45 **Abstract**

46 Melanin and cuticular proteins are important cuticle components in insect. Cuticle
 47 defects caused by mutations in cuticular protein-encoding genes can hinder melanin
 48 deposition. However, the effects of melanin variation on cuticular protein-encoding
 49 genes and the corresponding morphological traits associated with these genes are
 50 remain largely unknown. Using *Bombyx mori* as a model, we showed that the
 51 melanism levels during larval cuticle pigmentation correlated positively with the
 52 expression of cuticular protein-encoding genes. This correlation stemmed from the
 53 simultaneous induction of these genes by the melanin precursors. More importantly,
 54 the effect of the melanism background on the cuticles induced the up-regulation of
 55 other functionally redundant cuticular protein-encoding genes to rescue the
 56 morphological and adaptive defects caused by the dysfunction of some mutated
 57 cuticular proteins, and the restorative ability increased with increasing melanism
 58 levels, which gives a novel evidence that melanism enhances insect adaptability.
 59 These findings deepen our understanding of the interactions among cuticle
 60 components, as well as their importance in the stabilizing of the normal morphology
 61 and function of the cuticle.

62

63 **Introduction**

64 The prerequisite for the benefits of melanism to insect is not only the integrity of
 65 the melanin biosynthesis and regulatory pathway (Wilson *et al.* 2001; Liu *et al.* 2015;
 66 Mallet and Hoekstra 2016), but also the normal presence of the platform it relied on

67 (Wittkopp *et al.* 2003; Wittkopp and Beldade 2009; Andersen 2010; Moussian 2010;
68 Van Belleghem *et al.* 2017). For the insects, the most important fundamental platform
69 for the color pattern drawing is the cuticle (Hopkins and Kramer 1992; Andersen 2010;
70 Moussian 2010). During shaping the cuticle, the maintenance and stability of the
71 cuticle features depends on normal functional cuticular proteins and the interactions
72 with other components (such as chitin) (Hopkins and Kramer 1992; Guan *et al.* 2006;
73 Suderman *et al.* 2006; Andersen 2010; Moussian 2010; Chaudhari *et al.* 2011; Noh *et*
74 *al.* 2016). Due to the crucial roles of cuticular proteins on cuticle development, when
75 their coding genes are loss of function, the abnormal or defective cuticle will likely
76 affect the deposition and attachment of melanin, which is not conducive to the
77 performance of color pattern (Kanekatsu *et al.* 1988; Oota and Kanekatsu 1993;
78 Arakane *et al.* 2012; Jasrapuria *et al.* 2012; Wang 2013; Noh *et al.* 2015). Yet little is
79 known about the corresponding response mode of cuticular protein-encoding genes
80 via the alteration of the melanin biosynthesis or regulatory pathway.

81 Recently, several high throughput expression surveys showed that the abundance of
82 cuticular protein-encoding genes in different colored integuments varied in some
83 insect species, especially with evidently up-regulated in the melanic regions
84 (Futahashi *et al.* 2012; He *et al.* 2016; Wu *et al.* 2016; Tajiri 2017), and some of those
85 shared very similar expression patterns and functions (Nakato *et al.* 1994; Nakato *et*
86 *al.* 1997; Shofuda *et al.* 1999; Okamoto *et al.* 2008; Liang *et al.* 2010; Tang *et al.*
87 2010; Qiao *et al.* 2014). These studies implied that there are probably some
88 relationships between the promotion of melanism and the expression of cuticular

89 protein-encoding genes. Prior to this study, further exploring and understanding of the
90 potential relationships were unclear. Additionally, when melanism-promoting
91 instructions and defective cuticle proteins occur simultaneously, what are the effects
92 of their relationships on the presence of the corresponding morphological traits ?

93 In the Lepidoptera model, *Bombyx mori*, an intriguing phenomenon has been
94 reported that a larval melanic mutant, *Striped* (p^S , 2-0.0) is able to rehabilitate the
95 malformed body shape, as well as the adaptability defects of the *stony* mutant (*st*,
96 8-0.0) (Xiang 1995; Banno *et al.* 2005). A recent study clarified that a transcription
97 factor, *Apontic-like*, which boosts the expression of melanin synthesis genes in
98 epidermal cells, is responsible for the p^S mutant (Yoda *et al.* 2014). Besides this, there
99 are also multiple alleles with different melanism degrees at the *p* locus, including p^B ,
100 p^M , *etc* (Xiang 1995; Banno *et al.* 2005; Yoda *et al.* 2014). And the *stony* mutant (*st*,
101 8-0.0) which precisely caused by the deletion of a RR1-type larval cuticular
102 protein-encoding gene, *BmLcp17* (or *BmorCPR2*) showed hard and tight touch feeling,
103 uncoordinated ratios of the length of the internodes and the intersegment folds (I/IF),
104 bulges at intersegment folds, and severely defective locomotion and behavioral
105 activities in the larval stage (Qiao *et al.* 2014). In addition, the similarity of the gene
106 expression patterns and functional characteristics among some members of the
107 RR1-type larval cuticular protein-encoding gene family, such as *BmLcp18*, *BmLcp22*,
108 *BmLcp30* also suggest that they may play very similar roles as *BmLcp17* in shaping
109 the larvae cuticle (Nakato *et al.* 1994; Nakato *et al.* 1997; Shofuda *et al.* 1999;
110 Okamoto *et al.* 2008; Liang *et al.* 2010; Tang *et al.* 2010; Qiao *et al.* 2014). These

111 dispersed findings are linked through the epistasis of p^S to *stony*, then provide the
112 breakthrough and the exceptional genetic resources for exploring the interactions
113 between melanin and cuticular protein-encoding genes.

114 Here we illustrated that the transcripts levels of four cuticular protein-encoding
115 genes were positively correlated with the melanism degree of larval cuticle, which
116 were due to the simultaneous induction these genes by the intracellular melanin
117 precursors. Moreover, by importing melanism-promoting instruction into the *stony*
118 mutant, the cuticle deficiency rescued through functionally redundant compensation
119 by some other up-regulated cuticular protein-encoding genes, which a new evidence
120 that melanism as a beneficial trait. These findings deepen our understanding of the
121 interactions among genetic factors which shape morphological features in
122 lepidopteran, and emphasize the ecological and evolutionary significance of these
123 mutual interactions.

124

125 **Materials and Methods**

126 *Silkworm strains*

127 Wild-type strains Dazao ($+^p$) and melanic mutant strains p^M , p^S and p^B (Xiang 1995;
128 Banno *et al.* 2005; Yoda *et al.* 2014) were analyzed in this study. The darkness of
129 pigment was measured as mean OD value using Image J (<https://imagej.nih.gov/ij/>).
130 In terms of melanism degree, the body color of an individual that is homozygous at
131 one of the aforementioned melanic loci is darker than that of a heterozygous
132 individual (Xiang 1995; Banno *et al.* 2005). The albinism mutant *albino* (*al*) (Banno

133 *et al.* 2005; Fujii *et al.* 2013), non-diapause wild-type strain N4 (used for melanin
134 inhibition treatment) and *BmLcp17* deletion strain Dazao-*stony* (near isogeneic line of
135 Dazao, which have been backcrossed with Dazao over 26 generations) were supplied
136 by the Silkworm Gene Bank in Southwest University. The N4 strain and *al* mutant
137 were fed with artificial diet at 28°C, and the others were fed fresh mulberry leaves
138 under a 12 h/12 h light/dark photoperiod at 24 °C.

139 ***Chemicals and cell lines***

140 L-dopa (D9628), dopamine (H8502), tetrahydrofolic acid (BH₄) (T3125) and
141 2,4-Diamino-6-hydroxypyrimidine (DAHP) (D19206) were purchased from
142 Sigma-Aldrich (St. Louis, MO, USA). *BmNs* cell line was kept in our laboratory.

143 ***Mating combinations and progeny phenotypes identification***

144 The p^S and p^M strains were crossed with the Dazao-*stony* strain to generate the F₁
145 generation, respectively. The F₂ generation were produced by an F₁ self-cross, and
146 individuals of day 5 of the fifth-instar were collected to further use. The p^B strain was
147 crossed with the Dazao-*stony* strain to generate F₁ progeny, which mated with the
148 Dazao-*stony* strain to generate the BC₁ generation, and fed them until at day 5 of the
149 fifth-instar. Firstly, individuals of the F₂ or BC₁ generations were separated by their
150 cuticle pigmentation. Subsequently, their phenotypes were further classified by
151 morphological characteristics, touch feeling, and the ratios between the number of
152 internodes and intersegmental folds in the second, third, and fourth abdominal
153 segments based on an earlier method (Qiao *et al.* 2014).

154 ***Genotyping***

155 Because the p^S , p^M and p^B mutations are alleles at the p locus, they should be
156 located in proximity each other on the chromosome 2 (Xiang 1995; Banno *et al.* 2005;
157 Yoda *et al.* 2014). Based on the reported sequence of the gene corresponding to the p^S
158 allele, a polymerase chain reaction (PCR)-based molecular marker within of the
159 genomic region of the *Apontic-like* was designed. PCR screening were performed in
160 the p^X ($X=M, S$ and B) and Dazao-*stony* to obtain the polymorphism molecular marker
161 for p locus. Similarly, molecular marker was also designed within genomic region of
162 the *BmLcp17* for polymorphism screening of the *stony* locus. The primers used in this
163 study are listed in Table S1.

164 ***Association analysis of gene expression, phenotype and genotype***

165 Day 5 fifth-instar larvae of the Dazao or Dazao-*stony* strains were selected for
166 cuticle dissection. The cuticles of the semi-lunar marking region and the non-melanic
167 portion between the paired semi-lunar marking were finely dissected. Gene
168 expression levels of *BmLcp17*, *BmLcp18*, *BmLcp22* and *BmLcp30* in these regions
169 were compared. Gene expression patterns were determined for the dorsal epidermis of
170 abdominal segments (from semi-lunar marking to star marking) from day 5 of fifth
171 instar larvae (Dazao, $p^S/+$, $p^M/+$, $p^B/+$). Day 1 of second instar larvae of the *al* and
172 Dazao strains were also investigated. The same regions of dorsal epidermis regions
173 were collected from F₂-generation individuals with the p^S/p^S , *st/st*, and $p^S/+$, *st/st*
174 genotypes, as well as the p^M/p^M , *st/st* and $p^M/+$, *st/st* genotypes for gene expression
175 analyses. For all genotyped individuals, the ratios of the intersegment length to the
176 intersegment fold were also analysed using image J.

177 ***Melanin precursors-promoting and inhibition treatments***

178 The preparation and concentration of L-dopa and dopamine solutions were slightly
 179 modified according to the description by Futahashi (Futahashi and Fujiwara 2005),
 180 and filtered with a 0.22 μ m membranes before use. Cells were washed three times
 181 with Grace medium without melanin precursors to remove metabolites and other
 182 contaminants on the cell surfaces. Medium (0.8 mL) containing L-dopa or dopamine
 183 was added separately into each well, and the medium without melanin precursors was
 184 used as the control. Culture plates were sealed with tape, wrapped with foil and
 185 incubated at 28°C for 24 h for a gene expression analysis. For BH₄ feeding assays,
 186 the 30mM working solution was prepared by dissolving tetrahydrofolic acid into
 187 ddH₂O, and spreading it on an artificial diet for *al* mutants. The control was ddH₂O.
 188 Phenotype were observed and recorded from the second instar stage, and expression
 189 of cuticular protein-encoding genes was analysed. For the melanism-inhibition
 190 experiments, the wild-type strain N4 was used. Newly-hatched larvae were divided
 191 into treatment and control groups. Individuals in the treatment group fed with DAHP
 192 dissolved in 0.1M NaOH (15g/L), and individuals in the control group fed 0.1M with
 193 NaOH. Phenotypes observation and gene expressions detection were performed on
 194 day 1 of the second-instar larvae.

195 ***Quantitative RT-PCR***

196 Total RNA extraction, reverse transcription and Quantitative reverse
 197 transcription-PCR (qRT-PCR) conducted as described previously (Qiao *et al.* 2014).
 198 Three biological replicates were prepared for each condition, and *BmRPL3* was used

199 as the internal control. Primers are listed in Table S1.

200

201 **Results**

202 *Entirely distinct expression patterns of cuticular protein-encoding genes and the* 203 *cuticle appearance between melanic and non-melanic regions*

204 Expression patterns of *BmLcp17*, *BmLcp18*, *BmLcp22* and *BmLcp30* in melanic or
205 non-melanic epidermal regions are shown in Figure 1. These results, together with
206 earlier studies (Futahashi *et al.* 2012; He *et al.* 2016; Wu *et al.* 2016), revealed that the
207 gene expressions were significantly higher in melanic parts of the cuticle than in
208 non-melanic parts. Moreover, micro protrusions were more intensive in the melanic
209 regions than in the non-melanic regions, and accompanied by a higher amounts of
210 chitin (another important cuticle component (Hopkins and Kramer 1992; Moussian *et*
211 *al.* 2006; Andersen 2010; Moussian 2010; Chaudhari *et al.* 2011; Qiao *et al.* 2014),
212 and the reduction chitin content was reported to impede cuticle melanism (Moussian
213 *et al.* 2005)) (Figure S1A). These results showed that, regardless of the different
214 genetic basis of the melanic mutants or the melanic markings in the non-melanic
215 strains, excessive accumulation of melanin in the cuticle (accompany by the changes
216 in the surface structure and the chitin content of the melanic cuticle) was closely
217 related to the high expression levels of the cuticular protein-encoding genes.

218 *Expression level of larval cuticular protein-encoding genes positively correlated* 219 *with the degree of cuticle melanism*

220 To obtain further insights into the relationships between the melanin accumulation

221 and the expression of cuticular protein-encoding genes, we investigated gene
222 expression patterns using four p locus alleles (Dazao ($+^p$), p^M , p^S and p^B), which
223 showed gradually increasing melanin accumulation (Figure 2A). Gene expression
224 levels were gradually and significantly up-regulated with the increase in the degree of
225 melanism in cuticle (Figure 2B). These results further showed that the expression
226 levels correlated positively with the degree of melanism. Thus, the quantities of
227 cuticular proteins with similar or redundant functions was increased greatly by the
228 increasing the degree of melanism.

229 ***Typical stony phenotyped individuals masked after the introduction of melanic loci***
230 ***into the *BmLcp17* defection strain***

231 We assessed the effects of modulating the melanic background on the phenotypic
232 defects caused by the deletion of *BmLcp17*. After mating the p^B and *stony* parental,
233 the percentage of BC₁ individuals with melanism and the normal body shape in the
234 backcrossed population of the $p^B \times stony$ cross was 52 % (290/553; and theoretically, it
235 was 25 %), yet individuals with the melanism cuticle and *stony*-type body shape were
236 not found (theoretically should be almost equivalent to the number of individuals with
237 melanism cuticle and normal body shape) (Figure 3). In the cross of $p^S \times stony$, ~10.8%
238 (36/331) of F₂ progeny had an lighter melanism body color and smaller body size
239 (Figure 3). These individuals exhibited a little hard and tight touched body, but the
240 body was much softer than that of the *stony* mutant. Their intersegment folds bulged
241 slightly, and the length were significantly shorter than that of the internodes;
242 accordingly, their phenotypes slightly resembled the morphological features of the

243 *stony* mutant (Figure 3 and 4A). Even so, We did not find individuals with the typical
 244 *stony*-type body shape and also defective adaptability under the melanism background
 245 (theoretical ratio is 3/16). (Figure 3). Similarly, in the $p^M \times stony$ corss, only
 246 approximately ~11.7% (51/437) of the individuals of the F₂ population were very
 247 lightly melanic, but they exhibited obviously unusual morphological features (Figure
 248 3, Figure 4A). When compared with the ~10.8% F₂ individuals (aforementioned) from
 249 the $p^S \times stony$ cross, the touch feelings of individuals from the $p^M \times stony$ cross were
 250 tighter and firmer, and the intersegment folds bulged more obviously and had a higher
 251 proportion among the segments, meaning that their body features were closer to the
 252 phenotype of the *stony* mutant (Figure 3 and 4A) (Qiao *et al.* 2014). Nevertheless,
 253 melanic individuals showing the typical *stony*-type body features and defective
 254 adaptability still did not appear (theoretical ratio is 3/16) in the progeny from the $p^M \times$
 255 *stony* cross. Therefore, induction of the melanic mutation into individuals with a
 256 defective cuticular protein-encoding gene could mask the adverse phenotypes, and the
 257 masking effect was more remarkable with the increasing degree of melanism.

258 ***Other larval cuticular protein-encoding genes up-regulated evidently in the melanic***
 259 ***and non-stony phenotypic, but with mutated BmLcp17 genotypic offspring***

260 Using the molecular markers (closely linked to the *p* and *st* loci, respectively), we
 261 further genotyped the progenies with melanic color pattern and non-*stony* (including
 262 ambiguous *stony*-like) body shape. The results revealed that approximately 49% of
 263 the individuals showing a melanic color and normal body shape in the BC₁ population
 264 from the $p^B \times stony$ cross was the $p^B/+^{pB}$, *st/st* genotype (Figure 4A). The ratios of the

length of the internodes and the intersegment folds (I/IF) were ~4, which is very similar to that in $p^B/+^{pB}, +^{st}/st$ individuals, and also no significant differences as that in the wild-type individuals (Figure 4B) (Qiao *et al.* 2014). In the F_2 generation from the $p^S \times stony$ cross, approximately 9.3% of the individuals with the $p^S/p^S, st/st$ genotype and very few individuals (~1%) with the genotype $p^S/+^{pS}, st/st$ exhibited a melanic color and the normal body shape (Figure 4A). For $p^S/p^S, st/st$ genotyped individuals, the I/IF value was approximately 3.3 (Figure 4B). Although the I/IF value was lower than that in $p^S/_, +^{st}/_$ individuals (approximately 4, Figure 4B), it was much higher than that in the *stony* mutant (approximately 1.6 (Qiao *et al.* 2014)). Despite the slightly smaller body size of the $p^S/p^S, st/st$ individuals, their body shape was essentially normal (Figure 4A). The genotypes of those lightly melanic individuals, whose body shape was slightly like that of the *stony* phenotype (mentioned in Result 3), were all the $p^S/+^{pS}, st/st$, and the I/IF value of these individuals was approximately 2.7 (Figures 4A and 4B). In progeny of the $p^M \times stony$ cross, ~10.5% of the individuals with the $p^M/p^M, st/st$ genotype and ~0.7 % of the individuals with the $p^M/+^{pM}, st/st$ genotype showed a melanic color and subtle *stony* features (just very slight bulges) (Figure 4A). The body size of the $p^M/p^M, st/st$ individuals were smaller than those of the $p^M/_, +^{st}/_$ individuals. They exhibited a certain sense of hardness, and the I/IF ratio was approximately 2.8, which is in good agreement with their phenotypes (Figure 4B). Additionally, individuals showing very slight melanism and morphological features that were more similar to that of the *stony* mutant (mentioned in Result 3) were all the $p^M/+^{pM}, st/st$ genotype, and their I/IF values were

approximately 1.8, which is closer to that of the *stony* mutant (Figures 4A and 4B). In addition, the expression of cuticular protein-encoding genes in p^S/p^S , *st/st* individuals were significantly higher than that in $p^S/+^{pS}$, *st/st* individuals (Figure. 4C); a similar result was also obtained from the p^M/p^M , *st/st* and $p^M/+^{pM}$, *st/st* individuals (Figure 4C). Taken together, these results revealed that more cuticular proteins with similar functions were accumulated in the cuticle of melanic homologous individuals at the *p* locus. Based on the comprehensive and association analysis, we infer that melanic background effectively drove the expressions of cuticular protein-encoding genes with similar expression patterns and redundant functions, which compensated for the morphological and adaptability defects caused by the dysfunctional *BmLcp17* gene; and the law of compensatory abilities was $p^B/+^{pB}$, *st/st* > p^S/p^S , *st/st* > p^M/p^M , *st/st* ✱ $p^S/+^{pS}$, *st/st* > $p^M/+^{pM}$, *st/st*, which corresponds well with the gradual weakening of the degree of melanism (Figures 4 and Figure S3).

Content variations of melanin precursors affect the transcript amount of the cuticular protein-encoding genes

Due to the crucial material basis for the cuticle melanism (no matter what kind of genetic basis caused by) is the extensive accumulation of melanin precursors in the epidermal cells; thus, the essence that melanism tend to increase the expression of some cuticular protein-encoding genes should be driven by the relations between the accumulation of melanin precursors and the transcripts amount of the cuticular protein-encoding genes. The basal expressions of four cuticular protein-encoding genes were detected in *BmNs* cells (Figure S5) and indicated that regulatory pathways

controlling the expression of cuticular protein-coding genes in this cell line. Thus, this cell line was used to examine the effect of melanin precursors on gene expressions. After incubating *BmNs* cells with melanin precursors, the expression of cuticular protein-encoding genes was significantly higher in cells treated either by L-dopa or dopamine, compare with that in the control group (Figure 5 top (left)). Second-instar *al* mutant are characterized by albinism and a porous cuticle due to a mutation in sepiapterin reductase, which leads to the insufficient synthesis of the co-factor BH₄ during the synthesis of melanin precursors (Banno *et al.* 2005; Fujii *et al.* 2013). When treated with BH₄, these mutants had normal melanic body color (Lab unpublished contribution) (Fujii *et al.* 2013), and gene expressions were obviously higher than that in the control group (Figure 5 top (right)). These results suggested that the expression of cuticular protein-encoding genes was induced by increasing amounts of melanin precursors. We investigated the effects of DAHP, an inhibitor of guanylate cyclase hydrolase (GTPCHI), an important rate-limiting enzyme in the synthesis of BH₄ (Hamadate *et al.* 2008). Inhibiting BH₄ synthesis in wild-type second-instar larvae by blocking the synthesis of melanin precursors in epidermal cells caused individuals to lose their original melanic body color (Lab unpublished contribution). The gene expressions were also significantly reduced when compared with that in the control group (Figure 5 bottom). Thus, the content and variation of the intracellular melanin precursors were important factors for regulating the expression of cuticular protein-encoding genes. We concluded that the inducing effect of the melanin precursors on the expression of cuticular protein-encoding genes is the basis

331 for melanism promoting genes' transcription.

332

333 **Discussion**

334 Melanin is mainly deposited in the epicuticle and exocuticle, cross-linked with
 335 proteins in this layer, and involved in the formation of the melanic cuticular
 336 characteristics (Hopkins and Kramer 1992; Suderman *et al.* 2006; Andersen 2010;
 337 Moussian 2010; Hu *et al.* 2013). Some cuticular proteins located in the endocuticle
 338 may not be directly associated with the melanin, but the maintaining of the normal
 339 cuticle need to rely on the normal development and coordination between each cuticle
 340 layer, and these proteins are indispensable element in shaping the endocuticle
 341 (Moussian 2010; Cohen and Moussian 2016). Thus, we suppose that these
 342 endocuticular proteins may influence the transportation or accumulation of melanin
 343 through some indirect ways, to contribute to the unique features of the melanic cuticle.
 344 We indeed clearly observed that extensive star-like protrusions were present on the
 345 cuticle when a large amount of melanin accumulated (Figure S1). Similar correlations
 346 between cuticle structure and body color have been reported multiple times (Futahashi
 347 *et al.* 2012; Noh *et al.* 2016; Tan *et al.* 2016), imply that there should be some
 348 interactions between cuticular proteins and melanin. Although the exact interaction
 349 pattern between these two cuticular components is unknown, microscopic observation
 350 clearly shows that the deposition of an excessive amount of melanin affected the
 351 cuticle characteristics.

352 The expression profile of cuticular protein-encoding genes in melanic silkworm

353 mutants and the black markings of *Papilio* larvae supported the hypothesis that
 354 up-regulated cuticular proteins probably participate in the transport or maintenance of
 355 the corresponding pigments in a specifically colored cuticles (Figures 1, 2 and Figure
 356 S1) (Futahashi *et al.* 2012; He *et al.* 2016; Wu *et al.* 2016). Yet over-expression of
 357 cuticular protein-encoding genes *in vivo* cannot trigger (or induce) the formation of
 358 melanic cuticle (Tajiri *et al.* 2017). Therefore, we hypothesized that if instructions for
 359 melanin accumulation were included in the developmental program for which
 360 melanism is the original factor, other cuticle features and structures would adapt to the
 361 level of melanin accumulation, regardless of genetic background. The up-regulation
 362 of cuticular protein-encoding genes should be a necessary adaptation for the
 363 maintenance and stability of the structural characteristics and physical properties of
 364 melanic cuticles. The relationship of melanin and cuticular proteins at the
 365 ultrastructural level deserves special attention in follow-up studies.

366 Although the elaborate regulatory mechanism by which melanin precursors affect
 367 the expression of cuticular protein-encoding genes is unclear, our results revealed the
 368 existence of this regulatory phenomenon (Figure 5). Cuticle formation is regulated
 369 stringently by temporal and spatial patterns, the accumulation and oxidization of
 370 melanin precursors, and interactions such as crosslinking among other components
 371 should occur after the initial cuticle formation (Moussian 2010; Sobala and Adler
 372 2016; Tajiri 2017). Therefore, we propose that the cuticular proteins induced by
 373 melanin precursors are used to create a platform for further shaping and perfection of
 374 the melanic cuticle. When melanin-associated protein-encoding genes have similar

expression patterns and functions (Nakato *et al.* 1994; Nakato *et al.* 1997; Shofuda *et al.* 1999; Okamoto *et al.* 2008; Liang *et al.* 2010; Tang *et al.* 2010; Qiao *et al.* 2014), the production of large amounts of functionally similar cuticular proteins would be driven by the melanic background to guarantee construction and stability of the melanic cuticle. During this process, melanism would unlocks the complementary features of melanin-associated cuticular proteins (such as *BmLcp18*, *BmLcp22*, *BmLcp30*), rescued cuticular malformation caused by the loss of function of some cuticular proteins (such as defected *BmLcp17* in *stony* mutant). Because a special cuticle-forming pattern appears to be regulated by melanin accumulation, melanism may enhance insect adaptability to avoid the impairment of survival caused by mutations and/or functional loss of some cuticular proteins, and our results also add new evidence to explain how melanism can be a beneficial trait (Wilson *et al.* 2001; True 2003; Wittkopp *et al.* 2003; Wittkopp and Beldade 2009; Liu *et al.* 2015; Mallet and Hoekstra 2016).

As far as we known, there is no evidence to suggest that the four larval cuticular proteins (as structure proteins) and their orthologous can enter the nucleus and regulate gene expression by acting as transcription factors. In addition, our findings and some other studies showed that changes in the expression of one cuticular protein-encoding genes of R&R family did not affect the expression of other members (Figure S6, S7) (Arakane *et al.* 2012; Noh *et al.* 2015). Moreover, several studies reveal that organisms optimize resources allocation at gene or protein expression level (Liebermeister *et al.* 2004; Dekel and Alon 2005), and there is no report that the

cuticular proteins have long range morphogen effects (such as wingless) to regulate their encoding genes by feedback regulation from the cuticle to the epidermal cells; thus, the expression of melanin associated cuticle protein-encoding genes should be appropriately and simultaneously coordinated with the sufficient accumulation of intracellular melanin precursors, as a relatively direct, economical, efficient and convenient strategy. Furthermore, DAHP inhibits GTPCHI activity, but it does not directly impair the extracellular accumulation of melanin and protein–protein interactions in the cuticle. Finally, there is some evidence that melanin precursors regulate gene expressions via the receptors (Konradi *et al.* 1996; Berke *et al.* 1998; Westin *et al.* 2001). In summary, we hypothesized that the up-regulation of the four *BmLcp* genes were induced simultaneously by excessive amounts of melanin precursors, but should not be the interaction among these four genes on regulation level. To test our hypothesis, further analyses will be performed to determine the expression of the remaining *BmLcp* genes in some *BmLcps* mutant (such as defective *BmLcp17*) cell line by increasing or decreasing the melanin precursors content.

The markings were lighter in the *stony* mutant than in the wild-type strain, and were accompanied by the downregulation of melanin synthase genes (Figure S4). If the dysfunction of some cuticular proteins cannot be effectively supplemented, abnormalities of the cuticle structure and interactions of various cuticular components may occur, probably resulting in barriers to melanin deposition and metabolism. This dysfunction might be the reason why the $p^S/+^{pS}$, st/st (or $p^M/+^{pM}$, st/st) genotypes was lighter than the $p^S/+^{pS}$, $+^{st}/-$ (or $p^M/+^{pM}$, $+^{st}/-$) genotypes and had a different body

419 shape. Because the homozygous of p^B mutation is lethal (Xiang 1995; Banno *et al.*
 420 2005), we were unable to obtain F₂ progeny with the p^B/p^B , st/st genotype. However,
 421 we note that the $p^B/+^{pB}$, $+^{st}/st$ and $p^B/+^{pB}$, st/st genotype individuals had almost the
 422 same body shape and melanism (Figure 4A). Therefore, we propose that during
 423 cuticle formation, if the signal promoting melanism is sufficiently strong, sufficient
 424 melanin precursors should be generated. The contents of functionally redundant
 425 proteins induced by melanin precursors are sufficient to fill the gap generated by the
 426 dysfunction of some cuticular proteins, guaranteeing the normal accumulation of
 427 melanin. Therefore, we hypothesize a threshold for the melanism-promoting effect.
 428 When the accumulation of melanin precursors spans this threshold, the requirements
 429 for cuticular proteins with similar function are not lowered, even when one of them
 430 loses the function. This effect would guarantee the formation of a normal cuticle
 431 structure, ensuring subsequent pigmentation.

432 We propose the following regulatory model: when large amounts of melanin
 433 precursors induced by endogenous- and/or exogenous melanism-promoting factors, it
 434 may directly or indirectly induce the up-regulation of some cuticular protein-encoding
 435 genes. This upregulation guarantees the formation of normal structural features of the
 436 melanin cuticle. During this process, if some cuticular proteins lose function, other
 437 functionally redundant cuticular proteins induced by melanin precursors compensate
 438 for the functional defects. Compensatory intensity increases with increasing melanin
 439 accumulation. When melanin accumulation spans a certain threshold, compensation
 440 completely masks the defective phenotype caused by the malfunctioning genes. This

441 model adds to growing evidence that melanism may have pleiotropic effects that
442 enhance adaptability over and above the effect of melanin accumulation itself (Figure
443 6). Due to the coexistence of excess melanin and cuticular proteins is common in
444 other insects, and homologues the four *BmLcp* gene are widely distributed in the
445 Lepidoptera (Table S2), we presume that the above reciprocal action and its
446 corresponding biological significance are conserved in other Lepidoptera insects to
447 that in *Bombyx mori*.

448 In summary, we used crucial cuticle components to elucidate the mutual effects
449 among some key genetic factors, and the physiological significance of these mutual
450 effects during the development of the morphological features. Our findings contribute
451 a realistic basis for in-depth study on the interaction patterns of melanin and cuticular
452 proteins, and will also guide relevant studies in other Lepidopteran insects or other
453 insect species.

581 **Figure 1.** Expression of four larval cuticular protein-encoding genes in melanic and
 582 non-melanic integuments. A and B represent the gene expressions between the
 583 semi-lunar marking (black box) and the non-melanic region (between the semi-lunar
 584 marking, red box) in Dazao or Dazao-stony, respectively. Scale bar: 2 mm. C.
 585 Comparative analysis of gene expressions in the dorsal side of abdominal segments
 586 (from the third to the fourth segment, red box) between the p^S and Dazao strains.

587 Scale bar: 1 cm. D. Comparison of gene expressions between the second-instar *al*
588 mutant and the Dazao strain (melanic). The red hashtag symbol indicates the Fig. 1 D
589 we are showing is cited from the previous study of our lab group (Min *et al.* 2016)
590 with modification. Scale bar: 2 mm. *t*-test, n=3; * $p < 0.05$; ** $p < 0.01$; *** $p <$
591 0.001.

592

593 **Figure 2.** Expression of cuticular protein-encoding genes in integuments showing
594 different degree of melanism. A and B display comparisons of degree of melanism
595 and cuticular protein-encoding gene expression levels among four strains with mutant
596 alleles at the *p* locus. Scale bar: 1 cm. Ratios represent the ratios of gene expression
597 levels between two strains. Symbols (–, +, ++, and +++) represent the increment of
598 the degree of melanism. Star represents the melanin-associated cuticular
599 protein-encoding genes. *t*-test, n=3; * $p < 0.05$; ** $p < 0.01$.

600

601 Figure 3. Segregation patterns of the phenotypes of progenies from different crosses
602 of melanic mutant strains and the *stony* strain. In the segregated progenies, the first
603 item in the list (B,N), (B,st), (S,N), (S,st), (M,N), (M,st), (N,N) and (N,st) represents
604 p^B -, p^S - p^M - and Normal color patterns, respectively. The second item indicates body
605 shape features marked with non-*stony* type (N) and the *stony* type (st). It is
606 noteworthy that in (S, st-am+) and (M, st-am+), the second item represents the
607 ambiguous *stony* body shape. The size of “+” symbol represents the corresponding
608 degree of the ambiguous *stony* body shape. Superscript “T”s represent theoretical

609 values. Superscript “A”s represent actual values. Backslashes indicates that a value
610 was not obtained. Chi-squared test, * $p < 0.05$; ** $p < 0.01$.

611

612 Figure 4. Association analysis of the genotypes, phenotypes and gene expression
613 levels in segregated progenies from different crosses. A. Correlation analysis between
614 the genotypes and phenotypes in self-crossed or backcrossed progenies. Scale bar: 1
615 cm. White and red stars represent polymorphic bands at the $+^p$ and p^X loci ($X = B, S$ or
616 M), respectively. Red and white hash-tag represent polymorphic bands at the st and $+^{st}$
617 locus, respectively. Solid and dotted red arrows indicate the relative degree of bulging
618 (solid > dotted), respectively. Slashes show the genotypes within one phenotypic
619 category. The thickness of the slash represents the proportion of the corresponding
620 genotypes. Dotted backslashes indicate that the number of individuals with the
621 corresponding genotype is quite low. B. Ratios of the length of internodes and
622 intersegmental folds in the second, third, and fourth abdominal segments of
623 individuals with different genotypes (showing melanic body color) in the self-crossed
624 or backcrossed progenies. $n \geq 3$, t -test, ** $p < 0.01$. C. Gene expression analysis of
625 cuticular protein-encoding genes in homogeneous and heterogeneous individuals at
626 the p locus from self-crossed progenies of $p^S \times stony$, and $p^M \times stony$ under the
627 condition that the cuticle was melanic and the genotype was homozygous recessive at
628 st locus. $n = 3$, t -test, * $p < 0.05$; ** $p \leq 0.01$.

629

630 Figure 5. Effect of melanin precursors (top left: in cells) and BH_4 (top right: in vivo)

631 treatments on the expression of cuticular protein-encoding genes (t -test; $n = 3$, * $p <$
632 0.05 ; ** $p < 0.01$), and variations of gene expression levels in larval cuticle treated
633 with the inhibitor DAHP (bottom). $n = 3$, t -test, ** $p < 0.01$.

634

635 **Figure 6.** Schematic overview of the effect of melanin precursors on the expressions
636 of cuticular protein-encoding genes. Black solid circles represent the melanin.
637 Triangles represent the BmLcps with similar expression patterns and functions. Solid
638 and hollow triangles represent the normal and defective functions, respectively.
639 Brown rhombi represent other components (such as chitin) in the cuticle. Solid
640 double-headed arrow indicates the probable interaction between the endocuticular
641 proteins and other components. Combination of the single-headed arrow and the letter
642 ‘R’ indicate the repair of the potential defects through functional complementary.
643 Purple arrows show the direction in which the melanin precursors or cuticular proteins
644 flow from the haemolymph to the epidermal cells as well as from the epidermal cells
645 to the cuticle. Red arrows indicate the increased contents of melanin precursors or the
646 up-regulation of cuticular protein-encoding genes. Purple polyline arrows indicate
647 melanism-promoting factors produced by other genetic instructions. Double dovetail
648 arrows indicate the effect of melanin precursors on cuticular protein-encoding genes.
649 The question mark indicates that the details of induction (directly or indirectly) are
650 unclear.
