

Re-evaluating inheritance in genome evolution: widespread transfer of LINEs between species

Authors: Atma Ivancevic, Daniel Kortschak, Terry Bertozzi, David Adelson*

*Correspondence to: david.adelson@adelaide.edu.au

Horizontal transfer^{1,2} (HT) is the transmission of genetic material by means other than parent-to-offspring: a phenomenon primarily associated with prokaryotes. However, eukaryotic genomes contain transposable elements³ (TE), colloquially known as ‘jumping genes’ for their ability to replicate to new genomic locations. Long interspersed element (LINE) retrotransposons are TEs which move using a “copy and paste” mechanism, resulting in gene disruptions, chromosome rearrangements and numerous diseases such as cancer⁴⁻⁷. LINEs are autonomous; they can move into a new genome and immediately commence replicating. This makes them good candidates for HT. Growing evidence⁸⁻¹¹ shows that HT is more widespread than previously believed, although questions still remain about the frequency of HT events and their long-term impact. Here we show that LINE-1 (L1) and Bovine-B (BovB)^{12,13}, the two most abundant retrotransposon families in mammals, were initially introduced as foreign DNA via ancient HT events. Using a 503-genome dataset, we identify multiple ancient L1 HT events in plants and show that L1s infiltrated the mammalian lineage after the monotreme-therian split, in contrast with the current literature¹⁴. We also extend the BovB paradigm by identifying: more than twice the number of estimated transfer events compared to previous studies^{8,11}; new potential blood-sucking parasite vectors and occurrences in

new lineages (e.g. bats, frog). Given that these retrotransposons make up nearly half of the genome sequence in today's mammals³, our results provide the first evidence that HT can have drastic and long-term effects on the new host genomes. This revolutionizes our perception of genome evolution to consider external factors, such as the natural introduction of foreign DNA. With the advancement of genome sequencing technologies and bioinformatics tools, we anticipate our study to be the first of many large-scale phylogenomic analyses exploring the role of HT in genome evolution.

1 Three criteria are typically used to detect HT candidates: 1) a patchy distribution of the TE
2 across the tree of life; 2) unusually high TE sequence similarity between divergent taxa;
3 and 3) phylogenetic inconsistencies between TE tree topology and species relationships¹⁵.
4 To comprehensively test these criteria, we performed large-scale phylogenomic analyses
5 of over 500 eukaryotic genomes (plants and animals) using iterative similarity searches of
6 BovB and L1 sequences.

7

8 Our findings show that there are two phases in HT: effective insertion of the TE, followed
9 by expansion throughout the genome. Figure 1 shows that both BovB and L1 elements
10 have been horizontally transferred because of their patchy distribution across eukaryotes.
11 Both are absent from most arthropod genomes yet appear in relatively primitive species
12 such as sea urchins and sea squirts. Furthermore, both TEs are present in a diverse array of
13 species including mammals, reptiles, fish and amphibians. The main difference between
14 BovB and L1 lies in the number of colonised species. BovBs are only present in 60 of the
15 503 species analysed, so it is easy to trace their horizontal transfer between the distinct
16 clades (e.g. squamates, ruminants). In contrast, L1s encompass a total of 407 species,

17 within plants and animals, and they are ubiquitous across the well-studied therian
18 mammals. However they are surprisingly absent from platypus and echidna (monotremes).
19 There are only two possible explanations for this; either L1s were expunged shortly after
20 the monotreme-therian split but before they had a chance to accumulate, or monotremes
21 never had L1s. The first scenario is unlikely in the context of L1 distributions in other
22 eukaryotes. Consider the 60 currently available bird genomes: full-length L1s have all but
23 been eradicated from the avian lineage, but every bird species bears evidence of
24 ancient/ancestral L1 activity through the presence of fragments¹⁶. In contrast, there are no
25 L1 fragments in monotremes. We therefore conclude that L1s were inserted into a
26 common ancestor of therian mammals, between 160 and 191 Million Years Ago (MYA),
27 and have since been vertically inherited (see below).

28

29 The abundance of TEs differs greatly between species. As shown in Fig. 1, mammalian
30 genomes are incredibly susceptible to BovB and L1 expansion. More than 15% of the cow
31 genome is formed by these TEs (12% BovB, 3% L1). This is without considering the
32 contribution of TE fragments¹⁷ or derived Short INterspersed Elements (SINEs), boosting
33 retrotransposon coverage to almost 50% in mammalian genomes³. Even within mammals
34 there are noticeable differences in copy number; for example, bats and equids have a very
35 low number of full-length BovBs (<50 per genome) compared to the thousands found in
36 ruminants and Afrotherian mammals. The low copy number here is TE-specific rather
37 than species-specific; there are many L1s in bats and equids. Hence, the rate of TE
38 propagation is determined both by the genome environment (e.g. mammal versus non-
39 mammal) and the type of retrotransposon (e.g. BovB versus L1).

40

41 To develop a method for identifying horizontal transfer events, we used BovB, a TE
42 known to undergo HT. We clustered and aligned BovB sequences (both full-length
43 nucleotide sequences and amino acid reverse-transcriptase domains) to generate a
44 representative consensus for each species, and infer a phylogeny (Fig 2a shows the
45 nucleotide-based tree). The phylogeny supports previous results⁸ — with the topology
46 noticeably different from the tree of life (Fig. 1) — although we were able to refine our
47 estimates for the times of insertion. For example, the cluster of equids includes the white
48 rhino, *Ceratotherium simum*, suggesting that BovBs were introduced into the most recent
49 common ancestor before these species diverged. The low copy number in equids and
50 rhino, observed in Fig. 1, is not because of a recent insertion event. The most likely
51 explanation is that the donor BovB inserted into an ancestral genome, was briefly active,
52 lost its ability to retrotranspose and was subsequently inherited by its descendants.

53

54 The placement of arthropods is intriguing, revealing potential HT vectors and the origin of
55 BovB retrotransposons. For example, BovBs from butterflies, moths and ants appear as a
56 basal monophyletic group, sister to sea squirt *Ciona savignyi* BovB. The presence of
57 BovB in all these species suggests that BovB TEs may have arisen as a subclass of ancient
58 RTEs, countering the belief that they originated in squamates¹¹. The next grouping
59 consists of two scorpion species (*Mesobuthus martensii* and *Centruroides exilicauda*)
60 nestled among the snakes, fish, sea urchin and leech — a possible vector. But the most
61 interesting arthropod species is *Cimex lectularius*, the common bed bug, known to feed on
62 animal blood. The full-length BovB sequence from *Cimex* shares over 80% identity to
63 viper and cobra BovBs; their reverse transcriptase domains share over 90% identity at the
64 amino acid level. Together, the bed bug and leech support the idea⁸ that blood-sucking
65 parasites can transfer retrotransposons between the animals they feed on.

66

67 We extended the BovB paradigm to include 10 bat species and one frog (*Xenopus*
68 *tropicalis*). The bats were not included in the phylogenetic analysis because their BovB
69 sequences were too divergent to construct an accurate consensus. Instead, we clustered all
70 individual BovB sequences to identify two distinct subfamilies (Fig. 2b); one containing
71 all the horse and rhino BovBs as well as eight bat sequences, and the other containing the
72 remaining bat BovBs as well as the single BovB from *Xenopus*. We also included three
73 annotated sequences from a public database¹⁸ to resolve an apparent discrepancy between
74 the naming of BovB/RTE elements. Our results have several implications: first, bat BovBs
75 can be separated into two completely distinct clades, suggesting bat BovBs arose from
76 independent insertion events; second, the BovBa-1-EF bat clade may have arisen from an
77 amphibian species, or vice versa; and third, the naming conventions used in RepBase¹⁸
78 need updating to better distinguish BovB and RTE sequences. This third point is discussed
79 in the Supplementary Information (see Supp. Fig. 1).

80

81 In order to exhaustively search for all cases of BovB HT, we replicated the all-against-all
82 BLAST¹⁹ approach used in El Baidouri *et al.*²⁰ to detect individual HT candidate
83 sequences. Briefly, this compares all sequences within a database to generate BovB
84 clusters or families. We identified 215 HT candidate families which contained BovBs
85 belonging to at least two different eukaryotic species. Many of these were closely related
86 species; so to find the HT families most likely to be true events we restricted the analysis
87 to families that linked species in different eukaryotic Orders (e.g. Afrotheria and
88 Monotremata). We performed *a machina* validation for each candidate HT family:
89 pairwise alignments of the flanking regions to rule out possible contamination or
90 orthologous regions, and phylogenetic reconstructions to confirm discordant relationships.

91 A total of 22 HT families passed all of the tests, indicating at least 22 cross-Order HT
92 events. Many HT families included one or two reptile BovBs, and numerous mammalian
93 BovBs (see Supp. Table 6). This is important for determining the direction of transfer.
94 BovBs are thought to have entered ruminants after squamates¹¹. The single reptile element
95 in a family is therefore likely to be the original transferred sequence, supporting the theory
96 that retrotransposons undergo HT to escape host suppression or elimination²⁰. Altogether,
97 our results demonstrate that the horizontal transfer of BovB elements is even more
98 widespread than previously reported, providing one of the most compelling examples of
99 eukaryotic horizontal transfer to date.

100

101 We carried out the same exhaustive search in L1s, which presented a challenge because of
102 greater divergence and a strong vertical background. Producing a consensus for each
103 species was impractical as most species contained a divergent mixture of old, degraded
104 L1s and young, intact L1s. Instead, we used the all-against-all clustering strategy on the
105 collated dataset of L1 nucleotide sequences over 3kb in length (>1 million sequences
106 total). 2815 clusters contained L1s from at least two different species; these were our HT
107 candidates. As with BovBs, to improve recognition of HT we looked for families
108 displaying cross-Order transfer. Most non-mammalian L1s (insects, reptiles, amphibians)
109 had already been excluded because they definitively grouped into species-specific clusters,
110 even at low (50%) clustering identity. The remaining families were from plants and
111 mammals. After the validation tests, we found that all the mammalian candidate families
112 were very small (e.g. one L1 element per species), and located in repeat-dense,
113 orthologous regions in the genome most likely explained by vertical inheritance (see
114 Supp. Fig. 3). Thus, we found no evidence for recent L1 transfer since their insertion into
115 the therian mammal lineage and subsequent shaping of modern therian genomes.

116

117 Nevertheless, four plant families presented a strong case for L1 horizontal transfer (Fig
118 3a). High sequence identity was restricted to the elements themselves, there were more
119 than two L1 elements in each family, the sequences encoded open reading frames or had
120 intact reverse-transcriptase domains, and the phylogenetic reconstructions showed
121 evolutionary discordance. The number of elements in each family mimicked the patterns
122 seen with BovBs: very few elements from the ‘donor species’, and a noticeable expansion
123 of L1s in the ‘host species’. This indicates that transferred L1s can retain activity and
124 expand within their new host. Moreover, it contradicts the belief that L1s are exclusively
125 vertically inherited, and supports our conclusion that a similar event introduced L1s to
126 mammals. At this stage, we do not know the vector of transfer since none of the analysed
127 arthropods showed similarity to plant L1 sequences.

128

129 During our mining of candidate L1 HT families, we serendipitously discovered a chimeric
130 L1-BovB element present in cattle genomes (*Bos taurus* and *Bos indicus*), shown in Fig.
131 3b. This particular element most likely arose from a recently active L1 element (98%
132 identical to the canonical *Bos* L1-BT¹⁸) inserting into an active BovB (97% identical to
133 *Bos* BovB¹⁸). In fact, L1s and BovBs have accumulated to such extents in these two
134 genomes that they have created the ideal environment for chimeric repetitive elements.
135 With two reverse-transcriptase domains and high similarity to currently active L1/BovB
136 elements, this chimeric element has the potential to still be functional - presenting the
137 possibility for L1 elements to be horizontally transferred throughout mammals by being
138 transduced by BovBs.

139

140 In conclusion, both BovB and L1 retrotransposons can undergo HT, albeit at different
141 rates. We extracted millions of retrotransposon sequences from a 503-genome dataset,
142 demonstrating the similarly patchy distributions of these two LINE classes across the
143 eukaryotic tree of life. We further extended the analysis of BovBs to include blood-
144 sucking arthropods capable of parasitising mammals and squamates, as well as two
145 distinct clades of bat BovBs and the first report of BovB in an amphibian. Contrary to the
146 belief of exclusive vertical inheritance, our results with L1s suggest multiple ancient HT
147 events in plants and, strikingly, HT into the early therian mammal lineage. This transfer
148 allowed subsequent expansion of L1s and associated SINEs, transforming genome
149 structure, regulation and gene expression in mammals⁷ and potentially catalysing the
150 therian radiation.

Figures

Figure 1: Presence and coverage of L1 and BovB elements across eukaryotes. The Tree of Life²¹ was used to infer a tree of the 503 species used in this study; iTOL²² was used to generate the bar graph and final graphic. The red arrow marks the L1 horizontal transfer event into therian mammals between 163-191MYA. Branches are coloured to indicate which species have both BovB and L1 (green), only BovB (orange), only L1 (blue), or neither (black). Bar graph colours correspond to BovB (orange) and L1 (blue). An interactive version of this figure is available at: <http://itol.embl.de/shared/atma>.

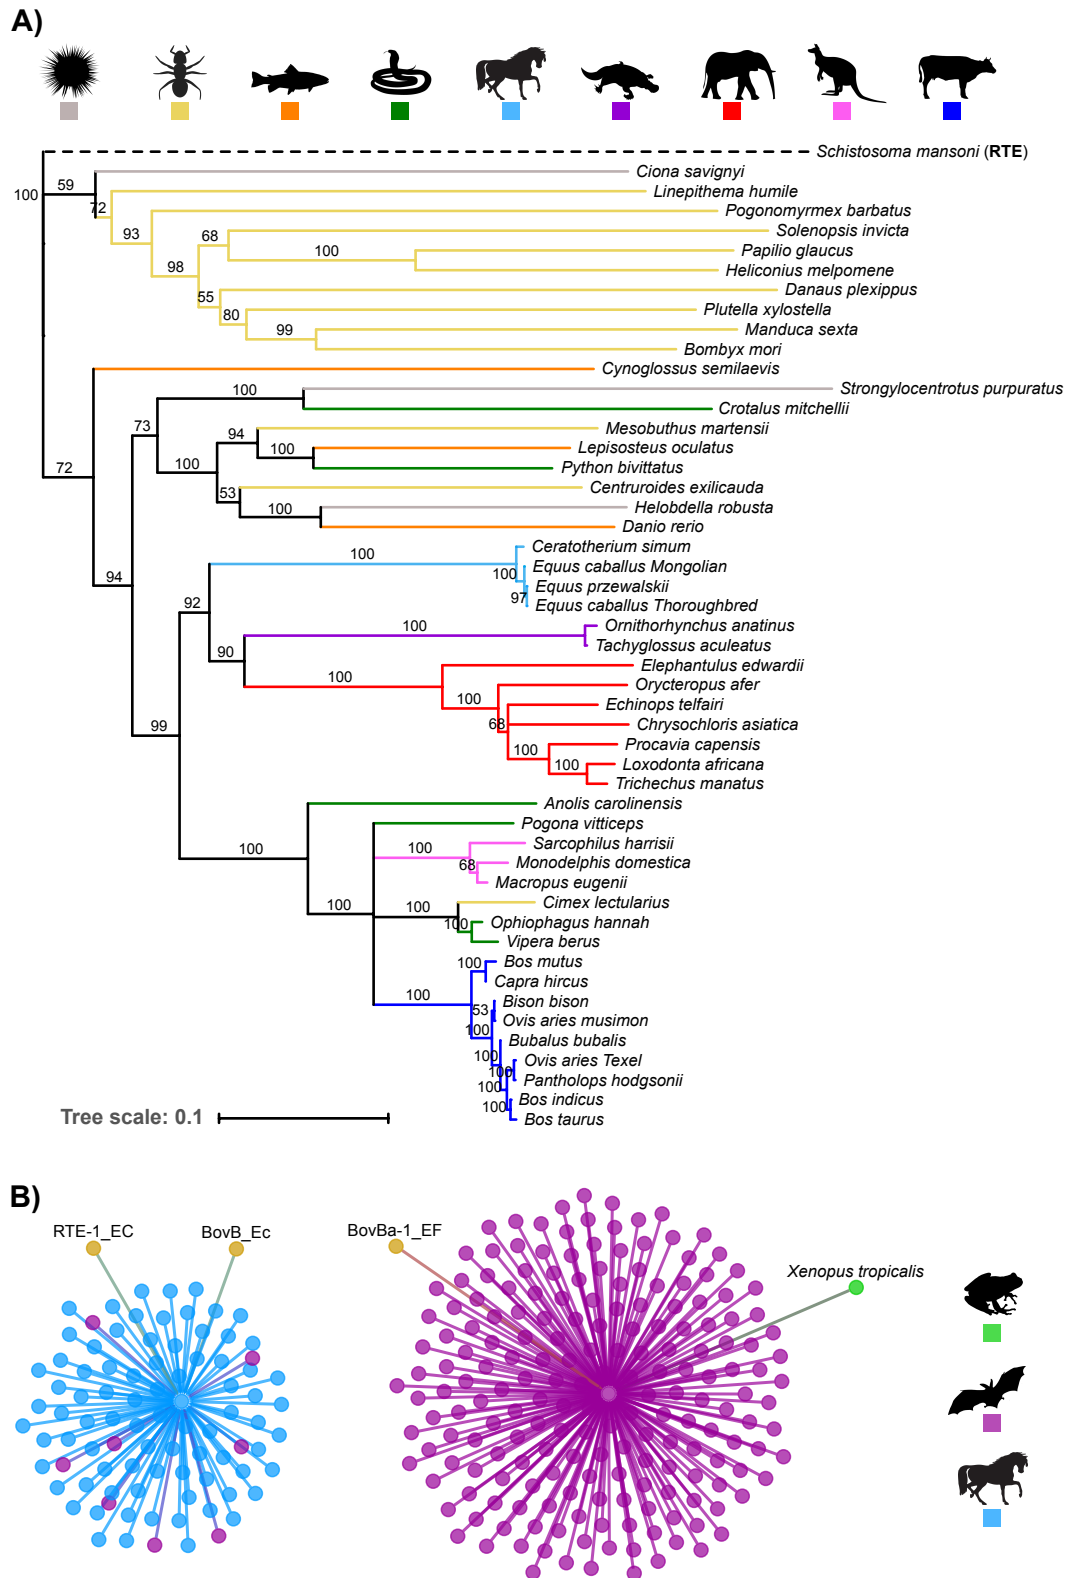

Figure 2: HT of BovB retrotransposons. (2a) Neighbour-joining tree (1000 bootstrap replicates) inferred using full-length nucleotide BovB consensus sequences, representing the dominant BovB family in each species. Nodes with confidence values over 50% are labelled and branches are coloured taxonomically. RTE sequence from *Schistosoma mansoni* was used as the outgroup. (2b) Network diagram representing the two distinct BovB clades in bats. Nodes are coloured taxonomically apart from the RepBase¹⁸ sequences (light brown). RTE-1_EC and BovB_Ec are shown to belong to a single family, while BovBa-1_EF-like bat sequences form a separate family containing a single full-length BovB from the frog *Xenopus*.

Figure 3: HT of L1 in plants and newfound chimeric L1-BovB element. (3a) TimeTree²³ illustrating the putative L1 horizontal transfer events between plant species. Shows only the species involved in HTs, and *Amborella trichopoda* as the outgroup. Background is coloured to match the ages in the geological timescale. (3b) Chimeric L1-BovB retrotransposon found in cattle genomes (*Bos taurus* and *Bos indicus*). L1-BT and BovB correspond to RepBase names¹⁸, representing repeats which are known to have been recently active. RVT_1 = reverse-transcriptase, EN = endonuclease domain. The orange bar is the length of the entire open reading frame.

Methods

Extraction of L1 and BovB retrotransposons from genome data

To extract the retrotransposons of interest, we used the methods and genomes previously described in Ivancevic *et al.* (2016)¹⁶. Briefly, this involved downloading 499 publicly available genomes (and acquiring 4 more from collaborations), then using two independent searching strategies (LASTZ²⁴ and TBLASTN¹⁹) to identify and characterise L1 and BovB elements. A third program, CENSOR²⁵, was used with the RepBase library of known repeats¹⁸ to verify hits with a reciprocal best-hit check. The raw L1 results have been previously published in Ivancevic *et al.*¹⁶ (Supplementary Material); the BovB results are included in the Supplementary Material.

Extraction and clustering of conserved amino acid residues

Starting with BovBs, USEARCH²⁶ was used to find open readings frames (ORFs), with function `-fastx_findorfs` and parameters `-aaout` (for amino acid output) and `-orfstyle 7` (to allow non-standard start codons). HMMer²⁷ was used to identify reverse transcriptase (RT) domains within the ORFs. RT domains were extracted using the envelope coordinates from the HMMer domain hits table (`-domtblout`), with minimum length 200 amino acid residues. The BovB RT domains from all species were collated into one file and clustered with UCLUST²⁶. This was done as an initial screening to detect potential horizontal transfer candidates. The process was then repeated with L1 elements.

Clustering of nucleotide sequences to build one consensus per species

The canonical BovB retrotransposon is 3.2 kb in length^{8,18}, although this varies slightly between species. In this study, we classified BovB nucleotide sequences $\geq 2.4\text{kb}$ and $\leq 4\text{kb}$ as full-length. We wanted to construct a BovB representative for each species.

Accordingly, for each species, UCLUST²⁶ was used to cluster full-length BovB sequences at varying identities between 65-95%. A consensus sequence of each cluster was generated using the UCLUST -consout option.

The ideal cluster identity was chosen based on the number and divergence of sequences in a cluster. E.g. for species with few BovBs, a lower identity was allowed; whereas for species with thousands of BovBs, a higher identity was needed to produce an alignable cluster. The final clustering identity and cluster size for each species are given in Supp. Table 1. Note that the bat species are not included in this table - they were clustered separated, due to the high level of divergence between BovBs.

This method was tested on L1 retrotransposons, but the results were not ideal; most species simply had too many L1 sequences. Other methods tested on both BovBs and L1s included using centroids instead of consensus sequences (this gave better alignments but was less representative of the cluster), and using the same clustering identity for all species (e.g. 80% - this did not work well for species with less than 100 elements in the genome).

Inferring a phylogeny from consensus sequences

Consensus sequences were aligned with MUSCLE²⁸. The multiple alignment was processed with Gblocks²⁹ to extract conserved blocks, with default parameters except min block size: 5, allowed gaps: all. FastTree³⁰ was used to infer a maximum likelihood phylogeny using a general time reversible (GTR) model and gamma approximation on substitution rates. Geneious Tree Builder³¹ was used to infer a second tree using the neighbour-joining method with 1000 bootstrap replicates.

Distinguishing RTEs from BovBs

All sequences which identified as BovB or RTE were kept and labelled accordingly to their closest RepBase classification¹⁸. However, there appeared to be numerous discrepancies with the naming: e.g. some RTE sequences shared >90% identity to BovBs, and vice versa. BovB retrotransposons are a subclass of RTE, and they were only discovered relatively recently. It is likely that several so-called RTE sequences are actually BovBs.

To determine which species had BovB sequences, and which only had RTEs, we used the species consensus approach to build a BovB/RTE phylogeny (see Supp. Figure 1). This effectively separated BovB-containing species from RTE-containing species. The RTE sequences were not included in further analyses.

Clustering of nucleotide BovB sequences from bats and *Xenopus*

A reliable BovB consensus could not be generated for any of the ten bat species because the sequences were too divergent and degraded. Some bat BovBs seemed similar to equid BovBs; others did not. Likewise, the single full-length BovB from frog *Xenopus tropicalis* was very different to canonical BovBs, sharing highest identity with the bats.

In an effort to characterise these BovBs into families, we grouped all full-length BovB sequences from the bats, frog, equids and white rhino into a single file. We also added two RepBase equid sequences (RTE-1_EC and BovB_Ec) and 1 RepBase bat sequence (BovBa-1_EF)¹⁸. After clustering, we expected to find one family of equid BovBs, the equid RTE sequence as an outlier, and numerous families containing bat and frog BovBs. The actual findings are described in the text (Fig. 2b). We used UCLUST²⁶ to cluster the sequences (function `-cluster_fast` with parameters `-id`, `-uc`, `-clusters`). The highest identity

at which there were only 2 clusters/families was 40%. At higher identities, the equid BovBs stayed together but the bat and frog BovBs were lost as singletons.

To confirm the clustering, we also used MUSCLE to align all the sequences and FastTree to infer a phylogeny (see Supp. Figure 2).

HT candidate identification - BovBs and L1s

We compiled all confirmed BovB and L1 sequences into separate multi-fasta databases (316,017 and 1,048,478 sequences respectively). The length cut-off for BovBs was ≤ 2.4 kb and ≥ 4 kb; for L1s, ≥ 3 kb. BovBs were analysed first to identify characteristics of horizontal transfer events.

To detect HT candidates, we used the all-against-all clustering strategy described in El Baidouri *et al.*²⁰. Briefly, this method used a nucleotide BLAST¹⁹ to compare every individual sequence in a database against every other sequence; hence the term all-against-all. BLAST parameters were as follows: -r 2, -e 1e-10, -F F, -m 8 (for tabular output). The SiLiX program³² was then used to filter the BLAST output and produce clusters or families that met the designated identity threshold.

For BovB sequences, we tested identities of 40-90%. High identity thresholds were useful for finding very recent HT events (e.g. over 90% identity between the bed bug and snakes). However, the majority of clusters contained several copies of the same BovB family from a single species - indicative of vertical inheritance. Using a lower identity threshold was more informative for capturing ancient HT events. At 50% identity, the clustering preserved the recent, high-identity HT events while also finding the ancient, lower-%identity HT events. We concluded that this was the best %identity to use for our particular dataset, considering it includes widely divergent branches of Eukaryota.

Clusters were deemed HT candidates if they contained BovB elements belonging to at least two different species. To reduce the number of possible HT clusters, we went one step further and kept only the clusters which demonstrated cross-Order transfer (e.g. BovBs from Monotremata and Afrotheria in the same cluster). All potential HT candidates were validated by checking that they were not located on short, isolated scaffolds or contigs in the genome. The flanking regions of each HT candidate pair were extracted and checked (via pairwise alignment) to ensure that the high sequence identity was restricted to the BovB region. This was done to check for contamination or orthologous regions. Phylogenies of HT candidate clusters were inferred using maximum likelihood and neighbour-joining methods (1000 bootstraps).

The same procedure was performed to screen for nucleotide L1 HT candidates. As an extra step for L1s, we also used all ORF1 and ORF2 amino acid sequences from a previous analysis¹⁶ to conduct similar all-against-all BLAST searches. However, the amino acid clusterings did not produce any possible HT candidates.

Data availability statement

Data generated or analysed during this study are included in the main text and Supplementary Material. Raw sequences are provided upon request.
