Abstract

Factor V Leiden (F5L) is a common genetic risk factor for venous thromboembolism in humans. We conducted a sensitized ENU mutagenesis screen for dominant thrombosuppressor genes based on perinatal lethal thrombosis in mice homozygous for F5L (F5L/L) and haploinsufficient for tissue factor pathway inhibitor (Tfpi+/−). F8 deficiency enhanced survival of F5L/L Tfpi+/- mice, demonstrating that F5L/L Tfpi+/- lethality is genetically suppressible. ENU-mutagenized F5L/L males and F5L+/− Tfpi+/− females were crossed to generate 6,729 progeny, with 98 F5L/L Tfpi+/- offspring surviving until weaning. Sixteen lines exhibited transmission of a putative thrombosuppressor to subsequent generations, with these lines referred to as MF5L (Modifier of Factor 5 Leiden) 1-16. Linkage analysis in MF5L6 identified a chromosome 3 locus containing the tissue factor gene (F3). Though no ENU-induced F3 mutation was identified, haploinsufficiency for F3 (F3+/−) suppressed F5L/L Tfpi+/- lethality. Whole exome sequencing in MF5L12 identified an Actr2 gene point mutation (p.R258G) as the sole candidate. Inheritance of this variant is associated with suppression of F5L/L Tfpi+/- lethality (p=1.7x10^-6), suggesting that Actr2p.R258G is thrombosuppressive. CRISPR/Cas9 experiments to generate an independent Actr2 knockin/knockout demonstrated that Actr2 haploinsufficiency is lethal, supporting a hypomorphic or gain of function mechanism of action for Actr2p.R258G. Our findings identify F8 and the Tfpi/F3 axis as key regulators in determining thrombosis balance in the setting of F5L and also suggest a novel role for Actr2 in this process.
Significance Statement (120 words max):

Venous thromboembolism (VTE) is a common disease characterized by the formation of inappropriate blood clots. Inheritance of specific genetic variants, such as the Factor V Leiden polymorphism, increases VTE susceptibility. However, only ~10% of people inheriting Factor V Leiden develop VTE, suggesting the involvement of other genes that are currently unknown. By inducing random genetic mutations into mice with a genetic predisposition to VTE, we identified two genomic regions that reduce VTE susceptibility. The first includes the gene for blood coagulation Factor 3 and its role was confirmed by analyzing mice with an independent mutation in this gene. The second contains a mutation in the Actr2 gene. These findings identify critical genes for the regulation of blood clotting risk.

Keywords:

Venous thromboembolism, Factor V Leiden, ENU mutagenesis
Introduction

Venous thromboembolism (VTE) is a common disease that affects 1 to 3 per 1000 individuals per year (1). VTE susceptibility exhibits a complex etiology involving contributions of both genes and environment. Genetic risk factors explain approximately 60% of the overall risk for VTE (2). Recent large-scale genome-wide association studies (GWAS) confirmed \textit{ABO}, \textit{F2 F5, F11, FGG} and \textit{PROCR} as thrombosis susceptibility genes, with only two additional novel loci, TSPAN15 and SLC44A2 identified (3-6), leaving the major component of VTE genetic risk still unexplained.

The Factor V Leiden variant (\textit{F5}\text{\textsuperscript{L}}) is a common inherited risk factor for VTE with an average allele frequency of 3.5% in the European population (7-9). \textit{F5}\text{\textsuperscript{L}} is estimated to account for up to 25% of the genetically-attributable thrombosis risk in these populations (7). However, penetrance is incomplete, with only \textasciitilde{}10% of \textit{F5}\text{\textsuperscript{L}} heterozygotes developing thrombosis in their lifetimes. The severity of thrombosis also varies widely among affected individuals (10), limiting the clinical utility of \textit{F5}\text{\textsuperscript{L}} genotyping in the management of VTE (11).

The incomplete penetrance and variable expressivity of thrombosis among \textit{F5}\text{\textsuperscript{L}} patients can at least partially be explained by genetic interactions between \textit{F5}\text{\textsuperscript{L}} and other known thrombotic risk factors such as hemizygosity for antithrombin III or proteins C or S, as well as the common prothrombin 20210 polymorphism (10, 12, 13). However, \textasciitilde{}2% of \textit{F5}\text{\textsuperscript{L}} heterozygotes would be expected to co-inherit a mutation at one or more of these loci, suggesting that a large number of additional genetic risk factors for VTE and/or modifiers of \textit{F5}\text{\textsuperscript{L}} remain to be identified (3, 10).

Mice carrying the orthologous \textit{F5}\text{\textsuperscript{L}} mutation exhibit a mild to moderate prothrombotic phenotype closely mimicking the human disorder (14). We previously reported a synthetic lethal
interaction between $F5^L$ homozygosity ($F5^L/L$) and hemizygosity for tissue factor pathway inhibitor ($Tfpi^{+/+}$)(15). Nearly all mice with this lethal genotype combination ($F5^L/L$ $Tfpi^{+/+}$) succumb to widespread, systemic thrombosis in the immediate perinatal period(15).

ENU mutagenesis in mice has been used effectively to identify novel genes involved in a number of biological processes(16, 17). ENU-induced germline mutations transmitted from a mutagenized male mouse (G0) occur at ~1.5 mutations per megabase, at least 50 fold higher than the endogenous background mutation rate(18). Several previous reports have successfully applied an existing phenotype as a sensitizer to identify modifier genes. A dominant suppressor screen in Mecp2 deficient mice (Rett syndrome) identified a mutation in squalene epoxidase ($Sqle$) as a heritable suppressor, resulting in prolonged survival and amelioration of neurologic manifestations(19). Other successful sensitized screens include analysis of mouse mutants predisposed to diabetic nephropathy(20), a screen in Sox10 haploinsufficient mice identifying the Gli3 gene as a modifier of neurochristopathy(21) and identification of a mutation in the c-Myb gene as a dominant modifier for platelet count in Mpl deficient mice (congenital thrombocytopenia)(22). We now report the results of a dominant, sensitized ENU mutagenesis screen for suppressors of $F5^L/L$ $Tfpi^{+/+}$ dependent lethal thrombosis.

Results and Discussion

$F8$ deficiency suppresses $F5^L/L$ $Tfpi^{+/+}$ lethality

X-linked hemophilia A results in a moderate to severe bleeding disorder in humans and is caused by mutations in the $F8$ gene. To test whether the $F5^L/L$ $Tfpi^{+/+}$ lethal thrombotic phenotype is suppressible by hemophilia A in mice, triple heterozygous $F5^L/+\;Tfpi^{+/+}\;F8^{+/+}$ female mice were generated and crossed to $F5^L/L$ male mice (Fig. 1A). One quarter of conceptuses are expected to carry the $F5^L/L\;Tfpi^{+/+}$ genotype, with half of the total expected male conceptuses completely $F8$
deficient (F8'). Thus, 1/16\textsuperscript{th} of the offspring from this mating are expected to be F5\textsuperscript{L/L} Tfp\textsuperscript{+/-} F8\textsuperscript{-} (males). Similarly, 1/16\textsuperscript{th} of the progeny should be F5\textsuperscript{L/L} Tfp\textsuperscript{+/-} F8\textsuperscript{+/-} (females). A total of 163 progeny from this cross were genotyped at weaning, resulting in 8 F5\textsuperscript{L/L} Tfp\textsuperscript{+/-} F8\textsuperscript{-} male mice observed (and 0 F5\textsuperscript{L/L} Tfp\textsuperscript{+/-} F8\textsuperscript{+}, p=0.02) and 2 F5\textsuperscript{L/L} Tfp\textsuperscript{+/-} F8\textsuperscript{+/-} female mice (and 1 F5\textsuperscript{L/L} Tfp\textsuperscript{+/-} F8\textsuperscript{+/-}, p=0.9). These results demonstrate that F5\textsuperscript{L/L} Tfp\textsuperscript{+/-} thrombosis is genetically suppressible by F8 deficiency with nearly complete penetrance in F8\textsuperscript{-} male mice and are consistent with human studies demonstrating F8 level as an important VTE risk factor(23).

The F5\textsuperscript{L/L} Tfp\textsuperscript{+/-} phenotype is suppressed by dominant ENU induced mutations

A sensitized, genome-wide ENU mutagenesis screen for dominant thrombosis suppressor genes was implemented as depicted in Figure 1B. ENU mutagenized G0 F5\textsuperscript{L/L} males were crossed to F5\textsuperscript{L/+} Tfp\textsuperscript{+/-} females to generate G1 mice, which were screened by genotyping at weaning for F5\textsuperscript{L} and Tfp\textsuperscript{+/-}. Previously described visible dominant mutant phenotypes(24), including belly spotting and skeletal abnormalities, were observed in approximately 5.9% of G1 offspring, similar to the ~4.2% rate of observable mutants in previous studies(24). This is consistent with the ~20-30 functionally significant mutations per G1 mouse expected with this ENU mutagenesis protocol(25). Although 25% of G1 embryos from this cross are expected to carry the synthetic lethal F5\textsuperscript{L/L} Tfp\textsuperscript{+/-} genotype, most are lost at birth. Given a total of 6631 G1s for the other 3 genotypes observed at weaning (~1/3 for each), a similar number of F5\textsuperscript{L/L} Tfp\textsuperscript{+/-} G1 conceptuses, ~2210 (6631 X 1/3), would have been expected. The 98 live F5\textsuperscript{L/L} Tfp\textsuperscript{+/-} mice (45 females, 53 males) thus represented 4.4% of the expected with this genotype. Survival data were collected for 57 of the F5\textsuperscript{L/L} Tfp\textsuperscript{+/-} G1 mice, with 34 living past 70 days of age (precise dates of death were not available for the remaining 41 mice). No significant sex-specific differences in survival were observed (Fig. 1C).
Heritability for each of the 44 G1 putative suppressor mutants who lived to breeding age was evaluated by a progeny test backcross to C57BL/6J (B6) $F5^{L/L}$ mice. The observation of one or more $F5^{L/L}$ $Tfpi^{+/—}$ offspring surviving to weaning increased the likelihood that a particular Modifier of Factor 5 Leiden ($MF5L$) line carries a transmissible suppressor mutation. Out of the original 98 surviving $F5^{L/L}$ $Tfpi^{+/—}$ G1 mice, 75 produced no offspring surviving to weaning, either due to infertility or the above mentioned early lethality, with >50% of these mice (37 of 75) exhibiting a grossly runted appearance. Approximately half of the $F5^{L/L}$ $Tfpi^{+/—}$ G1 mice that attained breeding age (23/44) produced 1 or more G2 progeny surviving to weaning, 7 (2 males and 5 females) produced no $F5^{L/L}$ $Tfpi^{+/—}$ G2s, including 4 G1s with 8 or more offspring of other genotypes. Sixteen $F5^{L/L}$ $Tfpi^{+/—}$ G1 mice produced one or more $F5^{L/L}$ $Tfpi^{+/—}$ progeny when bred to B6 $F5^{L/L}$ mice (see Methods). These 16 potential thrombosuppressor mouse lines are designated $MF5L1-16$. The number of total progeny, genotypic distribution, and penetrance of the $F5^{L/L}$ $Tfpi^{+/—}$ mice in each line are listed in Table 1. Within these suppressor lines, mice with the $F5^{L/L}$ $Tfpi^{+/—}$ genotype were ~30% smaller than their $F5^{L/L}$ littermates at the time of weaning ($p<2.2\times10^{-16}$, Fig. 1D), with this difference maintained after outcrossing to the 129S1 strain (Fig. 1E).

Previous reports based on gene function in the specific locus test estimate an ENU-induced mutation rate of 1/700 loss of function mutations per locus for the ENU dosing regimen used here(26). This mutation rate predicts that our screen of 6,729 G1 progeny (2,210 $F5^{L/L}$ $Tfpi^{+/—}$ expected) should have produced ~3 mutations per gene averaged over the entire genome, with 54% of these mutations expected to be null(16), resulting in 1.5X genome coverage for loss of function mutations.
The _MF5L6_ suppressor mutation maps to a chromosome 3 interval containing _F3_

In order to map putative ENU-induced suppressor mutations, surviving _F5/L/L_ _Tfpipi+/-_ mice were intercrossed with _F5/L/L_ mice that had been backcrossed onto the 129S1/SvIMJ strain (129S1). Crosses between _F5/L/L_ and _F5/L+ _Tfpipi+/-_ mice (both _F5/L_ and _Tfpipi_ backcrossed > 12 generations onto 129S1) confirmed the lethality of the _F5/L/L_ _Tfpipi+/-_ genotype on the 129S1 background (Table S1). The 4 lines containing the largest number of genetically informative B6-129S1 mixed background _F5/L/L_ _Tfpipi+/-_ offspring (MF5L1, 6, 9 and 16) were used for gene mapping. Though the _MF5L1, MF5L9_ and _MF5L16_ lines were successfully expanded to pedigrees containing 27, 84, and 14 _F5/L/L_ _Tfpipi+/-_ informative offspring, respectively, genotyping for a total of ~800 markers in each cross failed to identify any loci with a LOD $\geq$3 (maximum LODs for _MF5L1=1.15_, _MF5L9=2.5_ and _MF5L16=1.61_). Though we cannot exclude cosegregation of more than one suppressor mutation, the absence of a clear linkage signal for each of these lines likely reflects complex mouse strain modifier gene interactions, which are known to significantly impact mouse phenotypes(10, 27) and confound linkage analysis(28). Consistent with this hypothesis, we have previously documented poorer survival to weaning in mixed B6-129S1 _F5/L/L_ mice compared to littermates(14). We extended these observations by the analysis of additional _F5/L+ and F5/L/L_ littermates, with mice of the _F5/L_ genotype demonstrating a 50% reduction in survival in the 129S1 versus B6 strain backgrounds (Table S1).

_MF5L6_ was maintained for 12 generations on both the mixed and B6 backgrounds and produced a total of 336 _F5/L/L_ _Tfpipi+/-_ mice (98 on the mixed B6-129S1 background and therefore useful for linkage analysis, See Table 1). Genome-wide SNP genotyping was performed on DNA from these 98 genetically informative _F5/L/L_ _Tfpipi+/-_ mice, with multipoint linkage analysis shown in Figure 2A. Since the genetic intervals around the _F5_ and _Tfpipi_ loci cannot be accurately
assessed for linkage, these regions of chromosomes 1 and 2 were excluded from linkage analysis (See Fig. 2A Legend and Methods). A single locus with a significant LOD score of 4.49 was identified on chromosome (Chr) 3, with the 1 LOD interval (117.3-124.8Mb) containing 43 refseq annotated genes (Fig. 2B).

The F3 gene located within this interval (Chr3:121.7 Mb) (Fig. 2B) encodes tissue factor (TF), a procoagulant component of the hemostatic pathway that has TfpI as its major regulator. Quantitative or qualitative deficiencies in F3 are thus highly plausible candidates to suppress the F5L/L TfpI+/− phenotype. To test F3 as a candidate suppressor of the F5L/L TfpI+/− phenotype, an independent F3 null allele was introduced and triple heterozygous F5L+/ TfpI+/− F3+/− mice were crossed to F5L/ B6 mice (Fig. 2C). Of 273 progeny genotyped at weaning, 13 F5L/L TfpI+/− F3+/− were observed (and 1 F5L/L TfpI+/− F3+/+, p=9.7x10−5). We also observed significantly fewer male than female F5L/L TfpI+/− F3+/− mice (2 vs. 11 p=0.03). Thus, haploinsufficiency for F3+/− suppresses the synthetic lethal F5L/L TfpI+/− phenotype with incomplete penetrance (33%) that also differs by sex (10% for males and 67% for females). In contrast, the MF5L6 line exhibited an overall penetrance of 72.4%, with similar male/female penetrance. Gender-specific differences in venous thrombosis rates have previously been reported, including contributions from oral contraceptives and hormone replacement therapy(29-31). This difference in penetrance could be due to 129S1 strain effects in the MF5L6 line or differences between a F3 regulatory mutation in MF5L6 compared to the F3 loss of function allele used here.

Whole exome sequencing data analysis of a F5L/L TfpI+/− mouse from MF5L6 failed to identify an ENU variant in F3 or in any other genes in the nonrecombinant interval, or more broadly on the entire Chr3. This is a particularly gene rich region (Figure 2B), and errors in annotation could obscure the responsible variant. Of note, this interval also includes Slc44a3, a
paralog of Slc44a2, the latter previously identified as a potential modifier of VTE risk in humans (6). Although additional ENU variants were identified on other chromosomes, none co-segregated with the survival phenotype in line MF5L6 (Table S2). Sanger sequencing analysis of the full set of F3 exons and introns, as well as 5kb upstream of exon 1, also failed to identify an ENU-induced mutation. In addition, analysis of F3 mRNA levels in liver, lung and brain tissues of adult mice failed to identify any differences in the level of expression from the ENU-mutant compared to the wildtype allele (Fig. S1).

Taken together, these data suggest that an ENU-induced F3 regulatory mutation outside of the sequenced segment may be responsible for thrombosuppression in MF5L6, although we cannot exclude a regulatory mutation in another gene. Nonetheless, our findings demonstrate that F3/Tfpi balance plays a key role in thrombosis in the mouse, particularly in the setting of F5L, and suggest that modest variations in either F3 or Tfpi could be important modifiers of VTE susceptibility in humans.

**Whole exome sequencing identifies candidate ENU suppressor variants for 8 MF5L lines**

Whole exome-next generation sequencing (NGS) was performed on genomic DNA from an index F5L/Tfpi+/- mouse (from the G2-G5 generation) from each of 8 MF5L lines, including the 4 lines described above, as well as 4 additional lines with large pedigrees (MF5L5, MF5L8, MF5L11, MF5L12). The mean coverage of sequenced exomes was more than 90X, with >97% of the captured region covered with at least 6 independent reads (Table S3). A total of 125 heterozygous variants were identified as candidate suppressor mutations, with 79 variants affecting protein sequence (Table S2). Of the total mutations, 54.4% were nonsynonymous single nucleotide variants (SNVs), followed by UTR (17.6%), synonymous (14.4%) and stopgain SNVs (7.2%), with the remainder being comprised of indels, splicing, and stoploss mutations.
The most common mutation events were A/T→G/C transitions (35.3%), while C/G→G/C transversions were the least represented (2.5%). This spectrum of mutations is consistent with previously published ENU experiments(32). Variants exhibiting no recombination with the Tfpi locus on Chr2 (17 variants) were excluded from further analysis (See Methods). Sanger sequencing confirmation was performed for 62 variants, including all nonsynonymous and stopgain mutations. These variants were then checked for parent of origin (either the G1 mutagenized progeny or its non-mutagenized mate) as well as the original mutagenized G0 male. Forty-seven of these variants were identified in the G1 mouse but not in the G0 or non-mutagenized parent, consistent with ENU-induced mutations. The remaining 15 mutations were either NGS sequencing errors (11/15), de novo (2/15), or transmitted from the non-mutagenized parent (2/15) (Table S2).

Each SNV was analyzed in additional MF5L mice from the line in which it was identified. None of the thrombosuppressive exonic ENU-induced variants identified in lines MF5L1, 5, 6, 8, 9, 11 and 16 segregated with the lethal phenotype as tested by Kaplan-Meier analysis using a significance threshold of p<0.05(33). Of the 7 candidate ENU-induced SNVs identified from whole exome sequence analysis for the MF5L12 line, 1 was an NGS sequencing error and 6 were validated by Sanger sequencing as consistent with ENU-induced mutations in the G0 mice (Table S2). For each of these 6 SNVs, co-segregation with the survival phenotype was tested by Kaplan-Meier analysis of the first 31 F5L/L Tfpi+/− mice generated from the MF5L12 line. Only one variant, a nonsynonymous SNV in the Actr2 gene (c.772C>G, p.R258G, Actr2G), demonstrated a significant survival advantage when co-inherited with the F5L/L Tfpi+/− genotype (p=1.7x10−6) (Fig. 3A).

*Actr2 as a thrombosuppressor gene*
The gene Actr2, ARP2 actin related protein 2, encodes the ARP2 protein, which is an essential component of the Arp2/3 complex (34). ARP2, along with ARP3 and five other independent protein subunits (ARPC1-5), forms the evolutionarily conserved seven-subunit Arp2/3 complex (35). Arp2/3 is a major component of the actin cytoskeleton and is found in most eukaryotic cells including platelets (36). Arp2/3 binds to the sides of actin filaments and initiates the growth of a new filament, leading to the creation of branched actin networks that are important for many cellular processes (37). Loss of Arp2/3 function can have severe consequences, as illustrated by the embryonic lethality of mice homozygous for an ARP3 hypomorph (38). In hemostasis, the Arp2/3 complex is necessary for actin-dependent platelet cytoskeletal remodelling events, which are essential for platelet activation and degranulation (39-41). The Actr2<sup>+/G</sup> mutation results in a p.R258G substitution in exon 7 of Actr2, at a highly conserved amino acid position, with arginine present at this position for all 60 available vertebrate sequences (https://genome.ucsc.edu), as well as in plants and fungi (Fig. 3B). In addition, no variants at this position have been identified to date in over 120,000 human alleles (42).

**Actr2 hemizygosity is incompatible with survival**

We attempted to generate an independent Actr2 knockin (Actr2<sup>G</sup>) allele by CRISPR/Cas9 genome editing (Fig. S2, Fig. S3, and Methods). Though highly efficient gene targeting was observed in blastocysts (Fig. S3), transfer of 275 injected embryos into foster mothers resulted in no surviving pups with a successfully targeted Actr2 allele. These data suggest that heterozygous loss of function for Actr2 may be incompatible with survival to term. Consistent with this hypothesis, human sequencing data from the Exome Aggregation Consortium (ExAC), which includes 60,706 individual exomes, reports a loss of function intolerance for ACTR2 of
0.997(42). *ACTR2* mutations have not been previously associated with human disease (https://omim.org/entry/604221)(43), again consistent with early embryonic lethality. In addition, out of 373,692 mouse ENU-induced mutations listed in the Mutagenetix website, only 16 are located in the *Actr2* gene, with no predicted loss of function mutations (https://mutagenetix.utsouthwestern.edu/)(44). Taken together, these data strongly suggest that haploinsufficiency for *Actr2* is not tolerated in humans or mice. The viability of *Actr2*+/G mice suggests that the *Actr2*G allele is either hypomorphic or a unique gain of function mutation distinct from simple haploinsufficiency. Similarly, analysis of ExAC data suggests that 4 of the 6 other members of the Arp2/3 complex are intolerant to heterozygous loss of function in humans(42). Our findings suggest that subtle alterations in *Actr2* function, and potentially in other components of the actin cytoskeleton, could alter hemostatic balance and play a previously unappreciated role in thrombosis susceptibility.

The identification of novel factors involved in the regulation of hemostasis is challenging, as genes leading to marked shifts in hemostatic balance resulting in either severe bleeding or thrombosis are straightforward to identify clinically in humans, whereas subtle shifts are likely to escape detection given the multiple layers of buffering built into the complex hemostatic system(10). Homozygous deficiency (which would not be tested by our dominant suppressor strategy) for a number of hemostatic factors results in clinical bleeding, whereas heterozygous carriers remain asymptomatic. Though a single mutation in the X-chromosomal Factor VIII (or IX) gene produces severe bleeding in humans and rescues the lethal *F5*+/+ *Tfpi*+/+ mouse phenotype (Figure 1A), a F8 gene mutation would not be transmitted from the ENU-mutagenized male-to-male offspring and thus would be undetected. Indeed, the dominant sensitized suppressor screen reported here was undertaken to identify genes for which modest
(<50%) reduction in function would significantly shift overall hemostatic balance. Such loci represent likely candidates for common human variation contributing to thrombosis and bleeding disorders. Gene variants with subtle yet significant antithrombotic effects represent attractive therapeutic targets because of a potentially wide therapeutic window with few unintended side effects. The finding of 98 $F5^{L/L}$ Tfpi$^{+/-}$ mice carrying putative thrombosis suppressor mutations (at an estimated 1.5X genome coverage) suggests that subtle alterations at a number of loci are capable of suppressing the $F5^{L/L}$ Tfpi$^{+/-}$ lethal thrombotic phenotype. The complex strain-specific genetic modifiers that confounded the genetic linkage analysis are consistent with this model. Nonetheless, our findings illustrate the particular importance of the $F3/Tfpi$ axis in thrombosis regulation (especially in the setting of $F5^L$), as well as the identification of Actr2 and the Arp2/3 complex as another potentially sensitive regulatory pathway for maintaining hemostatic balance.

Materials and methods

Detailed description of mouse strains and procedures for ENU mutagenesis, breeding, genetic mapping and genotyping, Sanger and whole exome sequencing, estimation of $F3$ allelic expression, generation of Actr2 CRISPR/Cas9 targeted mice and cells, the SURVEYOR nuclease assay, and statistical data analyses are provided Supporting Information.

Normal weaning and breeding ages are 20 days and 42 days, respectively. **D.** *F5*/* Tfpi*/* putative suppressor mouse were significantly smaller than their non-*F5*/* Tfpi*/* littermates. **E.** *F5*/* Tfpi*/* putative suppressors were smaller than their littermates of other genotypes (p<8.8 x 10^{-12} for B6, and p=2.2 x 10^{-16} for mixed B6-129S1) regardless of whether they were on the pure B6 or mixed B6-129S1 genetic backgrounds (p=0.327 between B6 and mixed backgrounds).

**Figure 2:** The *MF5L6* suppressor locus maps to Chr3. **A.** Linkage analysis for the *MF5L6* line. Alternating red and black is used to highlight the chromosomes. Chrs 1 and 2 were excluded from further analysis since they contain the *F5* and *Tfpi* genes, whose segregation was restricted by required genotypes at these loci. The Chr3 peak had the highest LOD score in the Chr3 subregion:117.3-124.8Mb (maximum LOD=4.49, 1 LOD interval, significance threshold of LOD >3.3(49)). **B.** The Chr3 candidate interval (Chr3:117.3-124.8 Mb) contains 43 refseq annotated genes, including *F3*. **C.** The mating scheme and observed distribution of offspring to test *F3* deficiency as a suppressor of *F5*/* Tfpi*/* phenotype. *F3*/* results in incompletely penetrant suppression of the *F5*/* Tfpi*/* phenotype.
Figure 3: The Actr2 R258G ENU-induced mutation is a potential thrombosis suppressor gene. A. Kaplan-Meier survival plot for F5\textsuperscript{L/L} Tfpi\textsuperscript{+/−} mice with and without the Actr2\textsuperscript{G} mutation. F5\textsuperscript{L/L} Tfpi\textsuperscript{+/−} Actr2\textsuperscript{+/G} mice exhibit significantly better survival than F5\textsuperscript{L/L} Tfpi\textsuperscript{+/−} Actr2\textsuperscript{+/+} littermates (n=19 for Actr2\textsuperscript{+/G}, n=12 for Actr2\textsuperscript{+/+}, n=31 total). B. ARP2 amino acid R258 is highly conserved in animals, plants and fungi.

Penetrance was calculated as total *F5*<sup>L/L</sup> *Tfpi*<sup>+/−</sup> divided by ½ of the number of *F5*<sup>L/L</sup> *Tfpi*<sup>+/+</sup> littermates.
