Abstract

To achieve a stereotypic lineage, each embryo of *Caenorhabditis elegans* follows an invariant cell differentiation process arising from a combination of cell polarisation, asymmetric or symmetric divisions, combined with intercellular signalling processes. This pattern of embryonic cell differentiation is driven by regulated segregation of molecules occurring at each cell division, including polarity proteins or cell fate determinants, transcription factors, p-granules and mRNAs. These distribution patterns are coupled with a robust spatio-temporal orchestration of cortical actin dynamics, which also plays a crucial role in these processes. However, compared to other molecular contents, how the actin per se is segregated from the first asymmetric division onward remains poorly understood. This study presents a thorough quantification of the intracellular distribution from the zygote to the 4-cell stage of key actors related to actin polymerisation: two nucleators (a formin and the Arp2/3 complex), a capping protein and E-cadherin. We additionally developed a novel method to assess actin polymerisation capacities from single blastomere extracts. We found that actin-related signatures arise at these early stages and that differential mechanisms of protein segregation and homeostasis occur, depending both on the cell pair and on the protein considered. Notably, if asymmetric divisions correlated with unequal partitioning of actin-related contents in a process linked with embryonic polarity, differences were revealed between AB daughter cells upon their separation. Taken together, these actin-related asymmetric distributions are adding a layer to the complexity of cell fate acquisition mechanisms in the early embryo.

Introduction

  C. elegans embryogenesis combines both an invariant lineage and early cell specification from the zygotic stage onwards. A combination of symmetry-breaking events of different nature enables the "tour de force" of assigning each cell its identity, thus determining the fate of the respective lineages in the first few divisions (Gönczy and Rose, 2005; Rose and Gönczy, 2014a; Samandar Eweis and Plastino, 2020). Cellular polarisation of membrane-associated proteins, segregation of cell fate determinants, mechanical and chemical processes, non-uniform diffusion gradients, as well as phase separated granules or asymmetries in volume during division are a few examples of the required symmetry breaking events driving these cell differentiation events. The multiplicity of the factors involved is underlining the complexity of the scenario leading to the robust embryonic choreography at work throughout the *C. elegans* lineage.

  The rapid segregation of some cellular compounds has been intensively studied during the zygotic anterior-posterior polarisation stage established rapidly after fertilization and leading to the first asymmetric division. During this phase, two simultaneous and coupled mechanisms are at work: on one side the distribution of partitioning defective (PAR) proteins into two membrane domains defining the Antero-Posterior (AP) axis, and on the other side the establishment of a cortical acto-myosin contractility gradient, inducing flows along the same axis (Rose and Gönczy, 2014b; Samandar Eweis and Plastino, 2020). Cortical flow is dragging all actin-associated cortical proteins as well as membrane-associated proteins to the anterior side of the zygote, while flushing cytoplasm in the opposite direction. Advection due to frictional forces between the different layers (membrane, cortex and cytoplasm) but also chemical interactions between PAR proteins and some actin-binding proteins, notably modulating protein turnover in the cortex, are coupling flows to anterior-posterior polarity establishment (Delattre and Goehring, 2021; Goehring and Grill, 2013). Additionally PAR polarity at the membrane, via PAR-1 gradient kinase activity, defines cytoplasmic domains that are established most probably via differential molecular mobilities in the cytoplasm. Consequently, cytoplasmic concentration gradients are established in the zygote for different molecules including MEX-5, MEX-6, POS-1, PIE-1 or MEX-1 (Daniels et al., 2010; Griffin et al., 2011; Hoege and Hyman, 2013; Tenlen et al., 2008; Wu et al., 2015). The first asymmetric distribution of these cell fate determinants, between the larger AB daughter and smaller P1 daughter, is setting the stage for the following deterministic cell division pattern and invariant lineage of *C. elegans*.

  In addition to PAR polarity proteins, studies have already revealed the anterior enrichment of some proteins present in the cell cortex. First of all, the actin filaments show asymmetries either using the MOE-1 labelling system (Shivas and Skop, 2012; Velarde et al., 2007) or using the Lifeact ::mKate2 probe (Caroti et al., 2021; Reymann et al., 2016), even though these asymmetries are less prominent using the Lifeact::GFP or GFP::MOE probes (Hirani et al., 2019). The molecular motor, NMY-2, responsible for the contractility of the actin cortex (Pacquelet, 2017; Reymann et al., 2016; Scholze et al., 2018; Schonegg and Hyman, 2006) is highly asymmetrically in the cortex but is also showing gradients within the cytoplasm (Najafabadi et al., 2022), with locally restricted mobility in the anterior half (Tenlen et al., 2008). The scaffolding proteins, septin (Gilden and Krummel, 2010; Jordan et al., 2016; Nguyen et al., 2000), the E-cadherin HMR-1, implicated in adherens junctions (Padmanabhan et al., 2017), DYN-1, a protein that regulates endocytosis and actin comet formation (Ai and Skop, 2009; Shivas and Skop, 2012) as well as the Rho GTPase RHO-1 and CDC-42 and their Guanine nucleotide Exchange Factor (GEF) ECT-2 (Scholze et al., 2018) do all also show some levels of asymmetries in the zygote. Regarding an essential formin in the early embryo, namely CYK-1, it has been reported that it

is enriched in the extreme anterior cortex and then progressively switches to an increase in the extreme posterior cortex just before the anaphase cortical rotation (Zaatri et al., 2021). These results already point towards the presence of asymmetric distributions of actin-binding proteins as well.

In *C. elegans* embryo, the second dividing cell is AB, dividing symmetrically and giving rise to the two AB daughters: ABa and ABp, which are named according to their position along the antero-posterior axis. The third division is however asymmetric, in P1 cell a second PAR polarity gradient is established, leading to its asymmetric division into the larger ventral EMS cell and the smaller posterior P2 cell, from which will derive the germ cells lineage (Delattre and Goehring, 2021; Gan and Motegi, 2021; Gönczy and Rose, 2005; Horvitz and Herskowitz, 1992; Rose and Gönczy, 2014a; Sulston et al., 1983). Due to egg shell confinement and imposed cell-cell contacts of the diamond-shaped 4-cell stage, a signal from P2 leads to the induction of EMS and ABp but not of its sister cell Aba, which has no direct contact with P2 (Evans et al., 1994; Rocheleau et al., 1997). Thus, *C. elegans* provides a unique model to investigate both asymmetric and symmetric cell divisions key for cell identity determination, which follow robust and highly stereotyped patterns within an exceptionally rapid developmental timeline—in less than an hour.

Taken together, different studies have made the link between asymmetries of mechanical properties of the acto-myosin cortex such as contractility or chirality and early embryonic *C. elegans* lineage (Naganathan et al., 2018; Pimpale et al., 2020; Pohl and Bao, 2010), but it has never been explored if some single cell differences exist in terms of actin-nucleating capacities after the first division which may impact cell identity acquisition. Here, we explore to which extent proteins responsible for actin nucleation show cytosolic asymmetries in the early embryo and follow their recruitment to the cortex. A key question is whether this machinery imposes limited availability in some cells, thus restricting locally actin polymerization capacities (Carlier, 1998; Suarez and Kovar, 2016). To address this question, we characterised the global dynamics of four main actin-binding proteins known to impact actin polymerisation and cortical mechanics from the 1- to the 4-cell stage (Naganathan et al., 2018). We chose two actin nucleators, the formin CYK-1 and the Arp2/3 complex subunit ARX-2, as well as a capping protein, CAP-1 and the *C. elegans* E-cadherin, HMR-1. CYK-1 belongs to the formin family, its human orthologue DIAPH1 is essential for the first cell cytokinesis completion (Jordan et al., 2016; Severson et al., 2002; Swan et al., 1998). The Arp2/3 complex is required for cortical filament nucleation and stability in early embryogenesis (Severson et al., 2002; Yan et al., 2022) and is mandatory for cell migration during gastrulation (Knight and Wood, 1998; Roh-Johnson et al., 2012; Roh-Johnson and Goldstein, 2009; Yan et al., 2022). Interestingly, balanced nucleation via Arp2/3 and CYK-1 set filaments homeostasis and are required notably for timely assembly and constriction of the contractile ring during cytokinesis (Chan et al., 2018) and filopodia nucleation (Hirani et al., 2019). The capping protein CAP-1 is also essential for proper actin organisation during the zygotic stage or in the adult germline by oppositely restricting polymerisation (Ray and Zaidel bar, 2021). HMR-1 is an important player to control cortical mechanics and as such is essential during diverse morphogenesis events, including blastomere polarity establishment or gastrulation (Caroti et al., 2021; Padmanabhan et al., 2017). It is mainly involved in tethering the actin cortex to the cell membrane both at cell-cell contacts but also in non-junctional region where it additionally acts as a spatial regulator of Rho signalling (Padmanabhan et al., 2017).

To assess if actin polymerization capacity is equivalent in all cells of the early embryo and how actin cytoskeletal networks are inherited over the first few divisions, we performed a quantitative assessment of the availability of actin regulation machinery. To do so, we have set up a pipeline of live imaging spinning-disk microscopy and semi-automated quantitative image analysis, giving a reference

map in space and time of endogenously expressed proteins densities in each cell as an output. This method allowed us to follow protein spatio-temporal dynamics at both cortical and cytoplasmic planes and compare the differential segregation between cells during the early dynamic steps of *C. elegans* embryogenesis. To expand these *in vivo* results and probe more directly actin content itself, we performed *in vitro* actin polymerization assays on single cell extracts. Therefore, our data provide a unique map of actin-related proteins in early embryos, with asymmetries correlated to differences in cell identity.

Results

Actin binding protein distribution over the course of the few first divisions

In order to follow the spatio-temporal distribution of primary regulators of the actin polymerisation in the early *C. elegans* embryo, we took advantage of CRISPR/Cas9 GFP knock-in strains (Table 1) for two actin nucleators, the CYK-1 formin and ARX-2, a subunit of the Arp2/3 complex, as well as the capping protein CAP-1 and the cadherin HMR-1. We focused our analyses from the zygote to the 4-cell stage (Figure 1A). Endogenous CRISPR labelling ensures that the fluorescence intensity acquired via high-resolution, high-sensitivity microscopy accurately reflects the level of endogenous protein: the intensity of an equatorial section of the embryo being proportional to the cytosolic concentration. At this localisation, cytoskeletal proteins mostly diffuse freely in the cell volume but can also interact with the filaments populating the cytoplasm (Raja Venkatesh et al., 2024; Velarde et al., 2007) (Figure 1B). The cytosolic concentration can thus be considered as a pool of proteins that undergo transition between activated and inactivated states. Quantification of overall cytoplasmic fluorescence intensity revealed differences in the mean intensity between labelled proteins (Figure 1C). For instance, endogenously expressed CYK-1::GFP and HMR-1::GFP show the lowest fluorescence level at this stages, ARX-2::GFP and CAP-1::GFP being clearly higher. This result revealed differences in the expression levels of these cytoskeletal proteins in the early embryo.

Acquisition of the fluorescent intensity at the cortical plane allowed to access protein density at the cell cortex, thus reflects the actively engaged proteins. As expected, additional shorter lived actin-rich architectures were abundantly observed in the cortical plane: CYK-1 rich cytokinesis rings appearing at each cell cycle, Arp2/3 rich endocytosis patches (Nakayama et al., 2009; Shivas and Skop, 2012), lamellipodial extensions at cell-cell contacts and filopodia that are clearly distinguished by their characteristic tips labelled with CYK-1 (Hirani et al., 2019)(Figure 1B).

Cytosolic actin related proteins are differentially segregated between sister cells

To assess how actin related cytoskeletal proteins are inherited over the first few divisions in the early embryo, we followed the partitioning of the actin-binding proteins before and after each division step. We focused first on quantification of intensities in the cytoplasmic cross section of the embryo, thus on the global pool of proteins available. Single embryo quantifications of the time evolution of the mean intensity in each cell clearly showed some inequality of cytoplasmic mean intensities between sister cells (Figure 2A). For example, we observed that the mean cytoplasmic intensity in the larger AB cell is higher than in its smaller P1 sister cell for ARX-2::GFP and CAP-1::GFP but not very different for CYK-1::GFP. The ABp cytosolic fraction is enriched at the four-cell stage compared to ABa and EMS, and the smaller P2 shows significantly lower levels for all three proteins.

To better assess cell-to-cell variability and thoroughly compare embryos, we used two different quantitative approaches. First, we calculated the ratio of the mean intensity between each

cell pair taken at each time point (Figure S1). The time evolution in the cytosol showed a progressive increase of the ratio at the 2-cell stage but otherwise little variation (Figure S2A), we thus compared the averaged of these ratios over the duration of the whole cell cycle (Figure 3B, C, S3). The use of intensity ratio of two cells from the same embryo acquired at the same time point allowed to avoid the need of additional normalization between samples or strains and to correct for photobleaching. Second, we used the probability distribution function of the intensities found in each cell type to compile at each single time point, the global difference between each cell pair via the convolution of their probability distribution and normalised these differences by the overall levels of fluorescence intensity for each strain (Figure S1). In both approaches, we added a non actin binding protein, the highly expressed cytosolic mex-5p::mNG::Halo transgene, for assessing passive cytosolic distribution.

Our two methods of quantification of fluorescent intensities, used as a proxy of protein differential concentration between embryonic cells, lead to similar results (Figure 2B, C, S3A). They showed an imbalance in favour of AB after the first division notably for CAP-1::GFP, ARX-2::GFP and the cytoplasmic mNG, whereas CYK-1::GFP and HMR-1::GFP distributions were more balanced between AB and P1. At the 4-cell stage, we observed a slight but constant bias in favour of ABp compared to ABa for all three actin binding proteins as well as for mNG, whereas HMR-1 remained more equilibrated. Stronger enrichments were observed for EMS relative to P2 for all five proteins. In conclusion cytoplasmic differences visibly emerged from these first cell division patterns. Our results revealed more pronounced differences in cases of asymmetric divisions, although some differences were also observed in the AB daughter cells. Thus, these observations challenge the view that AB division is symmetric with many regards before the induction due to contact with P2 (Gan and Motegi, 2021; Priess and Thomson, 1987). Indeed, we observed that differences between ABa and ABp were observed as soon as division occurred (Figure 2A). In conclusion, each blastomere between the 1- to 4-cell stages contains a different set of cytosolic concentration of cytoskeletal proteins, defining a proper cell identity to each cell. Notably, the P1 and P2 cells were depleted of all protein content, presumably a hallmark of germ cells progenitors. Importantly, the presence of asymmetries in the segregation of cytosolic mNG::Halo proteins opens the possibility that asymmetries exist in terms of diffusion rates within the cytoplasm, irrespective of the nature of the protein (Hoege and Hyman, 2013). However, if some cytoskeletal proteins were seemingly segregated through passive diffusion, others such as CYK-1 and HMR-1 segregated more symmetrically, likely following a different segregation rule. To summarize, we conclude that actin-related cytoplasmic signatures can arise at these early stages in specific cells, presumably via distinct mechanism.

Proteins segregate either via conservation of concentrations or conservation of densities

We next asked whether cytosolic protein segregation is linked to cell volume differences after each division. We thus assed if correlation emerge between these two quantities for each cell pair. The embryo initially divides while maintaining a constant total volume, successive division can be either asymmetric or symmetric, leading to major volumetric differences (Cao and Wang, 1990). We used as proxy of cell-to-cell volume difference the ratio of the mid plane section area. In theory, two trends could be observed in correlative plots between volume ratios and concentration ratios after each division (Figure 2E). If the concentration is equally maintained between sister cells, the intensity profile should follow the vertical line (content asymmetry=1). With symmetric partitioning of protein quantities, the profile should align with the line x = y, reflecting volume-dependent distribution. Our correlative plots showed that CYK-1 intensity ratios spread vertically, thus favouring the hypothesis of conservation of concentrations irrespective of cell volumes differences (Figure 2D). CAP-1, HMR-1 and

mNG oppositely seemed to follow the second trend, along the x=y direction, suggesting conservation of quantities between daughter cells. ARX-2 was lying more in the middle of the two tendencies. These general trends of segregation might not be applicable for all cell divisions, as a close observation of cell positioning in these plots did show specific segregations depending on the cell pair. For instance, the symmetric sisters ABa/ABp were systematically lying close to the intersection y=x=1, while the ABa/EMS was found in its vertical slightly above, and the most asymmetric cell pair EMS/P2 were in most cases very close to the oblique x=y line. Taken together, these analyses revealed that differential mechanisms of protein segregation and homeostasis occur, depending both on the cell pair and on the protein considered.

Protein differential segregation can impact cortical abundance

Following these findings regarding cytoplasmic content segregation, we next investigated whether asymmetries in protein density also arose at the actin cortex. Note first that the cortical plane includes the actin cortex per se as well as many embedded actin architectures such as filopodia, endocytosis patches or lamellipodia. Second, in this part of the study, we referred to the cortex as the cell surface area facing the eggshell i.e. the cell-free cortex. We excluded the cell-cell contact interfaces, notably due to the impossibility of attributing the proteins found at each of these interfaces to one or the other neighbouring cell. We thus turned to the comparison of the quantification of the mean intensities at the cortical planes of each cell, following the same approaches used for the cytoplasmic plane. Inequalities were observed, for instance the mean cortical intensity in the larger AB cell was higher than in its smaller P1 sister cell, for CAP-1 and ARX-2 (Figure 3A). The ABp, ABa and EMS cortical fraction were enriched at the four-cell stage compared to the total mean intensity of the embryo and to the P2 cell (Figure 3A, S3B). Note that time evolution of intensity ratios at the cortex can be more sensitive to cytoskeletal rearrangement, notably cytokinesis ring assembly, as observed for the 2-cell stage for CYK-1 (Figure S2B). Globally, we found similar results in the cortex to those quantified in the cytoplasm, both for intensity differences (Figure 3B, S3) as well as for the intensity ratio between each cell pair (Figure 3C, S3). AB was enriched in all proteins except CYK-1 compared to P1; EMS was enriched for all proteins relative to P2, with some more significatively than others; overall ABp was enriched for all proteins except for HMR-1. These results were confirmed by the correlation plots of intensities between the two different planes of observations (Figure 3D). In all cases, we observed a good linear correlation (Figure 3D). For CYK-1 the slope was close to 1 but higher for CAP-1 and ARX-2 (slightly below 1.3, Figure S3D). Thus, cortical recruitment showed a strong correlation with the general availability of proteins in the cytoplasm at these stages. These results support the hypothesis that the cytoplasm constitutes a limited reservoir of available actin nucleators and capping proteins. This suggest that asymmetries in cytoplasmic concentration of proteins could affect the density of active proteins targeted to the actin cortical plane and thereby introduce cell specificity in the early embryo.

Protein differential segregation is dependent on embryonic polarity

We next assessed if the identified asymmetric distributions of cytoskeletal proteins were linked to anterior-posterior polarity establishment of the early embryo. We used RNAi of a polarity protein (*par-2)* to reduce the asymmetry of P0 and P1 divisions, thereby anteriorizing the embryo, synchronising the cell cycle at the 2-cell stage and leading to a disruption of cell positioning at the 4-cell stage (Beatty et al., 2013). Embryos subjected to RNAi(*par-2*) were classified in two categories according to its cell positions at the 4-cell stage: the loss of diamond shaped cell-cell contacts was

classified as strong phenotype (Figure 4A), whereas normal cell-positioning was considered milder. In all cases the divisions of AB and P1 happened synchronously, contrary to the WT condition. Quantifications were performed as previously described and revealed a clear reduction of the unequal partition of actin binding proteins, for all cell pairs (Figure 4B-D) and fully abolished in the strong phenotype category both in the cytoplasmic and in the cortical planes. This result confirmed that actin related cytoskeletal protein segregation was governed by embryonic polarity.

Novel method to probe single cell actin content

Beyond evaluating the differential abundance of actin-binding proteins, we further investigated whether embryonic cells might also exhibit variability in their actin content. Assessing actin monomers or filamentous concentration within a particular cell is a complex task which relies on indirect measurements and technical tricks (Cramer et al., 2002; Gonzalez Rodriguez et al., 2023; Kiuchi et al., 2007; Koestler et al., 2009; Lee et al., 2013; Malla et al., 2022; Skruber et al., 2018; Vitriol et al., 2015). Indirect labelling via phalloidin or Lifeact probes is possible but can lead to different results depending on the probe used (Caroti et al., 2021; Courtemanche et al., 2016; Hirani et al., 2019; Motegi and Sugimoto, 2006; Reymann et al., 2016; Skruber et al., 2018). We decided to develop an alternative method to assess actin content in a cell specific manner that is suitable to compare the few individual cells of the early *C. elegans* embryo. We used *in vitro* actin polymerization assays on single cell extracts to quantitatively evaluate both F-actin amount and polymerization capacities. Targeted UV laser ablation was used to perforate individual cells, leading to the extrusion of most of their cytoplasmic contents and the concomitant fragmentation of their actin networks (Figure 5A, S5). In the appropriate buffer condition containing Phalloidin-Alexa-488, we then followed the rapid actin polymerization outside of the cell ghost (Figure 5A, S5). Phalloidin, which binds to the side of filaments, labels both filaments assembled in the embryo prior ablation and those actively polymerizing in the cell extract. Oppositely, supplementation with low amount of purified monomeric actin coupled to Alexa-568, revealed only the filaments actively polymerizing after ablation- as the supplementation of G-actin is in the range of the critical concentration of actin bellow which spontaneous polymerization occurs (Figure 5A). Dual labelling allowed us to confirm that actin seeds are extracted from the lysed cell (green fragments) and rapidly elongate together with newly formed filaments, before reaching an equilibrium state when all G-actin is consumed (yellow fragments, Figure 5A, S5). Additionally, to verify that active polymerization is indeed at the origin of the filaments observed, a control condition was performed with Cytochalasin B, a drug inhibiting actin polymerization. This resulted only in short filaments observed in close proximity to the lysed cell (Figure 5A). To quantify which percentage of cellular actin is extruded and effectively released in the extract, experiments were conducted in presence or absence of detergent. As expected, addition of Triton Tx-100 to the medium lead to membrane disassembly, allowing the release of an increased amount of cellular content and increased the number of filaments observed (Figure 5A).

During the course of polymerization, we measured the fluorescence intensity in the area occupied by the extract. This integrated intensity rapidly reached a plateau value (Figure 5B, C). As in standard actin pyrene assays, the intensity at the plateau scales with the F-actin content at steady state. Using the mean intensity of this plateau we can estimate that experiments without triton represent 94% of the cellular content released in the presence of triton, thus supporting that a large amount of the actin cell content is released by UV ablation (Figure 5E). Applying the same quantification method, the presence of the Cytochalasin B led to a strong reduction of the intensity measured with Phalloidin labelling (14% F-actin remaining). Note that we observed a limited diffusion

of filaments around the embryo debris (Figure S5A), and constraining the experiment in a smaller volume via PDMS microwells did not yield different results. Thus, to maintain reasonable experimental throughput, we decided to simply restrain the quantification to the visible extract area containing the majority of filaments (Figure 5B). To conclude, our experimental design allows to distinguish polymerized and actively polymerizing filaments from a single cell extract bellow the nL volume range, thus quantitatively assess single cell total actin content.

Cell specificities are revealed in terms of actin polymerization capacity

This experimental design was used to compare single cell actin polymerization capacity from 1-cell to 4-cell stages. We quantified the total amount of released actin using Phalloidin labelling from single cell extracts. Note that triton was not performed in the following experiments, to avoid contamination from neighbouring cells. Measurements of the integrated fluorescence intensity over time for the different extracts increased and reached rapidly a plateau (Figure 6B), allowing us to estimate the total actin content extruded out of these cells following laser ablation (Figure 6C). After 15 min, the F-actin networks obtained for the different cell extracts showed significant differences (Figure 6A). P0 cell extracts assembled more filaments than all other single cell extracts, as expected from its large size. At the 4-cell stage, ABa, ABp and EMS were quite similar but P2 cells extracts showed minimal actin polymerisation, in agreement with previous *in vivo* observations. To estimate the differences in terms of actin concentration available for polymerisation within their cell of origin, we additionally normalised these values using either our measured midplane cell area prior ablation (Figure 6D) or published values of these cell volumes (Figure S5). Surprisingly in terms of actin concentration, P0 fell at the lowest position, P1 was over AB and EMS showed the highest values (Figure 6E). Thus, smaller cells such as P1 have lower actin content but maintain surprisingly a high actin concentration. This result might reflect the increase of surface to volume ratio that requires the polymerisation of additional actin cortex. Additionally, EMS larger estimates of actin concentration might be linked to its assembly of large lamellipodial protrusions extending over its neighbouring ABa and ABp cells. Altogether, first these results indicate that there is not a strict correlation between cell volume and the estimated actin content available for active polymerisation, notably for larger and smaller embryonic cells. Second, it confirms that there is a fine tuning of the availability of polymerizable actin in each of these differentiating embryonic cells in addition of differences in the availability of actin binding proteins.

Discussion

The early embryo relies initially on maternally provided proteins loaded in its large oocyte (Zacharias and Murray, 2016). In *C. elegans*, this initial pool of proteins is split through divisions into the different daughter cells, asymmetrically or symmetrically, along a fixed lineage and must be sufficient to ensure the success of these first initial divisions (Rose and Gönczy, 2014b). Asymmetries have already been characterised for several proteins, including cell fate determinants and differences in cell contents were shown to be drivers in the process of early cell identity acquisition. Regarding cytoskeleton proteins, only few studies mentioned asymmetries between cells, as for actin (Reymann et al., 2016; Shivas and Skop, 2012) or myosin (Munro et al., 2004; Pacquelet, 2017; Reymann et al., 2016; Schonegg and Hyman, 2006), for which a gradient of free NMY-2 molecules in the cytoplasm was recently characterised (Najafabadi et al., 2022). Our findings demonstrate that the temporal and spatial unequal partitioning of key actin assembly regulators—including a formin, the Arp2/3 complex,

capping proteins, and the cadherin HMR-1—occurs in both the cytoplasm and the cortical plane during cell division. Importantly, these asymmetries in actin-related content were found to depend on polarity cues. Furthermore, concentration gradients of freely diffusing actin-binding proteins can form within the cytoplasm, analogous to those previously described for cell fate determinants such as PAR proteins and MEX-5 (Daniels et al., 2010; Hoege and Hyman, 2013; Tenlen et al., 2008). Asymmetries in the inherited distributions of cytoskeletal proteins are likely to amplify cell to cell differences in terms of actin assembly dynamics along the lineage of the early *C. elegans* embryo.

Previous measurements focusing on CYK-1 single particle tracking to assess actin filament elongation rate between the 1-cell to 4-cell stage showed no significant differences in terms of elongation rate, suggesting no difference in the availability of actin monomers within embryos (Costache et al., 2022). An alternative hypothesis would be that filament growth is limited by another factor, such as profilin detachment rate from actin when incorporating into the filament, thereby masking changes in the availability of actin (Funk et al., 2019).

Modulating the availability of actin nucleators could be an alternative mechanism to modify differentially actin polymerisation capacities between cells, and in turn this would impact the physical properties of their cortex. For example, the hydrodynamic length is reduced by CYK-1, ARX-2 or CAP-1 depletion, leading to a decrease of cortical chiral flows in the zygote (Naganathan et al., 2018). More generally, the balance between actin nucleation via formin or Arp2/3 is controlling the density and degree of entanglement of actin networks, and the rate of filament capping is key to set filaments length. Note that all such changes in ABP activity also impact the amount of monomeric actin available and the ratio between monomers and filaments, thus providing feedback loops impacting actin homeostasis. To conclude, some tight regulation of concentration gradients of proteins such as CYK-1, ARX-2 and CAP-1 is important to define cell specificities both in terms of cytoskeletal architectures and dynamics scaling up to specificities in terms of mechanical properties. Going a step further, as actin cytoskeleton and cell mechanics are intrinsically linked to cell identity, we can hypothesise that these differences are possibly playing a role in the cell potency during these early embryonic stages.

Along the lineage the increase of surface to volume ratio is imposing a continuous increase of cortical surface coverage by actin filaments. Such necessity might explain the general increase in the content of actin binding proteins observed in our *in vivo* quantification between the 2-cell and 4-cell stage (Figure S3D). The P1 cell however stood out from the other cells, showing both a significative depletion of proteins as well as presented a specific reduction in the total amount of extruded actin. This raises the possibility that the P1 cell, and by extension the whole P lineage, is maintained in a state of low actin filament density. Oppositely EMS cells, in addition of showing high levels of ABPs, showed a high actin content when normalised by cell volume. These facts do correlate well with the capacity of EMS to build large lamellipodia extensions migrating over it neighbouring cells.

A surprising result from our work is the precocious asymmetry observed in AB daughter cells, ABa and ABp. Concentrations of CYK-1, ARX-2 and CAP-1 are spatially enriched in the ABp cell from AB division onwards (Figure 2A, 3A), thus indicating that a concentration gradient is probably set ahead or concomitant to AB division. This difference arises prior to the known Notch signalling event, in which direct contact between P2 and the ABp cell triggers ABp differentiation (Priess, 2005). In other words, asymmetric distribution of actin-related proteins can precede cell differentiation in this cellular context. On the other side our perturbation experiment also revealed that the asymmetry in the inheritance of actin related proteins is positioned downstream of cell polarity. Further perturbation experiments using partial RNAi depletion or mutants will have to be performed to decipher what is the mechanism at work accounting for these differences.

Waiting for these results we can however discuss on potential hypotheses. In the majority of the cases, all actin binding proteins do follow the same trend with respect to cell-cell ratios, indicating that there might be a generic mechanism at work to regulate the extend of the symmetry or asymmetric segregation. One hypothesis would be that cortices with higher actin densities, such as the anterior half of the zygote, while offering more numerous binding sites for actin binding proteins could induce a local gradient of cytoplasmic concentrations as well. Feedback mechanism might amplify these gradients over time: increase of local concentration of nucleators leading to increase in filaments thus more binding sites for ABPs. The binding and unbinding rates to actin filaments as well as overall turnover of actin networks would thus be key parameters controlling such mechanism. Observation of the distribution of the two Lifeact probes in the early lineage could support this hypothesis. Lifeact is a peptide binding to actin filament with fast binding and unbinding kinetics, it was previously shown that when coupled to mKate2 fluorescent probe its turnover was one order magnitude slower than when bound to GFP (Hirani et al., 2019). As a result Lifeact:mKate2 turnover is comparable to the turnover of cortical F-actin in the *C. elegans* cortex (Robin et al., 2014). In the early embryo, we have observed an enhanced asymmetry in Lifeact::mKate2 compared to Lifeact::GFP. It is notably enriched in the anterior side of the zygote up to the 4-cell stage (higher in AB at the 2-cell stage and more intense in Aba/ABp compared to EMS and P2). Our present quantitative analysis of actin related content is pointing towards the presence of an asymmetrical distribution along the same direction than this actin binding probe. In addition, our *in vitro* polymerisation assay also clearly points towards large differences in the total actin content between cells, even though it is less clear if these translate to effective differences in terms of available actin concentrations. In the future, a direct actin labelling method would be required to quantify with higher precision changes in actin densities between cells. To conclude, a minor anterior enrichment of cortical density in the zygote can be sufficient to maintain cellular asymmetry of a binding partner, which would be released upon disassembly of actin only. For this reason, we predict that the turnover rate of actin binding proteins might be key in the process of asymmetric inheritance in the lineage. Note that in *C. elegans* early embryo, actin turnover was estimated in the same range as CYK-1 formin bulk cortical turnover rate (Costache et al., 2022), thus this prediction could be valid, as well as for the Arp2/3 or Capping Protein which are thought to be longer-lived on actin filaments.

In the cell divisions studied, the transgenic highly expressed free fluorophore mNG::Halo was observed as not partitioning equally at each cell division. This has never been reported so far and might be a hint that gradients in overall protein mobility within the cytoplasm might exist and slightly influence protein concentrations in these large cells. However, some singularities to this general trend were also observed for some actin binding proteins, indicating that some specific mechanisms may also exist, either to maintain equality between the cells or oppositely to enhance a spatial distribution pattern. For instance, the CYK-1 formin is surprisingly equally distributed between AB and P1. This is not the case for the ARX-2 or CAP-1 which maintain more asymmetries overall in the cortex and cytoplasm before and after division. An alternative explanation for mNG::Halo asymmetry could reside in asymmetric distribution of organelles within the cytoplasm modulating via exclusion the amount of diffusive proteins. In addition, general cytoplasmic streaming in opposite direction to cortical flows could also play a role in the concentration gradient observed for these two proteins.

In conclusion, we have established a spatio-temporal map of the early *C. elegans* embryo with respect to actin and key ABPs at a high resolution. Our work raises the question of a potential embryonic control on differential cellular actin homeostasis and actin cytoskeletal steady states. We favour the hypothesis that concentration gradients could be sufficient to drive and maintain cellular

asymmetries both in the cytoplasm and cortex for some important actin binding proteins. Some of the acquired cell specific cytoskeleton properties might be instrumental in the subsequent steps of cell differentiation events in the early *C. elegans* embryo. This knowledge will be instrumental in future studies aiming at understanding how actin directly impacts cell differentiation processes.

Limitation of the study

Although we performed rigorous quantitative assessments of single cell contents, our study is subject to certain limitations that warrant consideration. First, due to a low thickness of the cell cortex we cannot exclude that fluorescence from the cytosol is impacting the fluorescence in the cortex, notably in the case of low density of protein recruitment in the cortex. This is especially the case for control mNG::HALO that does not attach specifically to the actin cortex. Similarly, as noted in the results section, our quantification focused on the cortex facing the eggshell, rather than on cell–cell contact regions, which are highly enriched in actin filaments. Another limitation comes from the fact that we cannot distinguish between active versus inactive proteins, notably for nucleators. Quantification of the availability of some key proteins required upstream in the signalling cascade would be complementary to our study to decipher the limiting factors. Finally, translating fluorescence intensity into accurate estimates of cellular concentrations represents significant challenges (Aroush et al., 2017; Gonzalez Rodriguez et al., 2023; Kiuchi et al., 2007; Koestler et al., 2009; Malla et al., 2022; Vitriol et al., 2015) and many additional parameters need to be considered while doing so. Notably, the cytosolic volume—distinct from the total cell volume due to organelles—can influence concentration estimates (Rodriguez et al., 2023), especially in P-lineage cells enriched in P-granules. For this reason, the use of cell volume as a mean to normalise the released actin content in order to compare possible actin concentration between cells should be taken with precaution.

Materials and Methods

Strains maintenance

Animals were cultured at 20°C on Nematode Growth Medium plates seeded with OP50 (Brenner, 1974) at 20°C. The strains used in this study are presented in the following table.

Table 1: Newly generated strains for this study

Strain	Genotype	Source
ACR004	*cyk-1(ges1[cyk-1::GFP + LoxP; unc-119(+)])III ; ltIs44([pie-1p::mCherry::PH(PLC1delta1) +unc-119(+)])V*	This work
ACR013	*arx-2(cas607); ltIs44([pie-1p::mCherry::PH(PLC1delta1)+unc-119(+)])V*	This work
ACR011	*cap-1(ges3[cap-1::GFP + LoxP unc-119(+) LoxP])IV; ltIs44([pie-1p::mCherry::PH(PLC1delta1)+unc-119(+)])V*	This work
ACR089	*hmr-1(cp21[hmr-1::GFP + LoxP])I; ltIs44([pie-1p::mCherry::PH(PLC1delta1)+unc-119(+)])V*	This work
ACR090	*cpIs90[mex-5p::mNG::HaloTag::tbb-2 3'UTR + LoxP] II; ltIs44([pie-1p::mCherry::PH(PLC1delta1) + unc-119(+)])V*	This work
ACR147	*cyk-1(ges15[cyk-1::GFP+LoxP]) III ; ltIs44[pie-1p::mCherry::PH(PLC1delta1) + unc-119(+)]V*	This work

SWG019	cyk-1(ges1[cyk-1::GFP + LoxP unc-119(+) LoxP) III; unc-119(ed3) III.	(Reymann et al., 2016)
SWG300	cyk-1(ges1[cyk-1::GFP + LoxP unc-119(+) LoxP) III; unc-119(ed3) III.	
SWG052	cap-1 (ges3 [cap-1::GFP + LoxP unc-119(+) LoxP]) IV; unc-119 (ed3) III	This work
GOU2047	cas607 [arx-2::gfp knock-in]	(Zhu et al., 2016)
OD70	ltIs44[pie-1p::mCherry::PH(PLC1delta1) + unc-119(+)]V	(Audhya et al., 2007)
LP539	cpIs90[mex-5p::mNG::HaloTag::tbb-2 3'UTR + LoxP]II	(Dickinson et al., 2017)

Microscopy

L4 adults were collected on separate plates 24 hours before embryo imaging. Hermaphrodites were dissected on coverslip in M9 buffer and mounted under 2% agarose pad. Coverslip was sealed to slide with melted VALAP (1:1:1, Vaseline, lanolin and paraffin wax).

All microscopy samples were collected using an Inverted Nikon Eclipse Ti configured by Gataca Systems (Massy, France) and equipped with a Yokogawa CSU-X1 scan head, a simultaneous dual camera with two Prime 95B cameras (Photometrics) and a 100×1.4 NA objective lens. Simultaneous acquisition in dual colours was performed using 491nm and 561nm laser lines with a combination of emission filters for each camera (dual band 506-548/620.5-669.5 and 609/54) after splitting with a dichroic at 560 nm. Image acquisition was controlled by MetaMorph software (Molecular Devices, Sunnyvale, CA), in a temperature-controlled room set to 20°C. Imaging conditions were set to assure minimal photobleaching and no photo-toxicity in order to allow for live observation in 3 optical sections over 10 minutes of embryonic development but with sufficient sensitivity enabling the detection of low expressed levels of proteins (200ms exposure time with 20% power of 491nm laser and 30% for 561nm laser). Each Z-stack is timely separated by 10s for a total duration of 10min and maintained in focus using the Perfect Focus controller. Thus, each timepoint is composed of 3 different confocal planes spaced by 3µm, the cortical plane (Z=1), the intermediate plane (Z=2), the equatorial plane (Z=3).

***In vitro* cell extracts**

L4 adults were collected 24 hours before embryo imaging. Hermaphrodites were dissected on a cleaned coverslip coated with BSA 5% in 5µL of actin polymerization buffer (15 mM imidazole, pH 7.0, 74 mM KCl, 1.5 mM MgCl2, 165 mM DTT, 2 mM ATP, 50 mM CaCl2, 5 mM glucose, 30 mg/mL catalase, 155 mg/mL glucose oxidase, 0.75% methylcellulose) either supplemented with 1µL of Phalloidin-488nm (1:200 diluted in G-buffer; A12379) and/or 0,1µM of purified G-actin-Alexa568 (from rabbit, gift from Christophe Guerin, Laurent Blanchoin). For Cytochalasin B experiments, 1µM (diluted in DMSO; C6762) has been added to the actin polymerization buffer. For triton experiments, 0,1% of Triton TX100 has been added to the actin polymerization buffer. Coverslip was sealed to slide with VALAP (1:1:1, Vaseline, lanolin and paraffin wax). Imaging was performed on the same

microscope as described above; in single camera mode (filters: 525/50 (GFP) and 605/64 (RFP)) and using a different objective (Leica HC Plan Apo 100x/1.4-0.7oil WD 0.1mm). Cells of interest were lysed using UV laser ablation (iLas2 FRAP module from Gataca system equipped with a 355 nm, 0.6 ns pulsed, 5W laser (Teem Photonics)). Images were acquired prior ablation (notably a mid-plane section in phase contrast) and for 15 minutes after ablation in the plane adjacent to the coverslip with a framerate of 2s (30% laser power and 200ms exposure time). Focus was maintained using the Perfect Focus controller.

Image analysis (*in vivo*)

Cell outline was segmented using an interactive segmentation tool based on machine learning algorithms, ILASTIK (Berg et al., 2019). The training was performed on the equatorial (Z3) and the intermediate plane (Z2). The segmentation of the complete timelapse was then obtained automatically. As the Z1 plane was more prone to segmentation errors, we preferred to use the clean Z2 segmented regions adequately cropped to fit the cortical area in the Z1 plane.

In order to realign each embryo over its developmental time, we used a reference time point for each cell cycle - chosen as the onset of membrane ingression observed in the equatorial section (Z3) during cytokinesis onset (Chan et al., 2018) (Figure 1A).

We quantified the average fluorescence intensity for each cell at each time point and for each optical section using Matlab. Prior analysis, we corrected for inhomogeneity of the field of view. We used two approaches to compare intensities between cells. First, we performed cell to cell ratio for each time point either for cytosolic or cortical mean fluorescence intensities. This mean intensity ratio allowed us to estimate the relative proportion of fluorescently labelled proteins between cells. Second, we used the probability distribution function of the intensities found in each cell. We compiled the convolution of the normalized distributions for each cell pairs giving in a statistically significant manner the cell pair content differences for all time points (Figure S1). In order to normalize intensity differences between strains showing significative differences in the level of expression of the protein of interest, we normalized these differences using the embryo mean intensity taken for all samples and all frames. Correlation plots were performed, using the mean value of each cell to cell mean intensities ratio at the cortex and at the cytoplasm, fitting a linear model (f(x) = p1*x+p2) while excluding the outlier values with cortical ratio above 2 (Figure 4). The corresponding step by step annotated codes will be available upon publication on our Reymann lab Github.

Image analysis (extracts)

Quantification is performed using Fiji, Excel and RStudio. The last frame of the image sequence is used to define a region of interest manually. This ROI should include most of the actin filaments polymerised (Figure S5) while excluding the cell/embryo ghost. The success of the cell lysis is assessed and experiments for which cells did not burst properly are excluded from the analysis (flow of material out the cell is visible in phase contrast after ablation). Experiments for which abnormally low polymerisation is observed are also excluded. Measurement of the integrated fluorescence intensity is performed for each time frame and normalised using the first 10 frames, before averaging over the different embryos. The *C. elegans* embryonic cell volume and surface are taken from published publication (Thiels et al., 2021).

Acknowledgements

The authors would like to thank Sophie Quintin for critical comments on the manuscript; Karine Crell and Stephan Grill, notably for generating SWG300 strain as replacement of SWG004, as well as Pierre Gönczy and Guangshuo Ou for providing strains. Some strains were also provided by the CGC, which is funded by NIH Office of Research Infrastructure Programs (P40 OD010440). We warmly thank Christophe Guerin and Laurent Blanchoin for providing actin and actin binding proteins as well as for training us for microcavities fabrication. We would like also to particularly thank the Imaging Center of IGBMC (ici.igbmc.fr) for their assistance. We are also grateful to additional members of A-C.R. laboratory for discussion and technical assistance, as well as Christophe Reymann for insightful discussions on quantification methods.

Competing interests
The authors declare no competing or financial interests.

Funding
This work was funded by the French state funds through the Agence Nationale de la Recherche under the project JCJC ANR-19-CE13-0005-01 (ACR), and was supported by IdEx Grant from the University of Strasbourg (A-C.R.). This work of the Interdisciplinary Thematic Institute IMCBio+, as part of the ITI 2021-2028 program of the University of Strasbourg, CNRS and Inserm, was supported by IdEx Unistra (ANR-10-IDEX-0002), and by SFRI-STRAT'US project (ANR-20-SFRI-0012) and EUR IMCBio (ANR-17-EURE-0023) under the framework of the France 2030 Program. G.M. and R.B. are funded via the ANR JCJC granted to A-C.R. (ANR-19-CE13-0005-01) as well as respectively the FRM and La Ligue. A-C.R. is a CRNS investigator. N.A. is an Unistra technician personnel. We thank the France-BioImaging infrastructure supported by the Agence Nationale de la Recherche (*ANR-10-INBS-04, call ''investissements d'Avenir''*) for their support to the Imaging Center of IGBMC.

Figure Legend

Figure 1: Distribution of some actin binding proteins over the first few divisions
(A) Schematic representation of the early steps of embryogenesis. The red dashed lines correspond to the cytokinesis onset of each cell stage used as time reference. (B) Spatio-temporal distribution of proteins of interest (cyan) together with the membrane marker (PHPLC1δ1, red), at the cortex (left column) and equatorial plane of the embryo (right column). Scale bar is 10 μm. (C) Overall mean fluorescent intensity in each cell measured in the cytoplasm (mean ± standard deviation).

Figure S1:
(A) Example of a cell segmentation output from Illastik. Cell ROIs are used to extract intensities such as the ratio between AB and P1 cell pair at each time point. (B) Example of plots of normalised probability distribution of the intensities of these two cells (AB and -P1 are shown) as well as the convolution of these probability distributions (AB-P1). The extracted expected value and standard deviation of these probability distributions are referred to as cell-cell intensity difference in the main text. (C) Table of average fluorescence intensities for each cell measured in the cytoplasm (mean ± standard deviation) and used to normalise the probability distribution. (D) Table of the number of cells counted for each category. Note that some cells are removed for the analysis such as if the acquired and segmented cortical surface is two small (cortex out of plane).

Figure 2: Cytosolic proteins are often asymmetrically partitioned between sister cells
(A) Time evolution of the mean intensity at the equatorial plane in each cell for a representative single embryo expressing fluorescently labelled ABP. Dashed lines represent the evolution of the mean intensity of the embryo (all cells). (B) Ratio of intensities for each cell pair measured in the cytoplasm and averaged during the whole cell cycle. (C) Differences of cytoplasmic intensities for each cell pair, calculated via the convolution of normalised density probability distributions taken at each time point and normalised by the mean embryo intensity for each strain. Individual data points, mean values and standard deviations are shown for B and C.

Figure S2: Time evolution of relative protein abundances
Time evolution of the intensity ratio for the different cell pairs in the cytoplasm (A) and in the cortical plane (B). Time is aligned using the reference timing illustrated in Figure 1A (red dashed lines).

Figure 3: Protein densities show enhance differences at the cortex compared to the cytoplasm
(A) Time evolution of the mean intensity at the cortical plane in each cell for a representative single embryo expressing GFP-labelled ABP. Dashed lines represent the evolution of the mean intensity of the embryo (all cells). (B) Ratio of intensities for each cell pair measured in the cytoplasm and averaged during the whole cell cycle. (C) Differences of intensities for each cell pair at the cortex, calculated via the convolution of normalised density probability distributions taken at each time point and normalised by the mean embryo intensity for each strain. Individual data points, mean values and standard deviations are shown for B and C. (D) Correlation plot of mean intensities in the cortex and in the cytoplasm (all cells and all proteins). Linear model from the fit is shown as continuous line (f(x) = p1*x+p2) and f(x)=x is shown as dashed lines. Corresponding p1, p2 and R see Figure S3.

Figure S3:
(A-B) Relative cortical abundance of additional cell pairs of the 4-cell stage: ratio of intensities and differences of intensities in the cytoplasm (A) and in the cortical plane (B). (C) Correlation plot of intensities in the cortex and cytoplasm (all cells and proteins shown separately). Linear model from the fit is shown as continuous line (f(x) = p1*x+p2) and f(x)=x is shown as dashed lines. (D) Comparison of cytoplasmic intensities between the 2-cell state and 4-cell state (calculated using intensity differences between all cell pairs).

Figure 4: Perturbation of AP polarity impacts the distribution of actin binding proteins
(A) Representative images of embryos in absence and in presence of RNAi(*par-2*). Overlay of cortical CYK-1::GFP (cyan) together with the membrane marker in the mid plane section (PHPLC1δ1, red) are shown. Strong phenotypes are classified according to the abnormal 4-cell stage cell positioning (bottom right panel), while milder phenotypes maintain the normal cell-cell positioning as AB and P1 divided synchronously. In both RNAi conditions, the asymmetry in terms of volume is reduced for the cell pairs AB/P1 and EMS/P2. Scale bar is 10 μm. (B-C-D) Differences of intensities for each cell pair in the cytoplasm (B, C) or cortical plane (D), calculated via the convolution of normalised density probability distributions taken at each time point and normalised by the mean embryo intensity for each strain. The red fluorescence of PHPLC1δ1 in the mid plane section is used as a control of a diffusing protein, no asymmetry in the distribution is observed in case of RNAi(*par-2*).

Figure 5:
(A) Representative images of a single cell extraction using UV laser ablation, image of the cell prior ablation and just after the induced local cut (red scissors). Representative images of *in vitro* polymerisation from such single cell extracts after 15min in the different conditions. (B) Illustration of the two processes cell lysis via laser ablation with or without detergent. Image of the region of interest used for quantification purposes. (C) Time evolution of the integrated intensity profile of P0 cells in different experimental conditions and values obtained in the plateau region (D) together with the calculated percentage taken the +triton condition as reference. (E) Time evolution of the integrated intensity profile in the phalloidin and G-actin conditions.

Figure 6:
(A) Representative images of *in vitro* polymerisation from single cell extracts just after ablation and after 15min of polymerisation. Scale bar is 10 μm. (B) Time evolution of the integrated intensity profile of these cells and intensity values obtained in the plateau region (C). N is the number of cells analysed for each category. (D) Quantification of midplane area from phase contrast images prior ablation. (E) F-actin density is calculated using the plateau intensity value normalised by the midplane area of the corresponding cells, mean (diamond) and median (circle) are shown.

Figure S4:
(A) Large field of view of a representative cell-extract polymerised in presence of 0.1μM G-actin-Alexa568 after UV laser ablation. The remaining embryo ghost is out of plane (dashed circle). Scale bar 20 μm. (B) F-actin density is calculated using the mean plateau intensity value normalised by published volumed of the corresponding cells. (C) Correlation between experimental mid plane cell area and published cell volumes.
