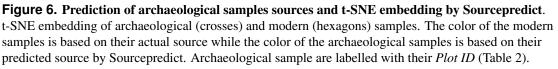

Figure 5. Embedding of reference modern gut microbiomes.

(a) t-SNE embedding of the species composition based on sample pairwise Weighted Unifrac distances for training modern gut microbiomes training samples. Samples are colored by their actual source. (b) t-SNE embedding of the species composition based on sample pairwise Weighted Unifrac distances for source prediction of modern test samples. The outer circle color is the actual source of a sample, while the inner circle color is the predicted sample source by Sourcepredict.

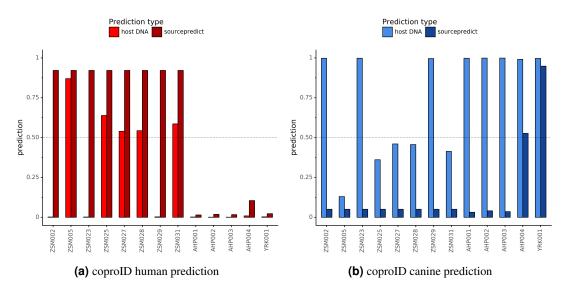

Figure 7. Host DNA and Sourcepredict source prediction for paleofeces samples. The vertical bar represents the predicted proportion by host DNA (lighter fill) or by Sourcepredict (darker fill). The horizontal dashed line represents the confidence threshold to assign a source to a sample.

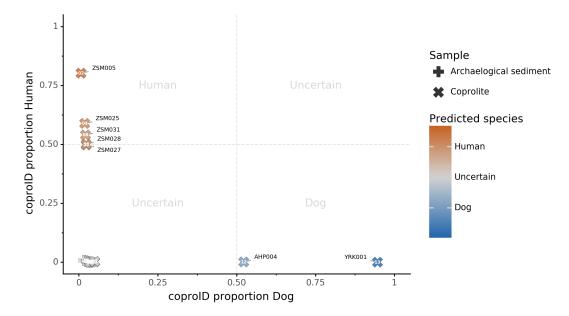

Figure 8. coproID source prediction.

Predicted human proportion graphed versus predicted canine proportion. Samples are colored by their predicted sources proportions. Samples with a low canine and human proportion are not annotated.

301 DISCUSSION

Paleofeces are the preserved remains of human or animal feces, and although they typically only preserve 302 under highly particular conditions, they are nevertheless widely reported in the paleontological and 303 archaeological records and include specimens ranging in age from the Paleozoic era (Dentzien-Dias et al., 304 2013) to the last few centuries. Paleofeces can provide unprecedented insights into animal health and 305 diet, parasite biology and evolution, and the changing ecology and evolution of the gut microbiome. 306 However, because many paleofeces lack distinctive morphological features, determining the host origin of 307 a paleofeces can be a difficult problem (Poinar et al., 2009). In particular, distinguishing human and canine 308 paleofeces can be challenging because they are often similar in size and shape, they tend to co-occur 309 at archaeological sites and in midden deposits, and humans and domesticated dogs tend to eat similar 310 diets (Guiry, 2012). We developed coproID to aid in identifying the source organism of archaeological 311 paleofeces and coprolites by applying a combined approach relying on both ancient host DNA content 312 and gut microbiome composition. 313

coproID addresses several shortcomings of previous methods. First, we have included a DNA damage-314 filtering step that allows for the removal of potentially contaminating modern human DNA, which may 315 otherwise skew host species assignment. We have additionally measured and accounted for significant 316 differences in the mean proportion of host DNA found in dog and human feces, and we also accounted for 317 differences in host genome size between humans and dogs when making quantitative comparisons of host 318 DNA. Then, because animal DNA recovered from paleofeces may contain a mixture of host and dietary 319 DNA, we also utilize gut microbiome compositional data to estimate host source. We show that humans 320 and dogs have distinct gut microbiome compositions, and that their feces can be accurately distinguished 321 from each other and from non-feces using a machine learning classifier after data dimensionality reduction. 322 Taken together, these approaches allow a robust determination of paleofeces and coprolite host source, that 323 takes into account both modern contamination, microbiome composition, and postmortem degradation. 324

In applying coproID to a set of 20 archaeological samples of known and/or suspected origin, all 7 non-fecal sediment samples were accurately classified as "uncertain" and were grouped with soil by Sourcepredict. For the 13 paleofeces and coprolites under study, 7 exhibited matching host and microbiome source assignments and were confidently classified as either human (n=5) or canine (n=2). Importantly, one of the samples confidently identified as canine was YRK001, a paleofeces that had been recovered from an archaeological chamber pot in the United Kingdom, but which showed an unusual diversity of parasites inconsistent with human feces, and therefore posed issues in host assignation.

For the remaining six unidentified paleofeces, three exhibited poor microbiome preservation and were 332 classified as "uncertain", while the other three were well-preserved but yielded conflicting host DNA 333 and microbiome assignments. These three samples, ZSM002, Z023, and ZSM029, all from prehistoric 334 Mexico, all contain high levels of canine DNA, but have gut microbiome profiles within the range of 335 NWHR humans. Classified as "uncertain", there are two possible explanations for these samples. First, 336 these feces could have originated from a human who consumed a recent meal of canine meat. Dogs 337 were consumed in ancient Mesoamerica (Clutton-Brock and Hammond, 1994; Santley and Rose, 1979; 338 Rosenswig, 2007; Wing, 1978), but further research on the expected proportion of dietary DNA in human 339 feces is needed to determine whether this is a plausible explanation for the very high amounts of canine 340 DNA (and negligible amounts of human DNA) observed. 341

Alternatively, these feces could have originated from a canine whose microbiome composition is 342 shifted relative to that of the reference metagenomes used in our training set. It is now well-established 343 that subsistence mode strongly influences gut microbiome composition in humans Obregon-Tito et al. 344 (2015), with NWHR and WHU human populations largely exhibiting distinct gut microbiome structure, 345 as seen in (Figure 5a. To date, no gut microbiome data is available from non-Westernized dogs, and all 346 reference dog metagenome data included as training data for coproID originated from a single study of 347 labrador retrievers and beagles Coelho et al. (2018). Future studies of non-Westernized rural dogs are 348 needed to establish the full range of gut microbial diversity in dogs and to more accurately model dog gut 349 microbiome diversity in the past. Given that all confirmed human paleofeces in this study falls within 350 the NWHR cluster (Figure 6), we anticipate that our ability to accurately classify dog paleofeces and 351 coprolites as canine (as opposed to "uncertain") will improve with the future addition of non-Westernized 352 rural dog metagenomic data. 353

354 CONCLUSIONS

We developed an open-source, documented, tested, scalable, and reproducible method to perform the identification of archaeological paleofeces and coprolite source. By leveraging the information from host DNA and microbiome composition, we were able to identify and/or confirm the source of newly sequenced paleofeces. We demonstrated that coproID can provide useful assistance to archaeologists in identifying authentic paleofeces and inferring their host. Future work on dog gut microbiome diversity,

especially among rural, non-Westernized dogs, may help improve the tool's sensitivity even further.

361 ACKNOWLEDGMENTS

We thank David Petts, Zdeněk Tvrdý, Susanne Stegmann-Rajtár, and Zuzana Rajtarova for contributing archaeological samples to this study. We thank the Guildford Museum (Guildford Borough Council

Heritage Service) and Catriona Wilson for allowing us to analyze the chamber pot paleofeces sample

³⁶⁵ from Surrey, UK. The sample from Derragh, Ireland was excavated by Discovery Programme, an all-

³⁶⁶ Ireland public center of archaeological research supported by the Heritage Council, during field work

in 2003 to 2005 as part of the Lake Settlement Project. This work was supported by the US National

³⁶⁸ Institutes of Health R01GM089886 (to C.W. and C.M.L.), the Deutsche Forschungsgemeinschaft EXC

³⁶⁹ 2051 #390713860 (to C.W.), and the Max Planck Society. Author contributions were as follows: M.B.

and C.W. designed the research. B.C., M.C.W., D.J., C.A.H., and R.W.H. performed the laboratory

experiments. M.B., C.J., M.C.W, and T.H. analyzed the data. M.B. developed the bioinformatics tools

and pipelines. C.W., K.R., K.B., L.G.F., A.P., A.K., W.T.J.K, R.P., I.S., D.S.G., J.Y., T.S.K, N.M., H.C.,

and C.M.L. provided materials and resources. C.W., A.He., and A.Hü. supervised the research. M.B.

³⁷⁴ wrote the article, with input from C.W., A.Hü., KR and the other co-authors.

375 DATA AND CODE AVAILABILITY

Genetic data are available in the European Nucleotide Archive (ERA) under the accessions PRJEB33577 and PRJEB35362. The code for the analysis is available at github.com/maxibor/coproid-article.
