Running Title: DHA Supplementation Augments Lupus Nephritis Remission

Keywords: NZBWF1 mouse, lupus nephritis, omega-3 fatty acid, prednisone, cyclophosphamide

Abstract

Background: Managing lupus nephritis (LN) remains challenging due to relapses after immunosuppressive induction and toxicity from long-term glucocorticoid (GC) maintenance therapy. Dietary omega-3 fatty acids prevent LN onset in preclinical models, but their role in maintaining remission post-induction remains unstudied.

Methods: The silica-accelerated LN (SALN) model using lupus-prone NZBWF1 mice was used to evaluate how docosahexaenoic acid (DHA), an omega-3 fatty acid, influenced LN remission durability after cyclophosphamide (CYC) induction, alone or with a modest dose of prednisone (PDN). Mice received intranasal silica weekly from 8 to 11 weeks. After LN developed at 21 weeks, groups were injected weekly with CYC (HED=31 mg/d) or vehicle (VEH) for 8 weeks, during which CYC groups also received control, DHA (HED=5 g/d), PDN (HED=9 mg/d), or DHA+PDN diets. Disease activity was monitored via proteinuria, autoantibodies, and survival. Six weeks post-CYC, multi-organ histopathology and immunohistochemistry were assessed.

Results: VEH-treated mice developed severe LN with early death. CYC slowed disease temporarily in control- and PDN-fed mice; relapses occurred after cessation. DHA or DHA+PDN increased tissue omega-3 levels and prolonged remission. PDN and DHA monotherapies and co-therapy improved survival, but DHA+PDN was most effective at sustaining remission as reflected by reduced histopathologic markers of lupus severity in the kidney, spleen, lung, and brain.

Conclusion: DHA+PDN optimally maintained LN remission after CYC, supporting omega-3 supplementation as a potential GC-sparing strategy to improve immunosuppressive therapy and prevent relapses.

Highlights

- Frequent post-immunosuppressive treatment flares and the toxicity from long-term maintenance therapy with glucocorticoids (GCs) limit effective management of lupus nephritis (LN).

- The silica-accelerated lupus nephritis (SALN) model in NZBWF1 mice mimics the gene–environment interactions of human SLE and LN, enabling synchronized and efficient preclinical studies of drug and nutritional interventions.

- Short-term immunosuppressive therapy with cyclophosphamide (CYC) induces temporary remission of LN and extrarenal inflammation and autoimmunity in SALN mice, which can be extended through monotherapy with either dietary supplementation with omega-3 docosahexaenoic acid (DHA) or a moderate dose of the GC prednisone (PDN).

- Combining maintenance therapy with DHA and PDN proved more effective than monotherapy in enhancing the durability of post-CYC LN remission and in reducing extrarenal inflammation and autoimmunity in the lung, spleen, and brain.

- These preclinical findings show that dietary supplementation with omega-3s such as DHA may offer a safe, affordable, GC-sparing adjunctive option for managing LN and SLE.

Introduction

Systemic lupus erythematosus (SLE) is a severe, multifactorial autoimmune disease that causes immune-mediated damage across multiple organs, including the skin, spleen, lungs, brain, and kidneys [1-4]. Its onset and progression are driven by complex gene–environment interactions and characterized by recurrent flares that substantially increase morbidity and the risk of irreversible organ damage. Lupus nephritis (LN) is a major complication that can progress to end-stage renal disease when inadequately controlled [1,4,5].

Conventional therapy for advanced proliferative LN (Class III or higher) typically follows a two-phase paradigm to quell renal inflammation, suppress autoimmunity, and promote durable remission [6]. The induction phase uses potent immunosuppressants such as cyclophosphamide (CYC) to achieve LN remission, followed by a maintenance phase to sustain remission and limit cumulative damage, using tapered doses of glucocorticoids (GCs) like prednisone (PDN) together with other drugs, such as mycophenolate mofetil [7,8]. Although these regimens are effective, GCs have myriad adverse effects—including serious infections, fatigue, metabolic and cardiovascular complications, type 2 diabetes, bone loss, reproductive and hepatic toxicity, and bone marrow suppression—that pose ongoing challenges in selecting drugs, determining treatment duration, and designing tapering strategies. Importantly, prematurely reducing or stopping maintenance therapy significantly increases the risk of relapse and flaring [9]. Recent advances in biologic and targeted therapies have expanded the LN armamentarium and can theoretically reduce GC exposure [6], yet their high cost and restricted availability remain significant barriers for the ever-growing population of patients without adequate insurance coverage [10].

There is increasing recognition that dietary modulation has value as a complementary strategy for

treating persistent inflammatory and autoimmune diseases, an emphasis reflected in initiatives such

as the NIH Strategic Blueprint on Precision Nutrition and the NIH-Wide Strategic Plan for

Autoimmune Disease Research [11,12]. Consistent with this recognition, many clinicians are

adopting dietary counseling into routine SLE care [13], and there is particular interest in precision

nutrition approaches that target the tissue lipidome by increasing consumption of omega-3

polyunsaturated fatty acids (PUFAs) [14-16]. Western dietary patterns, typically enriched in omega-

6 PUFAs such as linoleic acid (LA) from seed oils and arachidonic acid (ARA), formed by LA

elongation and found in animal fat, are associated with worsening of chronic inflammatory states

driven by ARA-derived metabolites [17]. In contrast, diets or supplements rich in marine-derived

omega-3 PUFAs—especially docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA),

sourced from microalgae, krill, or cold-water fish oils—can attenuate inflammatory responses and

promote their resolution [18].

A well-established literature links DHA and EPA intake of 1 to 5 g/day to favorable changes in

cardiovascular risk biomarkers and outcomes, as well as clinical improvement in inflammatory

rheumatologic conditions [19-23]. Regulatory investigations confirm that combined EPA+DHA

supplementation up to 5 g/day is safe for adults [24]. This dosage costs approximately $2/day when

purchased over the counter as a stable, high-quality supplement [25]. Mechanistically, omega-3s are

rapidly incorporated into immune cell membranes and act by i) altering membrane fluidity and lipid

raft organization to modulate receptor clustering and downstream signaling, ii) dampening

activation of proinflammatory transcription factors such as NF-κB while activating others with anti-

inflammatory actions like PPAR-γ, iii) reducing proinflammatory gene expression and cytokine

production, iv) suppressing production of inflammatory ARA-derived leukotrienes, prostaglandins,

and thromboxanes by competitive inhibition, and v) serving as substrates for specialized pro-

resolving mediators that drive active resolution of inflammation and restoration of tissue homeostasis [15,18,26]. Remarkably, many of these molecular targets overlap with or complement those of GCs [27], offering promise of safe adjunctive omega-3 supplementation to reduce flare frequency and slow kidney damage in individuals with lupus.

Preclinical investigations in lupus-prone mouse strains over four decades have consistently shown that omega-3-enriched diets suppress or delay autoimmune responses, reduce the onset and progression of LN, and improve survival rates [28-53]. In contrast, diets high in saturated fats, monounsaturated fats, and omega-6s, typical of ultraprocessed foods, have been linked to increased autoimmunity and kidney damage. Building upon this base, our lab has developed an efficient gene–environment interaction model in autoimmune-prone NZBWF1 mice, in which short-term, repeated intranasal instillations of crystalline silica ($cSiO_2$), a well-known environmental trigger of lupus, accelerate systemic autoimmunity and LN by approximately three months, providing a highly reproducible silica-accelerated LN (SALN) platform [54,55]. Within this model, oral supplementation with microalgal oil–derived DHA at human-equivalent doses (HEDs) of 2 to 5 g/day provides broad dose-dependent protection, including: i) suppression of inflammatory, type I interferon, and autoimmune gene networks in the lung; ii) reduction of B- and T-cell infiltration and ectopic lymphoid structure (ELS) formation; iii) lowering of pulmonary and systemic autoantibody (AAb) titers; iv) prevention of glomerulonephritis; and v) prolonging survival [26,56-63]. Collectively, these studies position DHA supplementation as a suitable adjunctive strategy for reducing GC use during LN treatment.

The SALN model has been further leveraged to assess the preventive effectiveness of the PDN, demonstrating that oral pretreatment with a medium PDN dose (14 mg/day HED) substantially reduced $cSiO_2$-induced pulmonary ELS formation, AAb production, and inflammatory and

autoimmune gene expression in the lung and kidney. This dose also reduced splenomegaly and the severity of glomerulonephritis [64]. In contrast, low-dose PDN (5 mg/day HED) did not improve autoimmune symptoms, whereas a high-dose PDN (46 mg/day HED) caused severe GC-associated toxicity, leading to early cohort termination. Significantly, even at the effective medium dose, PDN caused muscle wasting and did not improve survival. This indicates a discordance between histopathologic improvements and death rates in SALN and confirms the narrow therapeutic window of long-term GC therapy [64]. Furthermore, these observations suggest that, within the constraints of the SALN model, DHA offers a more favorable balance between preventive effectiveness and tolerability than PDN.

Although a substantial amount of preclinical data supports the use of omega-3s in lupus, including research with DHA in SALN, these studies have primarily focused on preventing as opposed to treating established disease. This limits their relevance for patients with SLE who often present with active LN that requires remission induction. To address this gap, SALN was used here to assess whether adjunctive DHA supplementation can maintain LN remission after immunosuppressive induction with CYC, when administered either alone or combined with a moderate, clinically relevant dose of PDN. We show for the first time preclinical evidence that adjunctive DHA improves the efficacy of PDN, prolonging remission of both LN and extrarenal lupus pathogenesis. Accordingly, safe, inexpensive omega-3 supplementation might serve as a GC-sparing strategy to improve long-term disease management and reduce treatment-related toxicity in LN and SLE.

Materials and Methods

Animals

All experimental protocols were reviewed and approved by the Institutional Animal Care and Use

Committee (IACUC) at Michigan State University in accordance with the NIH guidelines (AUF #PROTO202400258). Female 7-week-old lupus-prone NZBWF1 mice were obtained from the Jackson Laboratory (#100008, Bar Harbor, ME), randomly assigned four per cage with free access to food and water, and kept at a consistent temperature (20–24 °C) and humidity (30–70%) with a 12-hour light/dark cycle.

Diets

Diet formulations were based on the nutritionally balanced semi-purified American Institute of Nutrition (AIN)-93G rodent diet containing 70 g soybean oil per kg of diet (AIN-93G rodent diet #110700, Dyets Inc., Bethlehem, PA) [65] (Supplemental Table 1). Four experimental diets were used in the study (Table 1). The (i) basal control diet (CON) was made by replacing the 70 g/kg soybean oil with 60 g/kg of high-oleic safflower oil (AVO high-oleic safflower oil, American Vegetable Oils, Inc., Commerce, CA) and 10 g/kg of corn oil (Mazola Corn Oil, ACH Food Companies, Inc., Oakbrook Terrace, IL) to supply essential fatty acids. For the (ii) DHA diet, 25 g/kg of high-oleic safflower oil was substituted in the basal CON diet with 25 g/kg of microalgal oil containing 40% DHA (DHASCO, DSM Nutritional Products, Columbia, MD), as described earlier [56,57]. This diet contained 10 g/kg DHA, modeling human DHA intake of 5 g per day on a caloric basis (Table 1). For a patient, this would be roughly equivalent to taking i) five triple-strength over-the-counter fish oil capsules daily, each containing approximately 1 g of omega-3 fatty acids or ii) five prescription-grade omega-3 capsules used to treat hypertriglyceridemia. For the (iii) PDN diet and the (iv) combined DHA+PDN diet, PDN was dissolved in a small amount of 100% (v/v) ethanol and added to both the basal CON and DHA diets at 10 mg/kg, as previously described [64]. This dietary level corresponds to an HED of 9.4 mg/day (Table 2) and was designated as "moderate" because it falls within the lower end of the medium dose range (7.5 to 30 mg/d) used in GC treatment

173   of rheumatic diseases [66].

Crystalline silica (cSiO₂)

cSiO$_2$ (Min-U-Sil-5, 1.5–2.0 μm average particle size, U.S. Silica, Katy, TX) was acid-washed in

1 M HCl at 100°C for 1 hour to remove surface contaminants that could obscure surface activity.

The cSiO$_2$ was then rinsed three times with sterile water and dried in an oven at 200°C to eliminate

water, endotoxins, and microbial contaminants. On each day of cSiO$_2$ instillation, a working stock

suspension of 40 mg/ml in Dulbecco's phosphate-buffered saline (DPBS) was prepared, then

sonicated for 1 minute using the Q125 Qsonica sonicator (Qsonica LLC, Newtown, CT) set to 2

minutes with pulses of 5 seconds on and 5 seconds off at 35% amplitude. After sonication, the

suspension was inverted and vortexed continuously during instillations to prevent cSiO$_2$ settling.

Experimental design

The experimental study design is depicted in Figure 1. NZBWF1 mice (7 weeks old) were started

on the CON diet, and one week later, they were anesthetized with 4% isoflurane and intranasally

instilled with 1.0 mg of cSiO$_2$ in 25 μl of DPBS once a week for 4 weeks [54]. The total cSiO$_2$ dose

(4 mg) approximately equals half of a human lifetime exposure according to guidelines set by the

Occupational Safety and Health Administration (OSHA)[67]. At 20 weeks of age, cSiO$_2$-treated

mice were divided into weight-based quartiles, with 1 mouse from each quartile housed together,

totaling 4 mice per cage. This grouping ensured balanced experimental conditions, reducing

confounding effects from body weight differences. At 21 weeks, when cSiO$_2$-treated mice exhibit

proteinuria (Supplemental Figure 1), cages were split into five treatment groups: (i) weekly DPBS

vehicle (VEH) intraperitoneal (IP) injections with the CON diet (cSiO$_2$/VEH/CON), (ii) weekly

CYC IP injections at 35 mg/kg body weight (bw) with the CON diet (cSiO$_2$/CYC/CON), (iii) weekly

CYC IP injections with a DHA diet (cSiO$_2$/CYC/DHA), (iv) weekly CYC IP injections with a PDN

diet (cSiO$_2$/CYC/PDN), and (v) weekly CYC IP injections with a DHA+PDN diet

(cSiO$_2$/CYC/DHA+PDN) (Figure 1). To reduce lipid oxidation products, diets were prepared every

two weeks, stored at -20°C until used, and provided fresh to the mice daily. Injections with VEH or

CYC ceased after 8 weeks, but mice remained on their respective maintenance diets for the

remainder of the study. Urine was collected weekly and tested for protein using reagent dipsticks

(Siemens Uristix 4, Malvern, PA). Plasma samples were collected biweekly, starting at 27 weeks of

age, for blood urea nitrogen (BUN) and AAb analyses. Mice were monitored daily for clinical signs

of moribundity (Supplementary Table 2) during feedings, and their body weights were recorded

weekly. Any mice meeting moribund criteria were immediately euthanized and necropsied. The

study concluded at age 35 weeks with a full necropsy of all remaining animals.

Necropsy and tissue selection for light microscopy

Mice were anesthetized at the end of the study with IP injections at 250 mg/kg bw of sodium

pentobarbital. A midline laparotomy was performed, and approximately 0.8 ml of blood was drawn

from the inferior vena cava and collected in heparinized tubes (MiniCollect Capillary Blood

Collection Tube #450477, Greiner Bio-One, Monroe, NC). Animals were euthanized by

exsanguination through the inferior vena cava. After death, the trachea was exposed, cannulated,

and the heart and lungs were excised en bloc. A volume of 0.7 ml sterile saline was instilled via the

tracheal cannula and then withdrawn to recover bronchoalveolar lavage fluid (BALF). A second

intratracheal saline lavage was performed, and the collected BALF was combined with the first

sample. Organs selected for light microscopy and digital image analysis were harvested at necropsy

and fixed in 10% neutral buffered formalin for at least 48 hours. The left kidney, spleen, and brain

were fixed by immersion, while the left lung lobe was fixed by fluid inflation via the trachea at 30

cm gravitational pressure as previously described [57].

After fixation, cross-sectional (transverse/coronal) tissue blocks were cut from the left kidney (1-2

blocks covering the entire organ), left lung lobe (4 blocks covering the entire lobe), spleen (2 mid-

blocks from the body of the organ), and brain (1 block with hippocampus, at the level of the inner

ear). Tissue blocks were paraffin-embedded and sectioned at 5 microns. Tissue sections were stained

histochemically with Hematoxylin and Eosin (H&E, all organs) or Periodic Acid Schiff (PAS,

kidney) and immunohistochemically stained for CD3+ and CD45R+ T and B lymphoid cells,

respectively (lung and kidney), IBA-1+ monocytes/macrophages (lung and kidney), and IBA-1+

microglia in the hippocampus (brain). Details for immunohistochemistry and specific antibodies are

provided in the Supplemental Materials.

Quantitative and semi-quantitative image analysis of histopathology

Digital images of histological sections were obtained with an Olympus VS200 slide scanner with

ASW software (V.3.2.1) at 20x magnification (Evident Scientific, Waltham, MA). Digitally scanned

images were viewed with Olympus OlyVIA software (V.2.8) and whole-slide image analyses were

conducted using QuPath image analysis software (V.0.5.1) [68]. Regions of interest (ROIs) were

annotated prior to each quantitative analysis (Lung, whole lung lobe sections; Kidney, renal cortex

in sections). Abundance of immunohistochemical stains (density of IBA-1+, CD3+, CD45R+) was

graphically expressed as the percent of ROI area. Thresholds were created to model staining

positivity per tissue type. Identical settings per stain were used to assess positivity among

experimental groups.

Semi-quantitative image analysis of histopathologic severity was conducted for specific lupus-

related lesions: membranous glomerulonephritis, renal tubular regeneration, accumulated protein in

renal tubular lumens, ectopic lymphoid structures (CD3+ T cells and CD45R+ B cells) in the kidney, white pulp hyperplasia in the spleen, and microgliosis in the hippocampus of the brain (IBA-1+ microglia). A board-certified veterinary pathologist (JRH) examined all digitally scanned images of routine H&E- and immunohistochemically stained tissue sections for $cSiO_2$-triggered lupus histopathology using unbiased blinded assessment (no previous knowledge of individual animal exposure or treatment). Lesion severity scores were recorded in a manner that is consistent with state-of-the-art guidelines for semi-quantitative pathology assessment [69]. Criteria for ordinal scoring were defined by percent of total tissue affected: 0 (no lesions) = 0% of total tissue; 1 (minimal) = less than 5%; 2 (mild) = 6 to 10%; 3 (moderate) = 11 to 50%; 4 (marked) = 51 to 75%; 5 (severe) = greater than 76%.

Red blood cell (RBC) fatty acid analysis

RBC fatty acid composition was analyzed using gas chromatography (GC) with flame ionization detection by OmegaQuant Analytics (Sioux Falls, SD) as described previously [63]. Briefly, after isolating RBCs from heparinized blood, fatty acid methyl esters (FAMEs) were prepared by heating the RBCs with 14% boron trifluoride-ethanol and hexane at 100°C for 10 minutes. The FAMEs were then extracted with hexane and analyzed on a Shimadzu GC-2010 chromatograph equipped with an SP-2560 100-m capillary column. Fatty acids were identified by comparison to a commercial standard (GLC OQ-A, NuCheck Prep). A total of 24 fatty acids were quantified and expressed as a percentage of the total identified fatty acids, including saturated, monounsaturated (cis and trans), and polyunsaturated (omega-3 and omega-6) species.

Autoantibody (AAb) measurement

IgG AAbs targeting silica-killed cell (SKC) autoantigens (AAgs) and dsDNA were measured using

an indirect ELISA based on a previously described method [70]. To prepare SKC AAgs, fetal liver-derived alveolar-like macrophages (FLAMs) from lupus-prone NZBWF1 mice were exposed to 50 µg/ml cSiO$_2$ for 20 hours to induce cell death. The supernatant was then collected and stored at -20°C until use. Poly-L-lysine-coated 96-well microplates were incubated with a blocking buffer (PBS, 2% [w/v] BSA, 0.05% [v/v] Tween 20), then coated with 50 µl per well of either SKC AAg diluted 1:20 or calf thymus dsDNA diluted to 2.5 µg/ml, both prepared in ELISA buffer (PBS, 0.1% [w/v] BSA, 0.05% [v/v] Tween 20). Next, diluted BALF (1:1,000) or plasma (1:5,000 and 1:10,000) was added to separate wells. A standard curve was generated using two-fold serial dilutions of a mouse anti-dsDNA antibody, with the highest concentration assigned a value of 2,000 arbitrary units (U). Bound AAbs were detected using HRP-conjugated goat anti-mouse IgG Fc antibody and K-Blue® Advanced Plus TMB Substrate, with absorbance measured at 650 nm.

Blood urea nitrogen (BUN) analysis

BUN was measured using the Ray Biotech Urea Nitrogen Detection Assay Kit (MA-BUN-5) per manufacturer's directions. Briefly, plasma samples were diluted 1:25, loaded onto a microplate, and then incubated with an enzyme solution of urease and NADH. After a brief shaking of the plate, absorbance was measured (340 nm) twice, with one minute between readings. The difference in absorbance between the two readings correlates with BUN concentration. BUN levels were determined using a standard curve.

Bronchoalveolar lavage fluid (BALF) cell quantitation and identification

Total cells in BALF were counted using a hemocytometer. Cytological slides were prepared by centrifuging 150 µl of BALF for 10 minutes at 40× g, air-drying, and staining with the Easy III Step Stain Kit (#ES902, Azer Scientific, Morgantown, PA). At least 150 cells were counted and

differentially identified as monocytes/macrophages, lymphocytes, or neutrophils based on
morphological criteria.

Statistical analysis

All treatment groups began with 8 mice. All statistical analyses were conducted using GraphPad
Prism 10 (V.10.6.1, Dotmatics, Boston, MA), with a p-value < 0.05 considered significant.
Parametric two-tailed t tests (with and without Welch's correction) or nonparametric Mann-Whitney
tests were used to compare the continuous quantitative data and the ordinal histopathological
severity scores between the cSiO$_2$/VEH/CON (negative control) and cSiO$_2$/CYC/CON (positive
control) groups, respectively. When comparing the continuous quantitative data across the treatment
groups (cSiO$_2$/CYC/CON, cSiO$_2$/CYC/DHA, cSiO$_2$/CYC/PDN, cSiO$_2$/CYC/DHA+PDN), several
statistical tests were performed: (i) parametric one-way ANOVAs along with the Brown-Forsythe
test of equal variances, (ii) parametric Brown-Forsythe and Welch one-way ANOVAs, and (iii)
Dunnett's and Tukey's multiple comparisons tests. When comparing the semi-quantitative ordinal
severity score data of the treatment groups, the nonparametric Kruskal-Wallis and Dunn's multiple
comparisons tests were used.

Results

Dietary DHA remodels RBC membrane fatty acid composition

The dietary DHA intervention was confirmed to induce systemic lipidomic changes by assessing
the fatty acid composition of RBC phospholipids, which serves as a biomarker of overall tissue lipid
status (Figure 2; Table 3) [71]. Mice receiving isocaloric DHA-supplemented diets

(cSiO$_2$/CYC/DHA and cSiO$_2$/CYC/DHA+PDN groups) exhibited significant increases (up to 10- to 12-fold) in DHA and other omega-3 fatty acids, including EPA and omega-3 docosapentaenoic acid (DPA). This increase was accompanied by a marked decrease in total omega-6 fatty acids (up to 50 to 70%), such as arachidonic acid, omega-6 DPA, and docosatetraenoic acid, with the exception of linoleic acid (LA), which was significantly elevated. Notably, RBCs from mice treated with DHA and PDN contained higher levels of DHA, EPA, and total omega-3s than those from mice receiving DHA alone, along with lower levels of ARA and total omega-6 fatty acids. In contrast, PDN treatment alone did not alter fatty acid profiles, indicating that the observed lipidomic changes were specifically attributable to dietary DHA intake.

DHA and PDN co-therapy after CYC induction prevents proteinuria relapse and death.

Consistent with previous studies in NZBWF1 mice [54,56,61], weekly intranasal cSiO$_2$ instillations for 4 weeks in control-fed mice resulted in two main clinical outcomes: proteinuria (Figures 3A-C) and shortened lifespan, with a median survival of 29.5 weeks (Figure 3D). CYC treatment alone reduced proteinuria, but relapses happened after stopping, as evidenced by increased proteinuria at week 33 (Figure 3A) , and increased median survival to 35 weeks (Figure 3D). Maintenance therapies with either DHA or DHA+PDN delayed relapse, whereas PDN alone did not. The percentage of proteinuric mice (Figure 3B) and mean proteinuria levels (Figure 3C) from weeks 21 to 35 were significantly lower in the CYC/DHA and CYC/DHA+PDN groups than in the CYC-only or CYC/PDN groups. Maintenance treatments also conferred a survival advantage, with median survival times for both monotherapies and combination therapy exceeding 35 weeks (Figure 3D).

Combining DHA and PDN maintenance therapy preserves renal structure and reduces macrophage infiltration.

Kidneys from cSiO$_2$/VEH/CON mice exhibited severe membranous glomerular nephritis, characterized by glomerular enlargement, extensive accumulation of Periodic acid Schiff (PAS)-positive glomerular membranous tissue, and proteinaceous casts in the renal tubules (Figure 4B). These features were absent in age-equivalent naïve mice from a prior study [61] and used here as a standard reference control (Figure 4A). Conversely, CYC treatment reduced glomerulonephritis (Figure 4C), and this improvement was further enhanced by DHA (Figure 4D) and PDN (Figure 4E). The group receiving combination therapy (cSiO$_2$/CYC/DHA+PDN) was the most protected from these pathological changes and displayed nearly normal renal structure (Figure 4F). Semi-quantitative scoring confirmed that the combination therapy decreased the LN severity score ($p < 0.01$) (Figure 4G), tubular protein score ($p = 0.11$) (Figure 4H), and tubular regeneration score ($p < 0.05$) (Figure 4I) compared to CYC treatment alone.

IHC staining for IBA1, a well-known marker for recruited inflammatory monocytes/macrophages [72], showed that, consistent with glomerulonephritis, cSiO$_2$ exposure caused significant infiltration of monocytes/macrophages into interstitial spaces surrounding renal tubules and glomeruli in ELS and some glomeruli (Figures 5A, 5B). While modestly reduced by CYC with DHA or PDN monotherapies (Figures 5D, 5E, 5G), IBA1+ monocyte/macrophage infiltration was most robustly reduced by co-therapy with CYC/DHA+PDN (Figures 5F, 5G). Accordingly, DHA+PDN co-treatment was the most effective of the three maintenance therapies in reducing local renal inflammation and preserving kidney structure.

DHA and PDN co-therapy prevents the formation of renal ELS

A key pathogenic feature of progressive LN is the formation of renal ELS [73-75]. The renal cortices

of cSiO$_2$-triggered mice that did not receive treatment contained large, organized ELS composed of co-localized aggregations of IBA1$^+$ macrophages, CD3$^+$ T cells, and CD45R$^+$ B cells (Figure 6A, C, E, G). Maintenance therapy with CYC/DHA+PDN effectively prevented this process, as kidneys from this group were mostly free of dense lymphoid cell aggregate infiltrates and lacked organized ELS architecture (Figure 6B, D, F, H). The kidney ELS score was lower (p<0.01) in the CYC/DHA+PDN co-therapy group compared to the CYC-only control group, while DHA or PDN monotherapies were less effective (Figure 6I).

Protective effects of DHA and PDN monotherapy and co-therapy extend to the lungs.

In NZBWF1 mice, age-related pulmonary perivascular and peribronchiolar lymphoid hyperplasia spontaneously occurs at 8 to 12 months of age, during which polymorphic lymphoid infiltrates, evocative of ELS, become dominated by CD4+ T cells, while B cells and antigen-presenting cells segregate into a peripheral cuff surrounding the T cell–rich area [76,77]. This occurs much earlier in the SALN model, where the lung is the hub for early cellular events that promote cSiO$_2$-induced autoimmunity and the progression of lupus [78]. Cellular analysis of bronchoalveolar lavage (BAL) fluid demonstrated that DHA and PDN monotherapies, as well as combination therapy with CYC, reduced total inflammatory cells, monocytes/macrophages, and lymphocytes compared to CYC alone (Figure 7A). Furthermore, combined DHA+PDN treatment exhibited a modest trend toward reduced local production of IgG autoantibodies against dsDNA and cSiO$_2$-killed cells (Figure 7B).

Histological examination of lung tissue showed that, as previously reported [54,55], strong perivascular ELS appeared in cSiO$_2$-treated mice (Figures 8C, D) and were absent in naïve mice (Figures 8A, B). Consistent with decreased cellularity in BAL fluid, ELS were markedly reduced in

371   the lungs of the CYC/DHA+PDN group (Figures 8K, L), while effects of monotherapies were more

372   modest (Figures 8G-L). Semi-quantitative scoring confirmed that the DHA+PDN combination

373   maintenance therapy significantly lowered lung ELS scores ($p<0.001$) (Figure 9A), the percentage

374   of CD3+ T cells ($p<0.05$) (Figure 9C), and the percentage of C45R+ B cells ($p<0.0001$) (Figure

375   9D).

PDN+DHA co-therapy suppresses $cSiO_2$-induced splenomegaly and systemic AAbs

The spleen is another potential source of systemic AAbs in NZBWF1 mice [79], and splenomegaly,

a key feature of spontaneous lupus progression in these mice, is accelerated by $cSiO_2$ treatment [64].

Therefore, to evaluate the effects of treatments on systemic autoimmunity, we compared spleen

architecture and plasma AAbs across the experimental groups. $cSiO_2$ caused significant white pulp

hyperplasia in mice (Figures 10B, H), which was not evident in age-equivalent naïve NZBWF1 mice

(Figure 10A). Lymphoid cell hyperplasia was not substantially affected by CYC alone (Figure 10C)

or by CYC in combination with DHA or PDN alone (Figures 10D, E); however, it was suppressed

in CYC-treated mice that received PDN+DHA (Figure 10F). For other indicators of splenomegaly,

spleen weight and area, DHA and PDN monotherapies showed modest reductions, while

DHA+PDN co-therapy showed marked decreases (Figures 10G, H, and I). Treatment effects on the

spleen were consistent with plasma dsDNA and SKC AAb levels (Figure 10J). After stopping CYC,

plasma IgG AAbs against dsDNA and SKC began to rise again within 4 to 6 weeks post-CYC

treatment in the CYC-only and CYC/DHA groups. This increase was consistently suppressed in

groups receiving PDN, either alone or with DHA. Overall, DHA potentiates PDN suppression of

splenomegaly and systemic AAb formation resulting from $cSiO_2$ instillation.

DHA and PDN co-therapy attenuates microglial cell activation in the brain

NZBWF1 mice have been used in neuropsychiatric lupus (NPSLE) research, with IBA1 positivity in the brain (i.e., microgliosis) and microglial activation serving as markers of central nervous system (CNS) inflammation [80-82]. In the hippocampus, $cSiO_2$/VEH/CON mice exhibited pronounced microgliosis, characterized by increased density and altered shape of IBA1$^+$ microglial cells (Figure 11A,B). This neuroinflammatory state was diminished in mice that received CYC, CYC/DHA, and CYC/PDN (Figures 11C, D, and E), and was maximally reduced in mice receiving CYC/DHA+PDN co-therapy, which displayed a more resting microglial appearance (Figure 11F). This was further reflected in markedly lower microgliosis scores for the PDH+DHA co-therapy group, suggesting that the benefits of this combination extends to reduced CNS-related inflammation (Figure 11G).

Discussion

LN remains difficult to manage, and there is a significant need for innovative strategies that sustain long-term remission while enabling a meaningful reduction in GC doses. Observational SLE studies have linked higher omega-3 intake and circulating DHA with diminished disease activity as reflected in SLAQ scores and better patient-reported outcomes, including reduced pain and improved sleep [83-85]; however, randomized controlled trials (RCTs) have yielded mixed results. Akbar et al. [22] reported variable benefits across nine RCTs that differed in duration (10–52 weeks), sample size (12–85 participants), and dosage (0.54–3.60 g EPA; 0.30–2.25 g DHA).

Several studies reported improvements in clinical or serologic markers [86-90], while others observed only transient or no benefit [32,91-93]. A recent RCT using krill oil (4 g/day; 722 mg EPA, 384 mg DHA) showed positive effects in patients with high baseline disease activity (SLEDAI-2K $\geq$ 9) [16]. Overall, although omega-3 RCTs suggest a potential for modest improvement in SLE disease activity, small sample sizes, inconsistent dosing, varied populations, short follow-up periods, limited assessment of long-term tissue FA incorporation, and suboptimal control of confounding factors hinder clear interpretation. Therefore, the full extent of omega-3s' benefits for individuals with SLE and LN, along with how they interact with standard treatments, remains unclear.

Because omega-3 supplements are not patent-protected, large, highly optimized randomized controlled trials used to evaluate new drugs are impractical, stressing the importance of rigorous preclinical models to define their therapeutic potential in LN. In this context, the SALN model offers a stringent, translationally relevant platform for evaluating remission-maintenance strategies after immunosuppressive induction. Mechanistically, short-term, repeated cSiO$_2$ exposure in NZBWF1 mice combines an environmentally relevant trigger with genetic susceptibility. Inhaled particles are initially phagocytosed by alveolar macrophages (AMs). This results in phagolysosome destabilization, inflammasome activation, and AM death via pyroptosis and necrosis, and ultimately the release of cytokines, chemokines, DAMPs, nuclear antigens, and cSiO$_2$ into the local environment [78,94] (Figure 12). These events, together with the long pulmonary half-life of cSiO$_2$, create a self-sustaining loop in which dying and activated AMs promote ectopic ELS formation in the lung, enhance T- and B-cell recruitment and activation, and accelerate the production of pathogenic AAbs. This process drives both pulmonary and systemic autoimmunity and results in severe, synchronized glomerulonephritis (GN) that resembles key features of human SLE and LN

[55,56]. Compared with the spontaneous NZBWF1 model, SALN presents a condensed,

synchronized multi-organ disease course, with LN developing within 3 months after the final $cSiO_2$

exposure. This allows intervention studies to be completed in 7 months, rather than 10 to 12 months

in the conventional NZBWF1 model.

Previous investigations employing SALN have shown that either DHA or PDN monotherapy can

prevent LN onset [56-58,60-62,95], but these studies mainly focused on disease prevention. The

present study is innovative because it endeavors to bridge this translational gap by using SALN to

assess DHA as an adjunct therapy to prolong CYC-induced remission, both alone and in

combination with a modest, clinically relevant dose of PDN in established LN. We report for the

first time that dietary DHA administered post-LN onset during and after immunosuppressive

induction prompts significant remodeling of tissue membrane lipid composition. This change is

associated with enhanced clinical and histopathological outcomes (Figure 12). Incorporation of

DHA and other omega-3 fatty acids into phospholipids, along with a reciprocal depletion of omega-

6 species, most notably ARA, indicates robust reprogramming of tissue lipid pools. In mice given

DHA+PDN, increases in total omega-3 and decreases in omega-6 were enhanced by 33 percent and

19 percent, respectively, compared with mice fed DHA alone. In the kidney, DHA, particularly

when combined with PDN, prolonged CYC-induced remission by delaying proteinuric relapse and

maintaining renal structure. This was evidenced by reduced macrophage infiltration, diminished

tubular protein deposition, and prevention of ELS formation.

The benefits of DHA combined with PDN were observed beyond the kidney. In the lung, this

combination reduced perivascular inflammation, ectopic lymphoid aggregates, and local

autoantibody production. Systemically, it decreased splenomegaly and circulating autoantibodies.

In the brain, DHA+PDN reduced hippocampal microgliosis and improved neural tissue health,

indicating a wider impact on neuroinflammatory pathways in the CNS. Collectively, this evidence indicates that DHA-rich nutrition, particularly when combined with PDN, exerts coordinated immune-modulating effects across multiple organs, enhances the durability of LN remission, and reduces extra-renal inflammation and tissue damage, thereby supporting its ability to augment SLE outcomes more broadly. Thus, adjunctive DHA may enhance conventional two-phase immunosuppressive therapy and is consistent with current rheumatology treatment approaches focused on sustained remission with reduced GC exposure [9].

The organ-level effects observed here in SALN align with the well-known immunomodulatory actions of omega-3 fatty acids. DHA and other omega-3s affect immune responses through interrelated structural, transcriptional, and metabolic pathways [17,18,96,97]. Their incorporation into membrane phospholipids alters lipid raft organization, increases membrane fluidity, and interferes with receptor clustering required for effective signaling through TLRs, TNFR, and IL1R [98]. At the transcriptional level, DHA suppresses NF-κB and activates PPARγ and NRF2, diminishing oxidative stress and decreasing expression of proinflammatory mediators such as IL6 and iNOS [99,100]. Additionally, omega-3s inhibit ARA production from plant-derived LA [101] and competitively inhibit the formation of inflammatory mediators from ARA, such as leukotrienes, prostaglandins, and thromboxanes [96]. DHA also serves as a precursor for proresolving mediators that promote efferocytosis, facilitating the clearance of apoptotic cells and supporting the resolution of chronic inflammation [97]. The evidence presented here is further consistent with preventive studies in NZBWF1 mice exposed to $cSiO_2$, where DHA elicits broad anti-inflammatory and immunoregulatory actions in the lungs [63]. Following a single intranasal $cSiO_2$ challenge, control-fed mice showed increased leukocyte influx, cytokine and chemokine levels, dead cell accumulation, and higher AAbs in BAL. In contrast, DHA-enriched diets lessened these responses,

including IL1α, IL6, GM-CSF, CCL2, CCL3, and CXCL10, and lowered autoimmune-related gene

signatures linked to type I IFN signaling, TLR activation, and lymphocyte activation, with predicted

suppression of regulators like TNFα, IL1β, IFNAR, and IFNγ.

The tissue-specific effects of PDN in SALN observed here are in accord with the known

immunomodulatory actions of GCs. Treatment with PDN and other synthetic GCs rapidly controls

inflammation in SLE and related rheumatic conditions by activating GR, which suppresses NF-

κB/AP-1–driven inflammatory pathways in lymphoid and myeloid cells and enhances anti-

inflammatory genes like GILZ and DUSP1 [102-104]. Non-genomic GR signaling further

contributes by inhibiting PLA2 and activating MAPK and cAMP pathways [102-104]. Additionally,

GCs modify lipid rafts by altering their lipid composition and physical properties, disrupting raft

formation in some immune cells while also recruiting GRs and related signaling complexes into

flotillin- or caveolin-rich raft regions, thereby affecting kinase signaling and gene regulation [105-

107]. Thus, the anti-inflammatory effects of DHA and PDN involve multiple parallel interconnected

mechanisms.

Using SALN, we previously found that pretreatment with a moderate PDN dose (14 mg/day HED),

taken orally via diet, significantly reduced $cSiO_2$-induced pulmonary ELS formation, AAb

production, and autoimmune gene expression in both the lung and kidney [64]. This treatment also

decreased splenomegaly and the severity of glomerulonephritis. Instead of reversing disease

signatures, this regimen reduced the magnitude and diversity of transcriptomic changes across

organs, showing a general suppression of autoimmune activation. Key adaptive immune modules—

including T-cell receptor signaling, antigen presentation, B-cell activation, and Fc-mediated effector

pathways—were particularly suppressed, especially in the lung. Overall, these prior findings show

that moderate-dose PDN provides widespread but incomplete transcriptional control over the $cSiO_2$-

induced autoimmune process, with innate and stress responses still partly active.

The PDN dose used in the present study was specifically chosen based on its narrow preventive

window in SALN: 14 mg/day HED reduces disease progression, 5 mg/day is ineffective, and

46 mg/day causes severe GC-related toxicity without providing a survival benefit [64]. This pattern

parallels clinical experience, in which high-dose GCs induce remission but carry significant

cumulative toxicity, and highlights that monotherapy suppresses inflammation without restoring

immune homeostasis [108]. Based on this prior study, herein we deliberately selected a suboptimal

intermediate dose (9.4 mg/day HED), positioned between previously ineffective and minimally

effective levels in SALN [64]. Clinically, this dose is near the lower end of moderate-dose GC

exposure: in a large SLE cohort, the mean daily PDN-equivalent dose during the first treatment year

was 19.4 mg, with about 60% of patients receiving ≥15 mg/day and only 17% maintained below

7.5 mg/day [109]. The 9.4 mg/day HED selected here represents a clinically significant exposure,

half of the dose usually employed during the first year of treatment, but still above the current treat-

to-target guidelines not to exceed 5 to 7.5 mg/day for SLE and LN maintenance.

Macrophages play a vital role in SLE development, driven by unresolved tissue inflammation,

defective removal of cellular debris, and persistent type I IFN signaling [110-112]. In a recent in

vitro study using a novel self-renewing AM model derived from embryonic NZBWF1 mouse liver,

we determined that DHA synergistically enhances the suppressive effects of low doses of the water-

soluble GC dexamethasone (DEX) on LPS-induced type 1 IFN-driven gene expression [27]. When

combined, subinhibitory levels of DHA and DEX led to over tenfold greater gene suppression than

either agent alone. This combination significantly reprogrammed inflammatory transcriptional

networks, decreasing activity in the NFκB, AP1, IRF, and STAT pathways while promoting

pathways associated with resolution and M2 polarization. These in vitro mechanistic insights align

with the in vivo SALN results discussed here, further supporting DHA as an adjunct therapy to GC and highlighting its potential to enhance treatment outcomes by targeting critical pathogenic pathways in SLE.

Interpretation of these data must consider several limitations. First, the relatively short experimental duration limits conclusions about long-term disease progression and survival, and formal dose–response relationships for both DHA and PDN—individually and together—are yet to be systematically established. Second, the study was intentionally designed to focus on remission maintenance, renal and extrarenal histopathology, and survival rather than a detailed mechanistic analysis of how upstream signaling pathways are affected by DHA and PDN. Third, variations in omega-3 types (DHA vs EPA) and bioavailability (ethyl esters, triglycerides, phospholipids) among formulations on the market may additionally impact treatment effectiveness [16]. Finally, the metabolic and immunological features of SALN may not fully parallel human SLE, so caution is necessary when extrapolating to diverse patient populations. Therefore, to address these limitations, future preclinical research using the SALN model should i) explicitly address dose–response relationships over an extended time period, ii) compare various therapeutic formulations and delivery methods (e.g., structured triglycerides or phospholipid conjugates), and iii) include lipidomic and transcriptomic profiling to understand better how DHA and PDN reprogram immune–metabolic networks across disease. Ultimately, well-designed multicenter clinical trials will be essential to determine the translational relevance and clinical significance of DHA-based adjunctive GC-sparing strategies in SLE and LN.

Conclusion

This study provides compelling preclinical evidence that DHA supplementation significantly enhances the efficacy of PDN in sustaining CYC-induced remission in LN. By leveraging a robust, translationally relevant model, we demonstrate that DHA exerts immunomodulatory effects that complement glucocorticoid mechanisms, resulting in prolonged renal and extrarenal protection. These findings highlight the potential of omega-3 fatty acids as safe, cost-effective adjuncts to conventional immunosuppressive regimens, offering a strategy to reduce glucocorticoid burden while improving long-term outcomes. If validated in clinical trials, DHA-based combination therapy could redefine LN management by integrating precision nutrition into standard care, thereby advancing treatment paradigms toward sustained remission with minimized toxicity.

Conflict of Interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

 Figure 1. Experimental design for determining how diets containing docosahexaenoic acid (DHA) and/or

 prednisone (PDN) impact the duration of cyclophosphamide (CYC)-induced remission in the silica ($cSiO_2$)-

 accelerated lupus nephritis (SALN) mouse model. Abbreviations: CON, control diet; VEH, vehicle. Letters: a)

 nephritis onset/initiate vehicle (VEH) or CYC injections; b) CYC discontinued; c) experiment terminated and mice

 necropsied when ≥50% CYC-treated CON-fed mice exhibited proteinuria (≥300 mg/dl).

 Figure 2. Consumption of DHA and DHA+PDN, but not PDN alone, skews cellular phospholipid profiles in

 erythrocytes from ω-6 PUFAs to ω-3 PUFAs. Data (mean+/-SEM) are expressed as percent of total fatty acids

 (TFA). *, **, ***, and **** indicate significant differences at the $p<0.05$, $p<0.01$, $p<0.001$, and $p<0.0001$ levels,

 respectively.

 Figure 3. DHA and PDN monotherapies and co-therapy influence the duration of CYC-induced remission of

 proteinuria and mortality in the SALN model over the 14-week experimental period. (A) Left panel, percent of

 mice with significant proteinuria (≥300 mg/dl); right panel, average proteinuria. (B) Average percent of mice with

 proteinuria (≥300 mg/dl) from weeks 21 to 35. (C) Average proteinuria from weeks 21 to 35. (D) Percent survival

 as determined using clinical scores indicative of a moribund state as described in Methods. Abbreviations: VEH,

 vehicle; CON, control diet. Symbols: *, **, ***, and **** indicate significant differences at the $p<0.05$, $p<0.01$,

 $p<0.001$, and $p<0.0001$ levels, respectively.

 Figure 4. DHA and PDN monotherapies and co-therapy prolong CYC-induced diminution of $cSiO_2$-accelerated

 lupus nephritis. (A-F) Light photomicrographs of Periodic Acid Schiff-stained (PAS) glomeruli (g) and adjacent

 cortical renal tubules (rt). (B) Membranous glomerular nephritis: dramatic glomerular enlargement with marked

 thickening of PAS$^+$ membranous tissue (arrow) and rt with luminal proteinaceous fluid (stippled arrow) in the

 kidney from the $cSiO_2$/VEH/CON mouse compared to (A) a representative section from a 34-week-old NZBWF1

 mouse not treated with $cSiO_2$ or drugs obtained from a previous study [61]. These renal lesions are markedly

 attenuated in the kidney from the (F) $cSiO_2$/CYC/DHA+PDN mouse. Histopathological lesions were scored by

pathologist as described in Methods for (G) lupus nephritis, (H) tubular protein, and (I) tubular regeneration.

Symbols: #, *, and ** denote statistically significant differences at the $p < 0.1$, $p < 0.05$, and $p < 0.01$ levels,

respectively. Solid symbols indicate mice that were taken at the final necropsy at week 35; half-open, half-closed

symbols denote moribund mice sacrificed prior to final necropsy.

Figure 5. DHA and PDN co-therapy extends CYC-induced suppression of cSiO$_2$-induced infiltration of

inflammatory IBA-1$^+$ monocyte-derived macrophages in the kidney. (A-F) Representative light photomicrographs

of renal cortex immunohistochemically stained for IBA-1$^+$ monocytes infiltrating peri-tubular and glomerular

interstitial tissue (arrows). Panel A is a representative section from a 34-week-old NZBWF1 mouse not treated

with cSiO$_2$ or drugs obtained from a previous study [61]. Letters: g, glomeruli; rt, renal tubules. (G) IBA-1$^+$ areas

were quantitatively scored as described in Methods. Symbol: * denotes a statistically significant difference at the

$p < 0.05$ level. Solid symbols indicate mice that were taken at the final necropsy at week 35; half-open, half-closed

symbols denote moribund mice sacrificed prior to final necropsy.

Figure 6. DHA and PDN co-therapy prolongs CYC-induced attenuation of cSiO$_2$-accelerated ectopic lymphoid

structure (ELS) development in the kidney. Representative light photomicrographs of (A, B) hematoxylin and

eosin (H&E)-stained renal cortex tissue and immunohistochemically stained for (C,D) IBA-1$^+$, (E,F) CD3$^+$, or

(G,H) CD45R$^+$ cells in renal cortex tissue from a (A, C, E, G) nontreated cSiO$_2$/VEH/CON mouse and a (B, D, F,

H) co-treated cSiO$_2$/CYC/DHA+PDN mouse. cSiO$_2$-induced renal influx of IBA-1$^+$ monocytes co-localized with

CD3$^+$ and CD45R$^+$ lymphoid cells (T and B cells, respectively) was markedly attenuated in co-treated mouse

compared to nontreated mouse. (I) ELS development was semi-quantitatively scored for severity by pathologist

as described in Methods. Symbol: * indicates a significant difference at the $p < 0.05$ level. . Solid symbols indicate

mice that were taken at the final necropsy at week 35; half-open, half-closed symbols denote moribund mice

sacrificed prior to final necropsy.

Figure 7. Influence of DHA and PDN monotherapies and co-therapy on cSiO$_2$-induced cellularity and AAbs in

bronchoalveolar lavage fluid (BALF). (A) Monocyte, neutrophil, lymphocyte, and total cell accumulation are

suppressed by DHA and PDN alone or as co-treatment. Symbols: #, *, **, ***, and **** indicate significant

differences at the $p<0.1$, $p<0.05$, $p<0.01$, $p<0.001$, and $p<0.0001$ levels, respectively. (B) IgG AAbs specific for

dsDNA and silica-killed cells (SKC) of CYC-treated mice instilled with $cSiO_2$ are modestly suppressed by DHA

and PDN co-treatment.

Figure 8. DHA and PDN monotherapies and co-therapy extend CYC-induced attenuation of $cSiO_2$-accelerated

ectopic lymphoid structure (ELS) development in the lung. (A-L) Representative light photomicrographs of H&E-

stained pulmonary tissue from the left lung lobe. Panels A and B are a representative section from a 34-week-old

NZBWF1 mouse not treated with $cSiO_2$ or drugs obtained from a previous study [61]. Peri-vascular ELS (arrows)

is markedly attenuated in lung from (K,L) co-therapy $cSiO_2$/CYC/DHA+PDN mouse compared to (C,D)

nontreated $cSiO_2$/VEH/CON and (E,F) $cSiO_2$/CYC/CON mice.

Figure 9. DHA and PDN monotherapies and co-therapy prolong CYC-induced reduction of $cSiO_2$-accelerated

ectopic lymphoid structure development in the lung. (A, B) ELS development and alveolar proteinosis were semi-

quantitatively scored for severity by pathologist as described in Methods. (C, D) $CD3^+$ and $CD45R^+$ cell densities

were quantitatively analyzed by digital morphometry as described in Methods. Symbols: *, **, and *** indicate

significant differences at the $p<0.05$, $p<0.01$, and $p<0.001$, levels, respectively. . Solid symbols indicate mice that

were taken at the final necropsy at week 35; half-open, half-closed symbols denote moribund mice sacrificed prior

to final necropsy.

Figure 10. PDN alone or DHA and PDN co-therapy with CYC suppress $cSiO_2$-accelerated splenomegaly. (A-F)

Light photomicrographs of H&E-stained splenic tissue. (A) Reference section from a 34-week-old NZBWF1

mouse not treated with $cSiO_2$ or drugs obtained from a previous study [61]. (B) Increased white pulp (wp) and

reduced red pulp (rp) in splenic tissue from $cSiO_2$/VEH/CON mouse that is markedly attenuated in (F) spleen from

mouse receiving $cSiO_2$/CYC/DHA+PDN treatment. Indicators of splenomegaly included (G) spleen weight, (H)

white pulp hyperplasia (semi-quantitative scoring by pathologist as described in Methods), and (I) mid cross-

sectional area of total spleen (quantitative analysis as described in Methods). (J) Influence of DHA and PDN

monotherapies and co-therapy on cSiO$_2$-induced AAbs in plasma. IgG AAbs specific for dsDNA and silica-killed cells (SKC) from CYC-treated mice instilled with cSiO$_2$ are modestly suppressed by PDN treatment alone and by DHA and PDN co-treatment at 33 and 35 weeks. Symbols: #, *, **, and *** indicate significant differences at the p<0.1, p<0.05, p<0.01, and p<0.001 levels, respectively. Mice sacrificed prior to final necropsy are indicated by half-open, half-closed symbols, and solid symbols indicate mice that made it to final necropsy at week 35.

Figure 11. DHA and PDN monotherapies and co-therapy prolong CYC suppression of cSiO$_2$-induced microgliosis. Representative photomicrographs of (A) H&E-stained cells and (B-F) immunohistochemically stained for IBA-1$^+$ microglial cells in the hippocampus of the brain. Microgliosis in the hippocampus from the (B) nontreated cSiO$_2$/VEH/CON mouse is markedly attenuated in (F) co-treated cSiO$_2$/CYC/DHA+PDN mouse. (G) Semi-quantitative severity scoring of microgliosis (IBA-1$^+$ cells) in the hippocampus as described in Methods. Brains were not taken from moribund mice at necropsy. Symbol: ** indicates a significant difference at the p<0.01 level.

Figure 12. Schematic summarizing how docosahexaenoic acid (DHA) supplementation influences prednisone (PDN) efficacy for the sustained maintenance of cyclophosphamide-induced remission in silica-triggered lupus. Inhaled crystalline silica (cSiO$_2$) initiates lung cell death and inflammation, inducing damage-associated molecular patterns (DAMPs), autoantigens (AAgs), type I interferons, and chemokines, which together drive robust infiltration by B cells, T cells, and macrophages, leading to ectopic lymphoid structure formation, AAb production, and immune complex (IC) formation. These immunological events in the lung amplify multiorgan pathology, including glomerulonephritis, IBA-1$^+$ macrophage accumulation, and lymphoid neogenesis in the kidney, splenic lymphoid hyperplasia, and microgliosis in the brain. Compared to single-agent regimens, combined DHA+PDN therapy exerts superior suppression of multisystem lupus pathology (DHA+PDN > PDN = DHA > control for kidney, lung, and brain; DHA+PDN > PDN > DHA > control for spleen), supporting additive benefits of omega-3 supplementation and long-term maintenance with modest steroid doses to reduce risk of flare and cumulative tissue injury. Supplemental Materials

- **Supplemental Methods:** Immunohistochemistry (IHC)
- **Supplementary Table 1.** List of key reagents, items, and kits
- **Supplementary Table 2.** Criteria for defining moribund condition of silica-treated NZBWF1 mice
- **Supplemental Figure 1**. Effects of DHA and PDN monotherapies and co-therapy on CYC-induced reduction of blood urea nitrogen (BUN) in the cSiO2-accelerated lupus nephritis mouse model

Supplemental Methods

Immunohistochemistry (IHC)

IHC was conducted as previously described (Pestka et al. 2021, Front. Immunol.12:653464). Briefly, formalin-fixed, paraffin-embedded samples were sectioned, placed on charged slides, and dried overnight at 56°C. The slides were then deparaffinized in xylene and rehydrated through using a dilution series of ethanol ending with distilled water. . Slides were immersed in tris-buffered saline pH 7.4 (TBS, Scytek Labs, Logan, UT) for 5 minutes to adjust the pH. Following TBS, retrieval protocols were applied according to the requirements of each primary antibody. Endogenous peroxidase activity was blocked for 30 minutes at room temperature in a solution of 3% hydrogen peroxide in methanol (1:4), then rinsed with running tap water, followed by several rinses in distilled water, and a 5-minute incubation in TBS containing Tween 20 (Scytek Labs, Logan, UT). After pretreatment, standard micropolymer complex staining steps were performed at room temperature using the Biocare Medical intelliPATH FLX automated IHC staining instrument. Rinses after each staining step were carried out with TBS autowash buffer containing surfactant (TWB945M, Biocare Medical, Pacheco, CA).

After blocking for nonspecific protein with rodent block M (Biocare Medical, Pacheco, CA) or IntelliPATH background punisher (IP974G20, Biocare Medical, Pacheco, CA) for 20 or 5 minutes, respectively, tissue sections were incubated with primary antibodies (anti-IBA1 1:3000, anti-CD3 1:200, anti-CD45R 1:250) in normal antibody diluent (Scytek Labs, Logan, UT). MicroPolymer Rabbit on Rodent HRP Polymer was used for the CD3 and IBA1 primary antibodies, and Rat on Mouse HRP Probe & Polymer for the CD45R primary antibody. To visualize the target proteins, the substrate Biocare Medical Romulin AEC Chromogen was incubated with the tissue for 5 minutes, then counterstained with CATHE Hematoxylin (Biocare Medical, Pacheco, CA) at a dilution of 1:10 for 1 minute. Afterwards, slides were air-dried, cleared, and mounted with synthetic mounting media.

Supplementary Table 1. List of key reagents, items, and kits.

Reagent, item, or kit	Vendor	Catalog Number
AIN-93G Purified Rodent Diet without Vitamin Mix	Dyets Inc.	110700
AIN-93G VX Vitamin Mix	Dyets Inc.	310025
LouAna Safflower Oil	LouAna Oils	
AVO high-oleic safflower oil	American Vegetable Oils, Inc.	
Mazola Corn Oil	Mazola	
Cyclophosphamide	Sigma-Aldrich	C0768-1G
Prednisone	Spectrum Chemical Mfg. Corp.	PR103-25GM
DHASCO, Microalgal Oil Containing 40% DHA	DSM Nutritional Products	
Crystalline Silica	U.S. Silica	Min-U-Sil-5
Polyclonal Rabbit Anti – Iba1Antibody	Wako Fuji	019-19741
Polyclonal Rabbit anti – CD3	Abcam	Ab5690
Monoclonal Rat anti – Mouse CD45R	BD Pharmingen	550286
Uristix 4	Siemens Healthineers	
CLINITEK Status+ Urine Analyzer	Siemens Healthineers	
Urea Nitrogen (BUN) Detection Assay Kit (Colorimetric)	RayBiotech	MA-BUN-5
Polyclonal Rabbit Anti-Mouse CD3 Antibody	Abcam	ab5690
Monoclonal Rat Anti-Mouse CD45R Antibody	Becton Dickinson	550286
Mouse Cytokine/Chemokine 44-Plex Discovery Assay® Array	Eve Technologies	MD44
Nunc 96-Well Flat Bottom MaxiSorp Immuno Plates	Thermo Fisher Scientific	442404
Corning® Phosphate-Buffered Saline, 1X without calcium and magnesium, PH 7.4 ± 0.1	Corning	21-040-CV
HyClone DPBS 10X without calcium, magnesium	Cytiva	SH30378.03
Poly-L-Lysine Solution, 0.1% (w/v)	Sigma Aldrich	P8920
Purified Native dsDNA, Calf Thymus	Alpha Diagnostic International	DNAD25-N-1
Anti-DNA Antibody, double stranded, clone BV16-13	Millipore Sigma	MAB030
Goat Anti-Mouse IgG (heavy-chain sp.)-HRP conjugate	Alpha Diagnostic International	40120
K-Blue® Advanced TMB Substrate	Neogen	319176

Supplementary Table 2. Criteria for defining moribund condition of silica-treated NZBWF1 mice[a]

Criteria	Method	Response	Score Assigned
Proteinuria[1,2]	Weekly monitoring	<2000 mg/dl = negative (NEG)	0
		>2000 mg/dl = positive (POS)	1
	Note: proteinuria scoring is cumulative over time		
	e.g., POS for proteinuria at 22 wks of age and POS at 23 wks of age = cumulative score of 2		
Weight Loss[2,3,4,5]	Weekly body weight	<10% loss = NEG	0
		10-14% loss = POS	2
		>15% loss = POS	4
	Note #1: loss of body weight will be calculated relative to body weight at onset of nephritis		
	Note #2: onset of nephritis defined as = 300 mg/dl proteinuria (determined in above measurements)		
Dyspenia[1,3,4,5,*]	Daily health check	Qualitative - NO	0
		Qualitative - YES	1
Ambulation[3,4,5,*]	Daily health check	Qualitative - NO	0
		Qualitative - YES	4
Rough Coat[3,4,5,*]	Daily health check	Qualitative - NO	0
		Qualitative - YES	1

[a] Table was reviewed by CAR Veterinarian Dr. Danielle Ferguson at Michigan State University. Mice receiving a score of 4 or more were euthanized. References for criteria previously published indicated by superscripts and noted below.
