277 **Abstract**

278 Anorexia nervosa (AN) is a complex and serious eating disorder, occurring in ~1% of individuals.
279 Despite having the highest mortality rate of any psychiatric disorder, little is known about the
280 aetiology of AN, and few effective treatments exist.

281
282 Global efforts to collect large sample sizes of individuals with AN have been highly successful,
283 and a recent study consequently identified the first genome-wide significant locus involved in
284 AN. This result, coupled with other recent studies and epidemiological evidence, suggest that
285 previous characterizations of AN as a purely psychiatric disorder are over-simplified. Rather,
286 both neurological and metabolic pathways may also be involved.

287
288 In order to elucidate more of the system-specific aetiology of AN, we applied transcriptomic
289 imputation methods to 3,495 cases and 10,982 controls, collected by the Eating Disorders
290 Working Group of the Psychiatric Genomics Consortium (PGC-ED). Transcriptomic Imputation
291 (TI) methods approaches use machine-learning methods to impute tissue-specific gene
292 expression from large genotype data using curated eQTL reference panels. These offer an
293 exciting opportunity to compare gene associations across neurological and metabolic tissues.
294 Here, we applied CommonMind Consortium (CMC) and GTEx-derived gene expression
295 prediction models for 13 brain tissues and 12 tissues with potential metabolic involvement
296 (adipose, adrenal gland, 2 colon, 3 esophagus, liver, pancreas, small intestine, spleen, stomach).

297
298 We identified 35 significant gene-tissue associations within the large chromosome 12 region
299 described in the recent PGC-ED GWAS. We applied forward stepwise conditional analyses and
300 FINEMAP to associations within this locus to identify putatively causal signals. We identified
301 four independently associated genes; *RPS26*, *C12orf49*, *SUOX*, and *RDH16*. We also identified
302 two further genome-wide significant gene-tissue associations, both in brain tissues; *REEP5*, in
303 the dorso-lateral pre-frontal cortex (DLPFC; $p=8.52 \times 10^{-07}$), and *CUL3*, in the caudate basal
304 ganglia ($p=1.8 \times 10^{-06}$). These genes are significantly enriched for associations with
305 anthropometric phenotypes in the UK BioBank, as well as multiple psychiatric, addiction, and

306 appetite/satiety pathways. Our results support a model of AN risk influenced by both metabolic
307 and psychiatric factors.

308 Introduction

309 Anorexia nervosa (AN) is a serious neuropsychiatric disorder presenting with low body weight, a
310 fear of weight gain or behaviours that interfere with weight gain, and a lack of recognition of
311 the seriousness of the illness. AN has the highest mortality rate of any psychiatric disorder¹, and
312 ranks among the leading cause of disability in young women worldwide. Despite this, little is
313 known about the biological mechanisms underlying AN development, and few effective
314 therapies and medications are available.

315
316 Findings from genetic and epidemiological research have encouraged broadening our
317 conceptualization of the aetiology of AN beyond purely psychiatric causes to incorporate
318 metabolic and other somatic factors in risk models. Recently, genome-wide association studies
319 have revealed the first significantly associated genomic locus for anorexia nervosa², as well as a
320 number of promising sub-threshold associations³⁻⁵, and intriguing pathway associations. Results
321 have implicated genes with both psychiatric and metabolic relevance, while polygenic risk score
322 analyses and LD-Score approaches have revealed significant genetic overlap with psychiatric,
323 metabolic and autoimmune diseases, as well as anthropometric traits.

324
325 The research findings underscore clinical observations as individuals with AN have an uncanny
326 ability to reach and maintain extraordinarily low body mass indices (BMI) and after successful
327 renourishment, their bodies often quickly revert to what may be an abnormally low set point².
328 Other observations include that individuals with AN tend to find eating aversive, and feelings of
329 fullness unpleasant; dieting, restricting, and binge-purge behaviours tend to alleviate
330 uncomfortable or painful associations with fullness in these individuals and reduce anxiety⁶.
331 Although aversion to fullness and low appetite could be driven by dysfunction of
332 neurobiological satiety pathways or altered levels of orexigenic hormones⁷, it is also possible
333 that specific metabolic or gastric dysfunction enables and perpetuates dieting behaviours.

334
335 Transcriptomic Imputation (TI) provides an opportunity to test the involvement of metabolic,
336 endocrine, adipose, and gastrointestinal (GI) tissues, as well as brain tissues, in the

337 development of AN. These approaches leverage well curated eQTL panels to create predictors
338 of genetically regulated gene expression (GREX)⁸⁻¹⁰. These predictors may be applied to large
339 groups of genotyped individuals, to identify case-control associations with predicted differential
340 gene expression. This approach circumvents many of the complications inherent in traditional
341 transcriptomic analysis; for example, the need to collect large number of inaccessible tissues,
342 which is particularly complicated in studies of early-onset psychiatric disorders¹¹. Further, the
343 prediction of genetically-regulated gene expression means that there is no ambiguity in
344 direction of effect; unlike in RNA-seq studies, where changes in gene expression may result
345 from medication, diet, exercise, or environmental exposures, genetically regulated gene
346 expression necessarily precedes disease onset⁸.

347
348 An intriguing aspect of transcriptomic imputation is the opportunity to calculate predicted gene
349 expression in a tissue-specific manner, and to use this to further inform our understanding of
350 disease aetiology. In this study, we used gene expression predictor models for 13 brain regions
351 (derived from CMC^{12,13} and GTEX^{8,14} data), as well as fifteen gastrointestinal, endocrine, and
352 adipose tissues, and compared patterns of gene expression changes between cases and
353 controls. We identified 37 significant gene-tissue associations, constituting eleven independent
354 signals. These genes together explained 2.38% of the phenotypic variance in our study,
355 including substantial proportions of variance explained by genes in brain tissues (51.5%),
356 gastrointestinal tissues (16.01%), endocrine (18.6%), and adipose tissues (13.9%), supporting
357 our theory of both psychiatric and metabolic contributions to AN risk. We identify genes with
358 intriguing patterns of association with anthropometric traits; for example, seven of our gene-
359 tissue associations are also significantly associated with BMI, weight, and waist circumference
360 in the UK BioBank.

361

362 **Methods**

363 **Samples**

364 Genotype data were obtained from the PGC-ED collection. These data included 3,495 cases and
365 10,982 ancestry-matched controls². Detailed diagnostic criteria used are described in the PGC-
366 ED GWAS of these data². Briefly, cases include individuals with lifetime diagnoses of either AN
367 (including both binge-purge and restrictive subtypes) or “eating disorder not other specified
368 (EDNOS)”, AN subtype. A small number of individuals with bulimia nervosa diagnoses were also
369 included if they also had histories of AN. Amenorrhoea was not required for diagnosis, as it
370 does not increase diagnostic specificity¹⁵⁻¹⁷. Exclusion criteria included schizophrenia,
371 intellectual disability, and medical and neurological conditions which may cause weight loss.

372

373 **Transcriptomic Imputation**

374 We imputed genetically regulated gene expression (GREX) using the CommonMind Consortium
375 derived Dorso-lateral pre-frontal cortex (CMC DLPFC) predictor database¹², as well as GTeX-
376 derived predictor databases including 12 brain regions, four endocrine tissue, eight
377 gastrointestinal/digestive tissues, and subcutaneous adipose tissue^{8,14} (Table 1). We imputed
378 GREX in all cohorts for which we had access to raw data using PrediXcan⁸.

379

380 We tested for association between GREX and case-control status in each cohort separately,
381 using a standard linear regression test in R. We included ten principal components as covariates
382 to correct for population stratification. Principal components were calculated from genotype
383 data. Raw genotype-based and summary-statistics based cohorts were meta-analysed using an
384 odds-ratio based approach in METAL¹⁸.

385

386 **Establishing a threshold for genome-wide significance**

387 We applied two significance thresholds to our data. First, we applied a threshold for each
388 tissue, correcting for the number of genes tested within that tissue (Table 1). Second, we
389 applied a stricter, overall threshold, correcting for all genes tested across all tissues
390 simultaneously (234,896 tests in total, $p=2.31 \times 10^{-7}$).

391 GREX is highly correlated across tissues^{14,19}, and consequently the tests across different tissues
392 are not independent. A Bonferroni correction may therefore be overly conservative, and under-
393 estimate the true degree of association in this study.

394

395 **Identifying independent associations**

396 We identified a number of genomic regions with multiple associations, as well as genes with
397 significant associations across multiple tissues. In particular, we identified a very large number
398 of gene-tissue associations (35 significant gene-tissue associations), in the same chromosome
399 12 locus identified in a recent GWAS by the PGC-ED group²⁰.

400

401 We applied two methods to identified independent signals in these complex genomic regions.
402 First, in regions with a small number of associated gene-tissue pairs (<5), we used “CoCo”, an
403 extension to GCTA-CoJo²¹. Briefly, CoCo applies the same stepwise forward conditional analysis
404 as in GCTA-CoJo, but allows specification of a custom linkage disequilibrium (LD) or correlation
405 matrix instead of obtaining LD from a reference panel. Here, we calculated a GREX correlation
406 matrix used this as the correlation matrix input to CoCo.

407

408 We used FINEMAP²², a shotgun stochastic search algorithm which identifies and ranks plausible
409 causal configurations for a region, to disentangle the complex gene-tissue association patterns
410 on chromosome 12. As for CoCo, we substituted a GREX correlation matrix in place of the
411 standard LD-matrix input file. We constructed a 95% credible set from probable configurations
412 specified by FINEMAP in order to identify significant gene-tissue associations within the region.

413

414 Additionally, we visually inspected patterns of correlation among the 35 gene-tissue
415 associations in the chr12 locus using the ‘heatmap.2’ function in the ‘gplots’ R package²³, and
416 identified distinct clusters of GREX within this heatmap using a dendrogram cut at height 4.

417

418

419

420 **Proportion of variance explained by tissue**

421 We calculated the proportion of phenotypic variance in our study jointly explained by all genes
422 reaching $p < 1 \times 10^{-04}$ in our analysis. We corrected for ten principal components and study
423 variables using a nested model.

424
425 We divided gene-tissue associations into four categories; brain, endocrine,
426 gastrointestinal/digestive, and subcutaneous adipose tissue. We used a series of nested models
427 to calculate the variance explained by gene-tissue associations for each category. For example,
428 the amount of variance explained by adipose-gene associations was calculated as the difference
429 between the variance explained by all genes, and the variance explained by all genes except
430 those associated in adipose tissue (eqn 1).

431

432 Equation 1: Nested model to calculate proportion of variance explained by adipose tissue

$$\text{Var}_{\text{Adipose}} = \text{Var}_{\text{All genes}} - \text{Var}_{\text{All genes except adipose}}.$$

433

434 **UK BioBank analysis**

435 We obtained publicly available GWAS summary statistics for the UK BioBank sample^{24,25}. We
436 analyzed summary statistics relating to three anthropometric traits; BMI (336,107 individuals),
437 weight (in kg; 336,227 individuals), and waist circumference (in cm; 336,639 individuals). We
438 obtained distributions of each trait from the UK BioBank search portal²⁶ (Suppl. Table 1).

439

440 Descriptions of phenotype curation, quality control, and association models used for the UK
441 BioBank sample are available elsewhere²⁵. Briefly, quantitative traits within the sample were
442 normalized using a rank-based inverse normal transform (INRT) prior to analysis, and analysis
443 was carried out using a linear regression. Beta values from these associations correspond not to
444 the 'unit' of the original trait (e.g., cm or kg), but to the 'unit' of the INRT, i.e., the standard
445 deviation of the original trait distribution. We confirmed this by simulating distributions
446 matching the UK Biobank traits in R, and performing an INRT on each trait.

447

448 We used MetaXcan²⁷, a summary statistic based software analogous to PrediXcan, to compute
449 gene-tissue associations for genes with $p < 1 \times 10^{-04}$ in our prediXcan PGC-ED analysis. In order to
450 compare association statistics between our PGC-ED and UK BioBank studies, we normalized
451 betas to account for the variance of a gene's GREX within each study.

452

453 **Pathway Analysis**

454 Pathway analysis was carried out using an adaptation to MAGMA²⁸. We manually assigned
455 prediXcan genic p-values to genes in order to carry out only the gene-set enrichment analysis in
456 MAGMA. We used Bonferroni-corrected prediXcan p-values as input for our MAGMA analyses,
457 in three stages; first, a Bonferroni-correction for the overall best p-value for each gene across
458 tissues; second, for the best p-value across brain regions; third, for the best p-value across non-
459 brain tissues.

460

461 We carried out two sets of pathway analysis. First, we tested a subset of pathways for which we
462 had prior hypotheses of involvement with psychiatric disorders^{29,30}, as well as genesets related
463 to orexigenic hormones, hunger, and satiety. Second, we carried out an agnostic pathway
464 enrichment test including ~8,500 pathways obtained from publicly available databases,
465 including KEGG^{31,32}, GO³³, REACTOME³⁴, PANTHER^{35,36}, BIOCARTA³⁷, and MGI³⁸. We included
466 only gene sets with at least 10 genes. Gene set enrichment results from the “competitive”
467 MAGMA analysis were used, and an FDR-correction applied within each stratum of our analysis.

468

469

470

471 Results

472 Association Tests

473 We calculated predicted gene expression for thirteen brain regions, four endocrine tissues,
474 eight gastrointestinal and digestive tissue, and subcutaneous adipose tissue (derived from CMC
475 and GTEx data^{8,14,19,39}) in 3,495 cases and 10,982 controls from the PGC-ED consortium, and
476 tested for association between predicted gene expression (GREX) and case-control status.

477
478 We identified 37 significant gene-tissue associations, and a further 22 sub-threshold
479 associations ($p < 1 \times 10^{-04}$; Suppl. Table 2). The majority of the significant associations (35/37)
480 correspond to the only known genome-wide significant locus for AN²⁰. We used FINEMAP²² to
481 identify independent signals within this region. We identified 12 likely gene-tissue associations
482 within this region, including four unique genes; *SUOX*, *RPS26*, *RDH16*, and *C12orf49* (Suppl.
483 Table 3). Visual inspection (Suppl. Figure 1) and hierarchical clustering (Suppl. Figure 2) of GREX
484 correlation patterns within this region indicate three distinct groups of associated genes, and
485 follow our FINEMAP results closely.

486
487 We identified two additional genome-wide significant gene-tissue associations (Table 2). First, a
488 region on chromosome two with three gene-tissue associations; increased expression of *CUL3*
489 in the caudate basal ganglia ($p = 1.86 \times 10^{-06}$), and increased expression of *WDFY1* and *FAM124B*,
490 in adipose tissue ($p = 6.11 \times 10^{-05}$, 6.73×10^{-05} , respectively). We applied a stepwise forward
491 conditional analysis in CoCo (following GCTA-COJO), using GREX correlations for all three genes
492 (Suppl. Table 4). Neither adipose tissue association remained significant after conditioning on
493 *CUL3*-Caudate ($p = 0.042$, 0.25 , respectively). Second, we identified decreased expression of
494 *REEP5* in the DLPFC ($p = 8.34 \times 10^{-07}$), and in the adrenal gland ($p = 6.68 \times 10^{-05}$); conditioning *REEP5*-
495 adrenal on *REEP5*-DLPFC completely ameliorates the signal ($p = 0.085$).

496
497 Additionally, we identified 22 sub-threshold associations ($p < 1 \times 10^{-04}$), including 17 independent
498 associations after stepwise conditional analysis (Table 2). In particular, we identified two genes
499 on chromosome 10 with decreased expression in the small intestine and colon (*MGMT*-small

500 intestine, *MGMT*-pituitary, and *FOXI2*-colon), and two genes with increased brain expression on
501 chromosome 17 (Supplementary table 2; *YWHAE*-hypothalamus, *NTN1*-nucleus accumbens).

502

503 **Comparing Tissue types**

504 Jointly, the genetically regulated gene expression (GREX) of our 28 gene-tissue associations
505 ($p < 1 \times 10^{-04}$) explain 2.38% of the phenotypic variance in our study. The majority of this variance
506 (51.5%) was explained by brain-gene associations, followed by endocrine (18.6%),
507 gastrointestinal/digestive (16.01%), and adipose tissues (13.9%).

508

509 **Associations with anthropometry**

510 We used publicly available GWAS summary statistics from the UK BioBank to test whether our
511 AN associated genes were associated with anthropometric phenotypes such as BMI, weight,
512 and waist circumference. We used a summary-statistics based approach analogous to
513 *predixcan*⁴⁰ (“MetaXcan”) to identify gene-tissue associations across all three traits, for all
514 genes reaching $p < 1 \times 10^{-04}$ in our analysis.

515

516 Three genes within our chromosome twelve locus were significantly associated with at least
517 one anthropometric phenotype in the UK BioBank sample (Table 3). The direction of effect was
518 epidemiologically consistent with our *predixcan* analysis across all genes. For example,
519 increased expression of *SUOX* in the colon, esophagus and spleen results in increased BMI
520 (~ 0.04 BMI units/unit of gene expression; $p < 1.28 \times 10^{-07}$), increased weight (~ 0.135 kg/unit of
521 gene expression; $p < 5.8 \times 10^{-08}$) in the UK BioBank, and decreased risk of AN in PGC-ED
522 ($OR = 0.98$ /unit of gene expression; $p < 5 \times 10^{-07}$) (Figure 2A). Similarly, increased expression of
523 *RPS26* and *RDH16* across multiple tissues is associated with increased AN risk, decreased BMI,
524 decreased waist circumference, and decreased weight (Figure 2B).

525

526 Increased expression of *REEP5* is associated with increased weight ($p < 2 \times 10^{-08}$) and decreased
527 AN risk. Three sub-threshold AN genes (*BARX1*, *MGMT*, *TRIM38*) are also associated with BMI
528 ($p < 2 \times 10^{-13}$), weight ($p < 2 \times 10^{-07}$), and waist circumference ($p = 1.35 \times 10^{-08}$), again with highly

529 significant concordance of direction of effect between studies. Three sub-threshold associated
530 genes, *BARX1*, *MGMT*, *TRIM38*, also follow this pattern of association.

531

532 This degree of shared signal and concordance of direction of effect is highly unlikely to occur by
533 chance (binomial test $p=2.39 \times 10^{-270}$). Interestingly, of the seven genes within our study that are
534 associated with BMI, weight, and waist circumference within the UK BioBank, six are associated
535 with AN in gastrointestinal tissues. The only brain-tissue based associated gene, *REEP5*, is an
536 olfactory gene with a potential role in taste and appetite. Although it is difficult to draw firm
537 conclusions given the small set of genes tested and the limited sample size of our study, these
538 results suggest that gene expression changes in metabolic tissues are more likely to have
539 general relevance for anthropometry and weight maintenance.

540

541 **Pathway analysis**

542 We performed pathway analyses on our AN prediXcan results across (1) all tissues, (2), brain
543 tissues, and (3) all non-brain tissues. For each set of results, we tested 174 gene sets with prior
544 hypotheses for involvement in psychiatric disorders, and ~8,500 pathways obtained from
545 publicly available databases.

546

547 Using the best p-value across all tissues, we identified 17 significantly enriched pathways (fdr-
548 corrected $p < 0.05$; Table 4). These include multiple calcium-gated voltage channel
549 pathways ($p < 0.002$), axon guidance ($p = 1.07 \times 10^{-04}$), Wnt signalling (9.93×10^{-04}), the post-
550 synaptic density (0.003), targets of the FMRP protein⁴¹⁻⁴⁵ ($p = 0.003$), as well as gene sets
551 corresponding to neurological disease such as Alzheimer's, Huntington's, and Prion Disease
552 ($p < 0.007$). We also noted enrichment of a pathway related to circadian entrainment
553 ($p = 0.0013$).

554

555 Interestingly, genes involved in synthesis secretion and deacylation of ghrelin were significantly
556 enriched within our results ($p = 0.0011$). Examining individual genes within this pathway
557 indicates that no single gene is driving the association; rather, the pathway includes multiple

558 sub-threshold associations across *KLF4*, *BCHE*, *IGF1*, *SPCS2*, *ACHE*, *PCKS1*, and *SPSC3*. Taken
559 together, these associations indicate lower baseline ghrelin expression in individuals with AN
560 than in controls. For example, AN cases have lower GREX of *KLF4*, *SPCS2* and *SPCS3*, all of which
561 stimulate ghrelin secretion⁴⁶. AN cases also have increased expression of *ACHE*, *IGF1*, *PCKS1*,
562 and *BCHE*, which inhibit ghrelin expression⁴⁷⁻⁴⁹. We also noted that GREX of ghrelin (GHRL) was
563 lower in AN cases than controls across 11/12 tissues tested.

564
565 Using exclusively brain-gene association statistics as an input to our MAGMA analysis resulted
566 in 51 significantly enriched pathways. 35/51 pathways were from the hypothesis-driven test;
567 these included circadian entrainment ($p=2.6 \times 10^{-04}$), addictive behaviors (nicotine, alcohol,
568 cocaine, and morphine dependence, $p<0.0045$), calcium-gated voltage channels, and a large
569 number of pathways related to processes in the post-synaptic density (Table 4), in line with
570 pathway results from other psychiatric disorders^{10,30,50,51}. A further 25 significantly enriched
571 pathways were identified in the agnostic analysis, including further evidence of circadian
572 entrainment ($p=1.39 \times 10^{-06}$), long-term potentiation ($p=4.44 \times 10^{-06}$), as well as multiple pathways
573 implicating ear and neuronal system development in mice ($p<1.2 \times 10^{-04}$). We noted enrichment
574 in cyclic-AMP metabolism pathways ($p<9.3 \times 10^{-05}$). This pathway includes dopamine receptor
575 gene *DRD1* ($p=8.85 \times 10^{-05}$), and *DRD5* ($p=3.5 \times 10^{-04}$), two receptors which are part of the
576 dopaminergic pathways affected by ghrelin in the VTA and nucleus accumbens^{52,53}, as well as
577 *GCG* (Glucagon; $p=1.3 \times 10^{-03}$), and *APOE* ($p=1.0 \times 10^{-03}$) which is associated with risk for
578 Alzheimer's disease. CREB phosphorylation through activation of CaMKII pathway was enriched
579 in our results ($p=5.25 \times 10^{-05}$). This pathway includes *AKAP9* ($p=2.1 \times 10^{-04}$), which regulates levels
580 of cAMP activity in the brain, and co-localizes with NMDA receptor NR1 which in certain brain
581 regions is involved in appetite and weight regulation⁵⁴⁻⁵⁶, as well as *GRIN2B* ($p=5.1 \times 10^{-04}$), which
582 is associated with neurite outgrowth and risky decision making^{57,58}.

583
584 Excluding brain-gene associations statistics from our pathway analysis results in only one
585 subthreshold association ($p=3.2 \times 10^{-04}$; *fdr*-corrected *p*-value 0.06) in our hypothesis-driven
586 pathway analysis, concerning circadian rhythms (albeit through a different pathway than

587 identified in the brain-only analysis). Our agnostic pathway analysis identified only one
588 significant association, with hyaluronic acid binding ($p=2.32 \times 10^{-08}$).

593

594

595

596

597 Discussion

598 AN is a complex and serious neuropsychiatric disorder, with one of the highest mortality rates
599 of any psychiatric disorder. As our research into the aetiology of AN develops and grows, we
600 identify increasing levels of complexity and heterogeneity; for example, recent GWAS studies,
601 LDscore analysis, and epidemiological evidence indicates both psychiatric and metabolic risk
602 factors for the disorder.

603
604 Here, we used gene expression prediction models for brain, gastrointestinal/digestive,
605 endocrine, and adipose tissues to predict genetically regulated gene expression (GREX) in 3,495
606 individuals with anorexia nervosa (AN) and 10,982 controls. We identified 12 independent
607 gene-tissue associations reaching tissue-specific significance, the majority of which lie in the
608 same chromosome 12 locus identified in a recent AN GWAS²⁰. In line with our hypothesis of
609 both psychiatric and metabolic risk having a role in AN, we identified genes with differential
610 expression in endocrine and gastrointestinal/digestive tissues, as well as in brain.

611
612 We calculated the phenotypic variance explained by the genetically regulated expression of
613 these 28 genes, and used a nested model to partition the variance according to tissue type.
614 Jointly, these explain 2.38% of the phenotypic variance in our study. The majority of this
615 variance (51.5%) was explained by brain-gene associations, followed by endocrine (18.6%),
616 gastrointestinal/digestive (16.01%), and adipose tissues (13.9%). The proportion of variance
617 explained by brain- and endocrine-gene associations is in line with the proportion of tests
618 carried out in each tissue (46.3% and 16.8%, respectively). Gastrointestinal/digestive genes
619 explain significantly less variance than we would expect given the large proportion of test
620 performed (16.01% vs. 32.3%, binomial test, $p=3.6 \times 10^{-04}$), while adipose tissue-genes explain
621 significantly more variance than we would expect (13.9% vs. 4.6%, $p=2 \times 10^{-04}$). This enrichment
622 of signal within adipose tissue is of particular interest given the demonstrated overlap between
623 adiposity and disordered eating patterns⁵⁹, AN risk factors⁶⁰⁻⁶², and clinical outcomes^{63,64}, as
624 well as our findings relating AN risk genes to anthropometric traits in the UK Biobank.

625

626 However, these calculations are based on the assumption that all gene-tests are independent;
627 in fact, we note high correlation of GREX between tissues, including a large number of co-linear
628 genes and tissues. The number of independent tests carried out is therefore likely to be
629 substantially lower than the number of tests used in our estimate, perhaps explaining why
630 gastrointestinal/digestive genes explain less variance than we would expect.

631
632 Among our gene-tissue associations are a number of genes which may be of particular interest.
633 For example, decreased expression of *REEP5* in the DLPFC is associated with increased risk of
634 AN. *REEP5* is a receptor accessory protein which promotes expression of olfactory receptors⁶⁵.
635 *Reep5*, together with *RTP1* and *RTP2*, is required for cell surface expression of odorants, and is
636 primarily expressed in olfactory neurons. The DLPFC has a high localized concentration of
637 olfactory neurons, and DLPFC volume is decreased in anosmic individuals⁶⁶. Olfaction is of
638 particular interest in eating disorders given its role in taste and desire for food, as well as in a
639 number of neurological disorders such as Alzheimer's and Parkinson's^{67,68}. Individuals with AN
640 have high rates of reported hyposmia and anosmia^{67,69-72}, and perform poorly in odor
641 discrimination tests, compared to healthy controls. Importantly, odor discrimination ability and
642 hyposmic status correlates more strongly with BMI than with any specific disordered eating
643 behavior, even among individuals with AN⁷³. Previous studies have also demonstrated
644 differential expression of olfactory genes following eight restoration in individuals with
645 Anorexia Nervosa⁷⁴. In line with this, we identified a direct correlation between *REEP5*
646 expression and body weight in the UK BioBank; each additional unit of gene expression
647 corresponds to ~140 g additional body weight, and an AN OR of 0.85. Taken together these
648 results suggest that *REEP5* may have a general role in body size and BMI through altered
649 olfactory cues, and may be of interest to researchers studying appetite and satiety, as well as
650 obesity, normal variation in BMI, and AN. *REEP5* has also been implicated in major depressive
651 disorder and antidepressant response in previous studies⁷⁵.

652 We identified four significantly associated genes within our complex chromosome 12 locus.
653 Three of these genes (*SUOX*, *RPS26*, *RDH16*) are significantly associated with AN across a range
654 of gastrointestinal tissues (Figure 1), and have highly correlated expression across almost all

655 non-brain tissues tested. All three of these genes are significantly correlated with
656 anthropometric traits in the UK BioBank analysis (Figure 2), and all have consistent directions of
657 effects with our AN prediXcan analysis: that is, the change in expression which increases body
658 size also decreases AN risk.

659 Little is known about the function of *C12orf49*, the fourth gene in this locus, although SNPs
660 within the gene have also previously been associated with BMI, waist circumference, and waist-
661 hip ratio⁷⁶. Taken together, this evidence implies that the locus on chromosome 12 is likely to
662 be generally associated with BMI and body size, rather than any specific eating disordered
663 behaviours. The fine-mapping and characterization of this locus supports our hypothesis of a
664 role for metabolic dysregulation in AN.

665
666 Increased expression of *CUL3* (Cullin 3) in the caudate basal ganglia was associated with
667 increased risk of AN in our study (OR=1.07). Dysregulation of *CUL3* is associated with
668 pseudohypoaldosteronism⁷⁷, a disorder characterized by sodium imbalance in the body and
669 often presenting with low body weight. Mutations in *CUL3* are associated with schizophrenia⁷⁸,
670 autism⁷⁹ and non-response to anti-depressants⁸⁰. Variants lying near to *CUL3* were identified in
671 the first GWAS of AN, although these did not reach genome-wide significance⁸¹.

672
673 Among our subthreshold gene-tissue associations, we identified a number of genes previously
674 associated with psychiatric^{13,78} and neurological disorders (for example, *FURIN*^{13,78,82},
675 *ADAMTS9*⁸³⁻⁸⁶, *MGMT*^{86,87}, *SMDT1*⁷⁸, *TMEM108*⁸⁸), as well as with abnormal behavioural
676 responses in knock-out mice models^{38,89-91} (*ADAMTS9*, *CITED4*, *FOXI2*, *FURIN*, *SMDT1*,
677 *TMEM108*). We also noted a number of genes with prior associations with anthropometric
678 traits, both in humans (*ADAMTS9*^{92,92-96}, *MGMT*^{94,97,98}) and in mice^{38,89-91} (*CITED4*, *FOXI2*,
679 *FURIN*, *RDH16*, *SMDT1*, *TMEM108*), as well as genes associated with gastric and esophageal
680 complaints (*BARX1*⁹⁹) in humans, and abnormal defecation patterns in mice^{38,89-91,100} (*RDH16*,
681 *CITED4*), and with disorders and traits known to be comorbid with AN (*TMEM108*¹⁰¹⁻¹⁰⁴).

682

683 Our pathway analysis identified a large number of significantly enriched pathways. In particular,
684 multiple pathways indicate a role for the post-synaptic density (including PSD95, targets of the
685 FMRP protein, glutamate receptor genes, among others), which has previously been implicated
686 in other psychiatric disorders. Four pathways are associated with addiction and addictive
687 behaviours, including nicotine addiction, alcoholism, cocaine addiction, and amphetamine
688 addiction. Illicit drug use is significant enriched among individuals with eating disorders, in
689 particular AN¹⁰⁵, although this is, to our knowledge, the first study identifying shared genetic
690 risk factors.

691
692 Circadian entrainment and clock genes are highly enriched among our data. Longstanding
693 hypotheses implicated disrupted circadian rhythms in a range of mood disorders, particularly
694 depression and bipolar disorder^{106–108}. Further, behavioural patterns in individuals with AN (for
695 example excessive exercise^{109–111} and lack of sleep) have long provided epidemiological
696 evidence for circadian rhythm disruption in AN. Circadian rhythms may also have a role in
697 regulating appetite and satiety pathways^{7,112,113}.

698
699 Our analysis also implicates pathways concerning taste and olfactory transduction, as well as
700 ghrelin secretion. Ghrelin is an orexigenic hormone with a documented role in appetite and
701 satiety^{114–118} as well as in gut motility^{117–119}. Our results suggest that individuals with AN may
702 have decreased circulating ghrelin levels due to increased genetically regulated expression of
703 ghrelin inhibitors, and decreased GREX of Ghrelin stimulators. Ghrelin enhances appetite and
704 increases food intake in humans; lowered baseline circulating ghrelin levels may begin to
705 explain decreased hunger and desire for food in individuals with AN. Previous studies have
706 documented dysregulation of ghrelin, leptin and glucagon in individuals with AN¹²⁰. However,
707 these studies are by definition performed after long periods of starvation or food restriction,
708 meaning that causation is difficult to disentangle from consequences of eating disordered
709 behaviours; it is likely that the increased ghrelin levels seen in these studies is a consequence of
710 long-term fasting, rather than causative. In this study, we assess only genetically regulated gene
711 expression (GREX), meaning that any associations identified are not affected by diet or

712 environment. Instead, these results may indicate an altered “baseline” level of circulating
713 ghrelin in individuals with AN.

714 There are a number of limitations that should be taken into account. First, the sample size of
715 our study is small, especially compared to GWAS sample sizes in other psychiatric
716 disorders^{121,122}. It is likely that increasing sample size substantially will yield many new insights
717 into the aetiology of anorexia nervosa, and that current sub-threshold associations may lose
718 significance as sample size increases. Similarly, transcriptomic imputation approaches rely on
719 large, well-curated reference panels in order to build GREX predictor models; here, we have
720 used reference panels constructed from GTeX^{8,14} and CommonMind Consortium data^{10,13},
721 including the largest collections of publicly available post-mortem brain tissues. We have shown
722 previously that there is a significant correlation between the sample sizes used to construct
723 these predictors and the number of genes included in each predictor database, and that a
724 number of these databases are therefore likely underpowered¹⁰.

725
726 Our analysis highlights the need for greater investigation into the complex aetiology of anorexia
727 nervosa. Transcriptomic Imputation allows us to identify significant gene-tissue associations
728 with anorexia nervosa, and indicates an excess of signal in adipose tissue. It is clear from these
729 results that both psychiatric and metabolic risk factors play a role in AN risk; these factors
730 should be carefully considered in the design of future studies, as well as in how AN is perceived
731 and considered by clinicians treating individuals with AN.

1007

1008 Brain tissue for the study was obtained from the following brain bank collections: the Mount
1009 Sinai NIH Brain and Tissue Repository, the University of Pennsylvania Alzheimer's Disease Core
1010 Center, the University of Pittsburgh NeuroBioBank and Brain and Tissue Repositories and the
1011 NIMH Human Brain Collection Core. CMC Leadership: Pamela Sklar, Joseph Buxbaum (Icahn
1012 School of Medicine at Mount Sinai), Bernie Devlin, David Lewis (University of Pittsburgh),
1013 Raquel Gur, Chang-Gyu Hahn (University of Pennsylvania), Keisuke Hirai, Hiroyoshi Toyoshiba
1014 (Takeda Pharmaceuticals Company Limited), Enrico Domenici, Laurent Essioux (F. Hoffman-La
1015 Roche Ltd), Lara Mangravite, Mette Peters (Sage Bionetworks), Thomas Lehner, Barbara Lipska
1016 (NIMH).

1017

1018 The Genotype-Tissue Expression (GTEx) Project was supported by the [Common Fund](#) of the
1019 Office of the Director of the National Institutes of Health, and by NCI, NHGRI, NHLBI, NIDA,
1020 NIMH, and NINDS. The data used for the analyses described in this manuscript were obtained
1021 from the [GTEx Portal](#) on 09/05/16. BrainSpan: Atlas of the Developing Human Brain [Internet].
1022 Funded by ARRA Awards 1RC2MH089921-01, 1RC2MH090047-01, and 1RC2MH089929-01.

1023

1024 UK BioBank analyses were carried out using results obtained from the Neale and Rivas Labs.
1025 Results were downloaded from the Global Biobank Engine (Global Biobank Engine, Stanford, CA
1026 (URL: <http://gbe.stanford.edu>) [September 30th, 2017]. The authors would like to thank the
1027 Rivas lab for making the resource available.

1035 We thank the Price Foundation for their support of recruiting patients, collecting clinical
1036 information and providing DNA samples used in this study. We also thank the Klarman
1037 Family Foundation for supporting the study. We thank the technical staff at the Center for
1038 Applied Genomics (CAG) at CHOP for generating genotypes used for analyses and the
1039 nursing, medical assistant and medical staff for their invaluable assistance with sample
1040 collection. Yiran Guo was funded by the 2011-2014 Davis Foundation Postdoctoral
1041 Fellowship Program in Eating Disorders Research Award. Dong Li was funded by the 2012-
1042 2015 Davis Foundation Postdoctoral Fellowship Program in Eating Disorders Research
1043 Award. Genome-wide genotyping for CHOP samples was funded by an Institutional
1044 Development Fund to CAG from CHOP. The study was additionally funded through the
1045 Electronic Medical Records and Genomics (eMERGE) Network (U01 HG006830) by National
1046 Human Genome Research Institute of National Institutes of Health, and also funded by
1047 donation from the Kurbert Family;

1149 Ulrike Schmidt receives salary report from the National Institute of Health Research Mental
1150 Health Biomedical Research Centre at South London and Maudsley National Health Service
1151 Foundation Trust and King's College London.

Figure 1: Genic associations in Anorexia Nervosa

A) We identify 37 significant gene-tissue associations across brain, GI/digestive, endocrine, and adipose tissues

B) 14 gene-tissue associations remain significant after applying CoCo and FINEMAP.

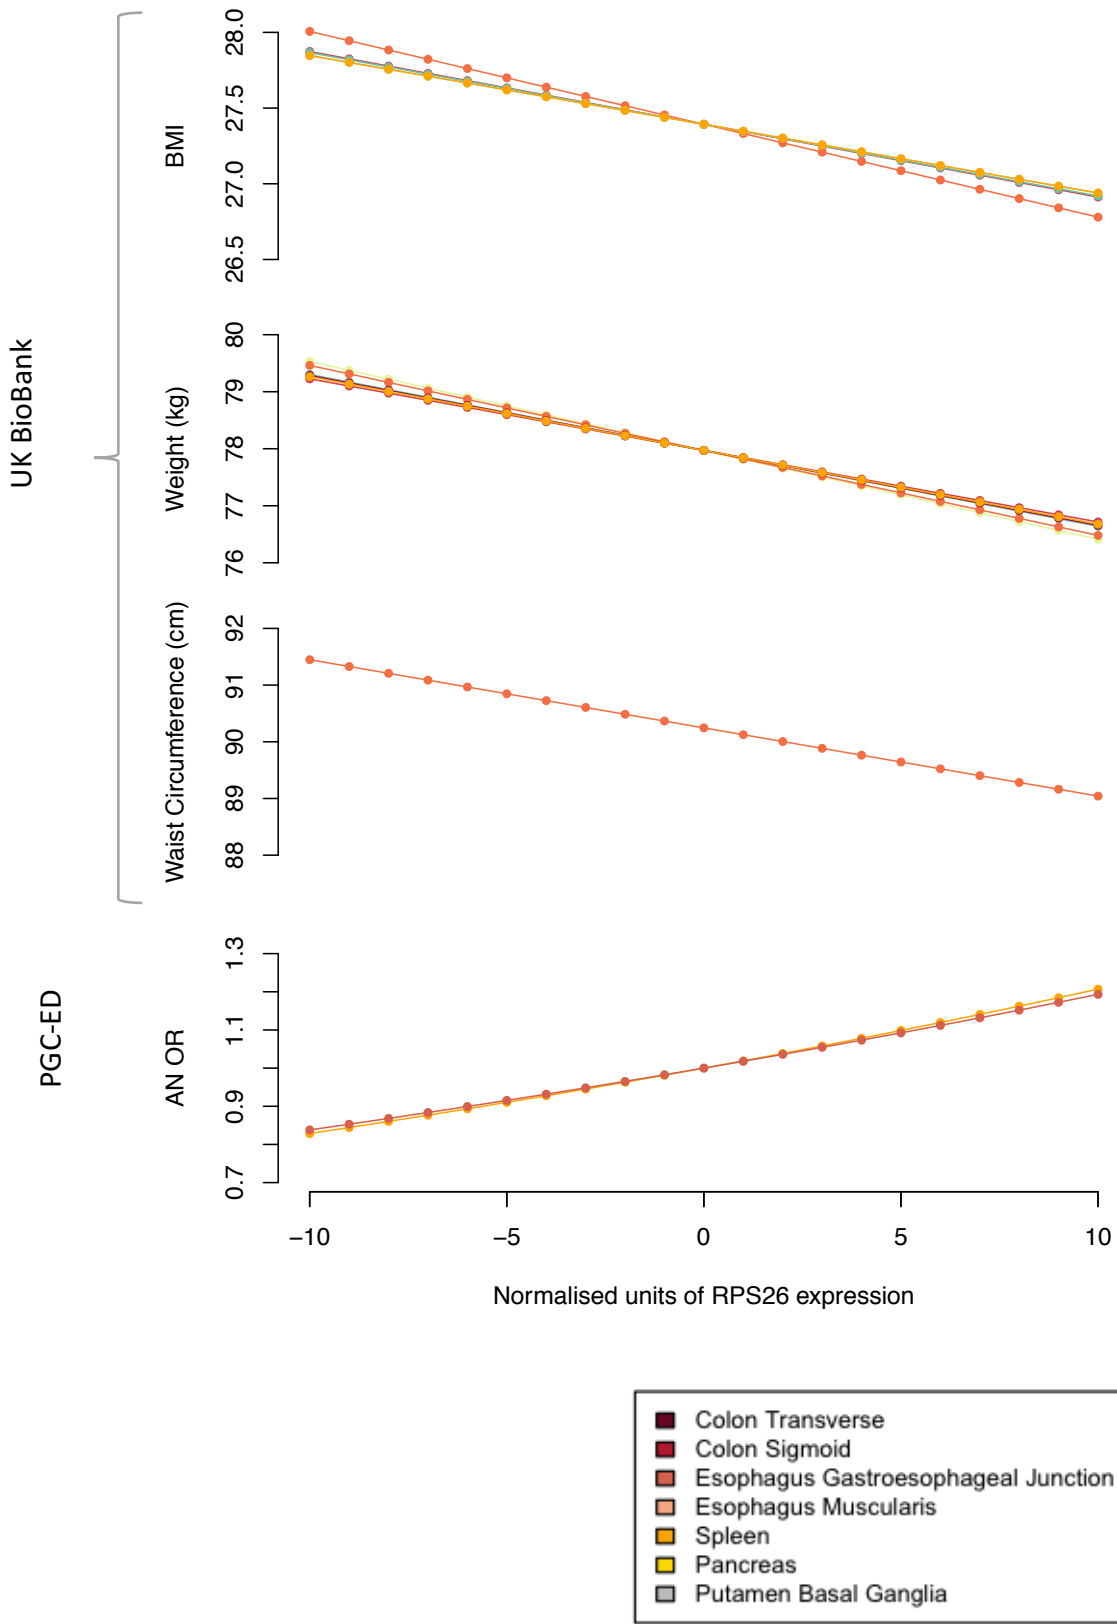

Figure 2A: Genetically regulated expression of *RPS26* is significantly associated with BMI, weight and waist circumference in the UK BioBank, and with AN in PGC-ED

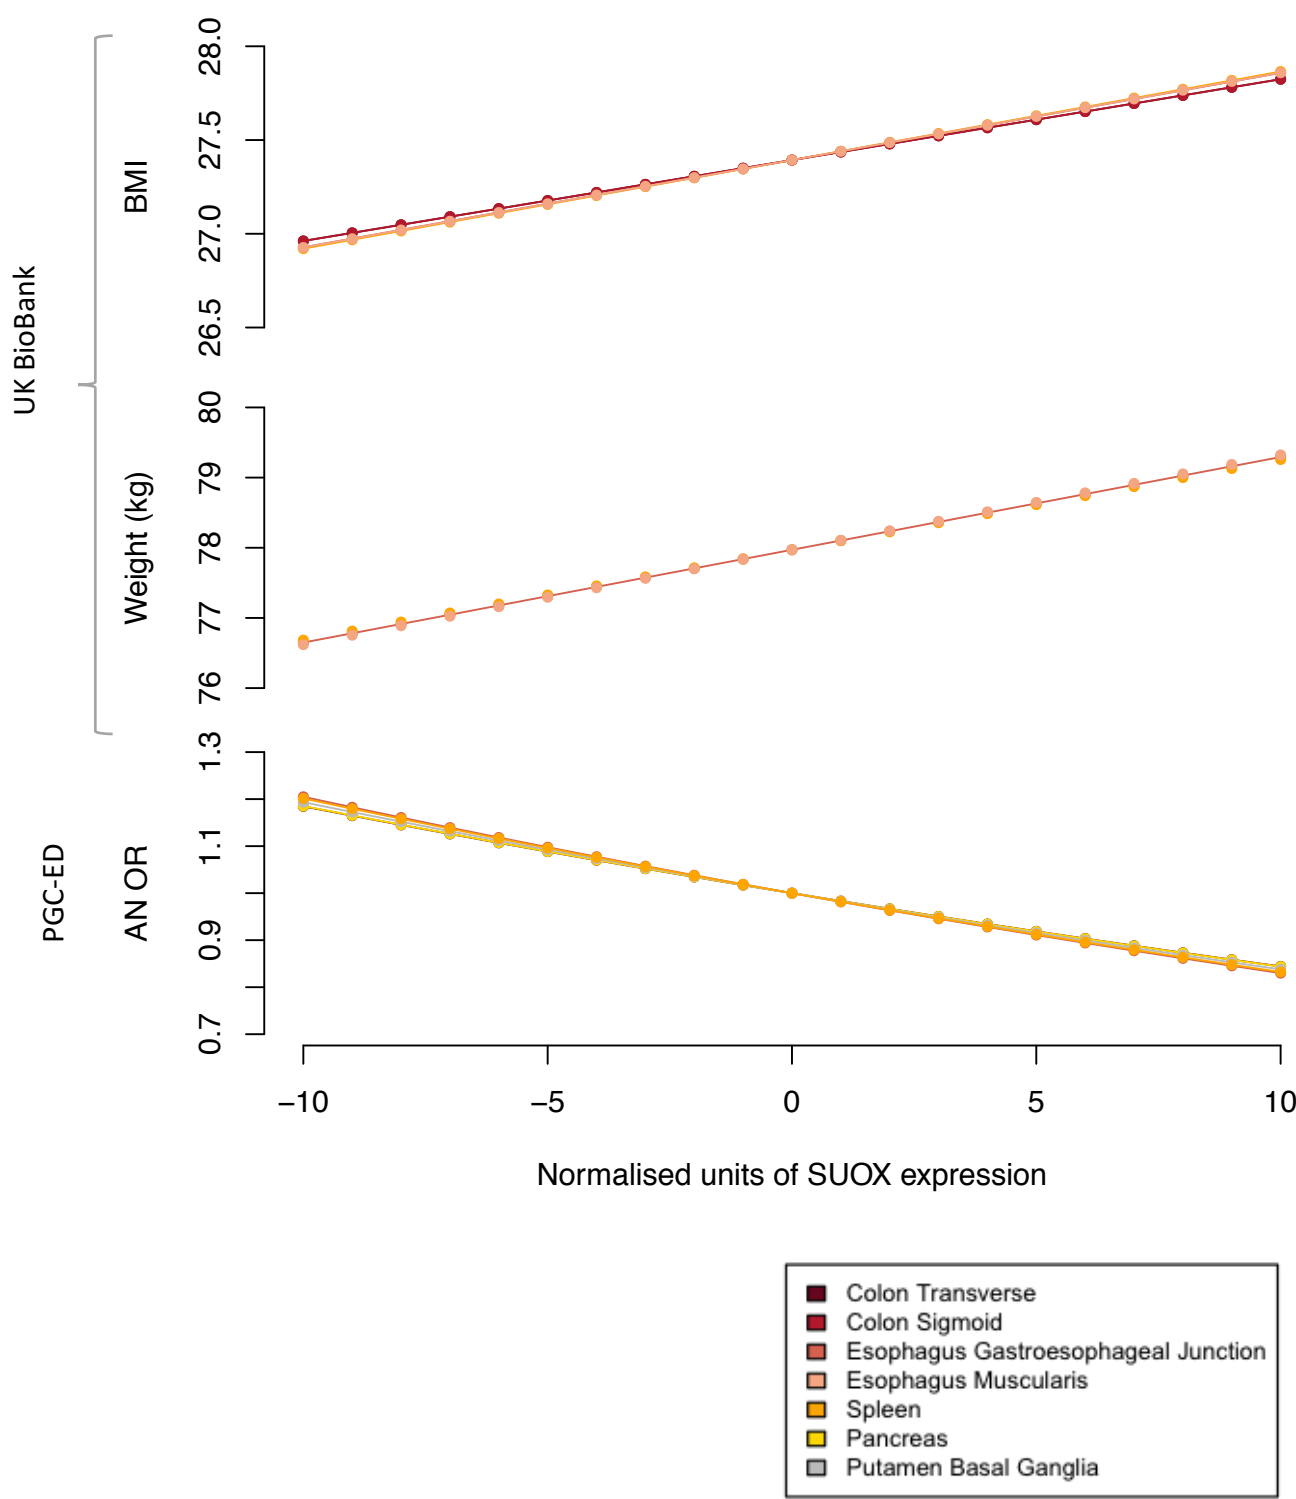

Figure 2B: Genetically regulated expression of *SUOX* is significantly associated with BMI and weight in the UK BioBank, and with AN in PGC-ED
