44   **ABSTRACT**

45   While the developmental principles of sensory and cognitive processing have been

46   extensively investigated, their synergy has been largely neglected. During early life, most

47   sensory systems are still largely immature. As a notable exception, the olfactory system

48   reaches full maturity during intrauterine life, controlling mother-offspring interactions and

49   neonatal survival. Here, we elucidate the structural and functional principles underlying the

50   communication between olfactory bulb (OB) and lateral entorhinal cortex (LEC) – the

51   gatekeeper of limbic circuitry – during neonatal mouse development. Combining

52   optogenetics, pharmacology, and electrophysiology *in vivo* with axonal tracing, we show that

53   mitral cell-dependent discontinuous theta bursts in OB drive network oscillations and time the

54   firing in LEC via axonal projections confined to upper cortical layers. Pharmacological

55   silencing of OB activity diminishes entorhinal oscillations. Moreover, odor exposure boosts

56   OB-entorhinal coupling at fast frequencies. Thus, early OB activity shapes the maturation of

57   entorhinal circuits.

63

64 INTRODUCTION

65 Coordinated patterns of electrical activity periodically entrain developing neuronal networks

66 in rhythms with a broad frequency spectrum. These patterns have been proposed to critically

67 shape brain maturation (1-3). Experimental evidence supporting this hypothesis has been

68 mainly provided for sensory systems. For example, in the visual and auditory systems,

69 spontaneous activity from sensory periphery (i.e., retina or cochlea) controls the formation of

70 cortical representations underlying stimulus perception (4, 5). Theta band spindle bursts and

71 gamma oscillations in the developing somatosensory system promote thalamo-cortical

72 connectivity and maturation of coupling with the motor system (6, 7). Overall, the

73 discontinuous oscillatory activity in sensory cortices during development has multifold origin,

74 including stimulus-independent activation in the periphery and entrainment of local cortical

75 circuits via chemical and electrical synapses (1, 8).

76 While less investigated, limbic circuits show similar patterns of coordinated activity

77 during early development, with discontinuous theta bursts (4-12 Hz) and superimposed fast

78 episodes (20-40 Hz) in beta-gamma frequency (9-13). Theta bursts facilitate unidirectional

79 communication from the CA1 area of intermediate/ventral hippocampus (HP) to the prelimbic

80 subdivision of the prefrontal cortex (PFC) via glutamatergic projections (14). As a

81 consequence of hippocampal theta drive, pyramidal neurons in local prelimbic circuits

82 generate beta-low gamma oscillations (15). Theta coupling between neonatal PFC and HP is

83 controlled by the lateral entorhinal cortex (LEC) that densely projects to both areas (11). The

84 complex organization of limbic circuits at early age raises the question, which mechanisms

85 control the gatekeeper function of LEC during early development. Similar to sensory

86 systems, the neonatal LEC could be driven by spontaneous activity from the sensory

87 periphery. Indeed, the adult LEC receives direct input from the olfactory bulb (OB) that, in

88 contrast to other sensory systems, bypasses the thalamus (16, 17). Mitral and tufted cells

89 (MTCs) represent the sole OB output neurons. Rather than simply relaying information, these

90 neurons are embedded in a complex network that controls odor information coding (18, 19).

91 The axons of MTCs terminate in entorhinal layer I on apical dendrites of layer II/III pyramidal

92   and stellate cells (20), which in turn form the perforant path projection to the hippocampal

93   formation (21, 22). Layer II/III neurons in LEC project back to OB (23), yet distinct entorhinal

94   populations are differently engaged in feedforward and feedback signaling during odor

95   processing (24). Thereby, odor-evoked activity in the adult controls the gateway function of

96   LEC interfacing HP and neocortical regions (25, 26).

97   While the sense of smell serves fundamental functions in newborn animals (27), the

98   role of olfactory inputs and OB activity for limbic circuit maturation remains unknown. Since

99   other sensory systems are still immature during early life – and thus their impact on limbic

100   circuits is negligible – this knowledge gap appears even more striking. Rodent pups are

101   blind, deaf and have limited sensorimotor abilities until the end of the second postnatal week

102   (28, 29). In contrast, the olfactory system maturates early and is considered to be fully

103   functional at birth, providing the major sensory stimulus in neonatal rodents. We hypothesize

104   that both odor-dependent and -independent coordinated activity in OB control the

105   entrainment of entorhinal networks during neonatal development. Here, we combine

106   optogenetics, electrophysiology, and pharmacology *in vivo* with anatomical tracing in

107   neonatal mice (postnatal day (P) 8-10) to elucidate the olfactory control of the functional

108   maturation of entorhinal circuits.

109

110

4

111   **RESULTS**

112   ***OB and LEC are reciprocally connected in neonatal mice***

113   In mice, MTCs mature during intrauterine life and their axons reach cortical targets during the

114   first two postnatal weeks (30). This time window coincides with the period of strong gating of

115   prefrontal-hippocampal networks by theta activity in LEC. To detail on the spatial patterns of

116   connectivity between OB and LEC in P8-10 mice, we performed an in-depth investigation of

117   axonal projections from MTCs to LEC and, *vice versa*, of entorhinal projections to OB. First,

118   we used Tbet-cre;R26-tdTomato mice (n=4) for intact-brain imaging of long-range projections

119   by electrophoretic tissue clearing and confocal fluorescence microscopy (Fig 1A, B). In these

120   mice, MTCs are genetically tagged (Fig 1C) (31). Already at P8, the lateral olfactory tract

121   (LOT) comprising MTC axons appeared fully developed and reached the posterior part of the

122   cerebrum, including piriform cortex (PIR) and LEC (Fig 1A, D). As previously shown in adult

123   rats (32), MTC axons were mainly confined to layer I of neonatal LEC (Fig 1D). Retrograde

124   tracing with Fluorogold (FG) injected into the LEC of P3-4 mice confirmed the direct

125   connectivity (Fig 1E). No differences between dorsal and ventral OB were detected with

126   respect to the density of MTC projections to LEC.

127   Second, we assessed the spatial organization of feedback projections from LEC to

128   OB. Unilateral injection of FG confined to OB of P3-4 mice (n=12) led to bright fluorescent

129   back-labeling of parental cell bodies in ipsilateral LEC that project to OB of P8-10 mice (Fig

130   1F). Their density was lower when compared to the cells detected in ipsilateral PIR. Most

131   labeled neurons were located in layer II and III (88.40%, 259/293, 3 pups, 11 sections). To

132   examine the neurochemical identity of entorhinal neurons projecting to OB, we counter-

133   stained the FG-labeled neurons for GABA and CamKII. While most OB-projecting neurons

134   (99.66%, 292/293) were negative for GABA, hence glutamatergic, a small fraction 0.34%,

135   1/293) was GABA-positive. Similarly, CamKII staining revealed that the large majority, but

136   not all FG-labeled cells, were glutamatergic (data not shown). These data indicate that top-

137   down projections from LEC to OB can be either excitatory or inhibitory, as recently described

138   for adult mice (33).

139   Taken together, the results of morphological investigation show that afferent and

140   efferent projections couple neonatal LEC and OB. While glutamatergic MTCs axons target

141   entorhinal layer I, glutamatergic and few GABAergic neurons in superficial layers of LEC

142   innervate the OB.

143   ***Continuous respiration-related activity and discontinuous theta bursts entrain the***

144   ***neonatal OB***

145   Despite abundant data on morphological development, the functional maturation of OB is still

146   largely unknown. In contrast to the retina and cochlea, which lack stimulus sensitivity at early

147   stages of postnatal development and only generate spontaneous activity, the OB processes

148   olfactory input already at birth (34). To elucidate the patterns of activity in the neonatal OB,

149   we performed multi-site extracellular recordings of local field potential (LFP) and multiple unit

150   activity (MUA) from the mitral cell layer in the dorsal and ventral OB of P8-10 mice *in vivo*

151   (n=49). Signal reversal between the internal plexiform layer (IPL) and external plexiform layer

152   (EPL), as well as the large MTC spikes served as physiological markers for confirming the

153   position of recording electrode set according to stereotaxic coordinates. In addition, the

154   location of DiI-labeled electrodes was confirmed after histological investigation *post mortem*

155   (Fig 2A, S1 Fig A, B).

156   Two patterns of coordinated activity were detected in OB (Fig 2B, C). First, we

157   recorded continuous low amplitude oscillations with slow frequency peaking at 2-4 Hz. Given

158   their temporal correlation and frequency overlap with respiration (median frequency: 2.37 Hz,

159   iqr: 2.12-2.70 of chest movements) (Fig 1C, D), we defined this activity as respiration-related

160   rhythm (RR). The RR reversed at the level of MTC layer and had larger amplitudes in EPL

161   and glomerular layer when compared to the activity in MTC layer (data not shown). Its

162   temporal relationship to the phase of the respiratory cycle differed between layers; the peak

163   of RR cycle in the granule cell layer (GCL) and its trough in EPL and glomerular layer

164   correlated with exhalation. Second, we recorded discontinuous high amplitude oscillatory

165   events with spindle shape in the neonatal OB (Fig 2B, C). These events had faster

166   frequencies when compared to RR with a peak within theta frequency band (4-12 Hz) (Fig

167   2D). Given their resemblance in shape and frequency dynamics to previously characterized

168   oscillatory events in neonatal cortical areas (9-11, 35), these events were classified as theta

169   bursts.

170   As reported for adult OB, prominent spiking characterized neonatal MTCs. Analysis of

171   single unit activity (SUA) after principal component analysis (PCA)-based sorting of units

172   revealed that the majority (80%) of spikes occurred during theta bursts. The firing rate during

173   bursts (median: 1.36 Hz, iqr: 0.25-3.23 Hz) was significantly (p=3.65×10^{-7}, Wilcoxon signed-

174   rank test, n=34 cells from 14 animals) augmented when compared to non-bursting periods

175   (median: 0.44 Hz, iqr: 0.09-1.48 Hz) (Fig 2E). To assess the temporal relationship between

176   oscillatory OB rhythms and MTC firing, we estimated the coupling strength between SUA and

177   RR as well as between SUA and theta bursts by calculating the pairwise phase consistency

178   (PPC), a bias-free measure of rhythmic neuronal synchronization (36). Both rhythms similarly

179   timed MTC firing (RR: median PPC: 0.21, iqr: 0.20-0.22 vs. theta burst: median PPC: 0.21,

180   iqr: 0.20-0.21., p=0.1664, Wilcoxon signed-rank test, 2 outliers removed, n=32 cells, Fig 2F).

181   In adults, dorsal and ventral OB subdivisions have distinct physiology and function.

182   MTC axons that originate in the dorsal OB are known to strongly project to amygdala and

183   mediate innate odor responses, whereas ventral OB accounts for processing of learned

184   odorants (37, 38). To assess whether distinct activity patterns entrain the dorsal vs. ventral

185   OB at neonatal age, we compared RR and theta bursts from both subdivisions (S1 Fig). The

186   power of RR was similar in both sub-divisions (dorsal: median 233.12 µV², iqr: 153.42-

187   418.09, n=7; ventral: median 335.75 µV², iqr: 195.91-452.52, n=10; p=0.54, Wilcoxon rank-

188   sum test). Similarly, theta burst occurrence (dorsal: median 4.65 bursts/min, iqr: 3.87-5.55;

189   ventral: median 5.09 bursts/min, iqr: 4.27-5.30, p=0.74, Wilcoxon rank-sum test), duration

190   (dorsal: median 6.76 s, iqr: 4.44-8.86 s; ventral: median 3.54 s, iqr: 1.65-5.01 s; p=0.09,

191   Wilcoxon rank-sum test), amplitude (dorsal: median 73.80 µV, iqr: 59.56-75.37; ventral:

192   median 66.59 µV, iqr: 59.10-72.37; p=0.67, Wilcoxon rank-sum test) and relative power

193   (dorsal: median 493.98 Hz, iqr: 430.71-763.00; ventral: median 452.63 Hz, iqr: 395.3-1071.6,

194   p=0.96, Wilcoxon rank-sum test) were comparable across OB subdivisions. These data

195   indicate that the dorsal and ventral OB show similar activity at early postnatal age. Except

196   otherwise indicated, further investigation focused on the ventral OB subdivision, taking into

197   account its role for learning processes in relation with the limbic system (38).

198   Coordinated patterns in the sensory periphery have been reported to critically depend

199   on the brain state, diminishing or even disappearing in the presence of anesthetics (39, 40).

200   In contrast, early oscillations in the developing brain have often been investigated in the

201   presence of urethane anesthesia (9, 35, 41, 42). Rodent pups spend most of the time

202   sleeping. The sleep-mimicking action of urethane might explain the similar patterns of

203   neuronal activity previously observed in anesthetized and sleeping rodent pups (14, 43). To

204   assess the urethane influence on RR and theta bursts, we recorded from both ventral (n=12)

205   and dorsal OB (n=6) of neonatal mice before and after urethane injection. Anesthesia did not

206   change the overall structure of OB activity, with continuous RR and discontinuous theta

207   bursts persisting (S2 Fig A, S1 Table). Both the power of RR and the occurrence of theta

208   bursts remained unchanged (S2B Fig). However, urethane anesthesia profoundly reduced

209   theta burst duration (S2B Fig), augmenting those time windows lacking theta band activity

210   and therefore, the fragmented appearance of neonatal activity in OB (S2B Fig).

211   These data indicate that, independent of OB subdivision and brain state, the neonatal

212   OB shows two main patterns of early oscillatory activity, continuous RR activity and

213   discontinuous theta bursts.

214   ***Mechanisms underlying the generation of continuous and discontinuous oscillatory***

215   ***activity in the neonatal OB***

216   To elucidate the mechanisms contributing to the generation of continuous RR and

217   discontinuous theta bursts in the OB of neonatal mice, we used two experimental

218   approaches. First, the temporal coupling between respiration and continuous 2-4 Hz

219   oscillations in OB suggests that nasal air flow contributes to RR generation. To test this

220   hypothesis, we reduced the nasal air flow by unilateral naris occlusion in P8-10 pups (n=12)

221   using a previously developed protocol (44, 45). MUA and oscillatory activity of OB were

222   recorded before and after naris occlusion with silicon adhesive (data not shown). While

8

223   unilateral deprivation did not change the overall structure of OB activity patterns, it reduced

224   the RR power from 396.05 µV² to 293.30 µV² (baseline: iqr 232.58-570.88 µV²; occlusion: iqr

225   136.10-410.14 µV², p=0.0009, Wilcoxon signed-rank test). By contrast, the theta bursts in OB

226   were not affected by naris occlusion (baseline: median: 643.45 Hz, iqr: 342.6-1009.7;

227   occlusion: median 700.35 Hz, iqr 284.5-1240.8; p=0.91, Wilcoxon signed-rank test).

228   Correspondingly, the firing rate during RR (baseline: median 1.18 Hz, iqr 0.26-2.45) as well

229   as coupling strength (i.e. PPC) between units and RR (baseline: median 8.50×10^{-4}, iqr 0-

230   0.0084, one outlier removed) decreased after naris occlusion (firing rate: occlusion: median

231   0.75 Hz, iqr 0.25-1.91, p=0.021 Wilcoxon signed-rank test; coupling strength: occlusion:

232   median -3.09×10^{-5}, iqr $-2.76^{\times 10^{4}}$-1.56×10^{-4}; p=0.049, Wilcoxon signed-rank test, one outlier

233   removed). The temporal structure (coupling strength for baseline: median 2.09×10^{-4}, iqr: -

234   0.0001-0.0015; occlusion: median -1.19×10^{-4}, iqr -3.54×10^{-4}-1.59×10^{-4}; p=0.19, Wilcoxon

235   signed-rank test, one outlier removed) of OB firing in relationship with theta bursts remained

236   unchanged after naris occlusion. Thus, RR activity, but not theta bursts critically depends on

237   nasal air flow.

238   The second experimental approach aimed at assessing the role of MTCs, the OB

239   projection neurons, to the generation of coordinated patterns of oscillatory activity. For this,

240   we selectively manipulated MTC firing by light in P8-10 pups bred from crossing hemizygous

241   Tbet-cre mice with R26-homozygous R26-ArchT-EGFP mice. By these means, MTCs of cre-

242   positive mice selectively expressed the proton pump ArchT fused with EGFP. Already at P8,

243   the fusion protein expression was robust both in MTC somata (S3A Fig) and axonal

244   projections targeting LEC, PIR and posterior cortical amygdala (Fig 3A). Cre-negative mice

245   were used as controls.

246   In a first experiment, we tested the efficiency of light-dependent MTC silencing in

247   neonatal OB by performing whole-cell patch-clamp recordings from biocytin-filled EGFP-

248   positive neurons (n=7 cells) in coronal slices containing the OB of P8-10 R26-heterozygous

249   Tbet-cre;R26-ArchT-EGFP mice (n=5) (S3A Fig). Yellow light pulses (595 nm, 5 s, 0.2-0.6

250   mW) triggered MTC hyperpolarization from -49.96 mV to -58.39 mV (baseline: iqr -57.28-

251   45.61 mV; light administration: iqr -63.10-48.89 mV, Wilcoxon signed-rank test, p=0.0078)

252   and, consequently, inhibition of firing (S3B Fig). Since MTCs are strongly interconnected

253   within local circuits, we tested whether light pulses caused MTC silencing also in the

254   presence of synaptic inputs. To mimic such inputs, we paired the light stimulation with

255   depolarizing current pulses of different intensities. Upon injections ≤ 60 pA, light stimulation

256   still efficiently blocked action potential discharge in ArchT-EGFP-expressing MTCs (S3C

257   Fig).

258   Next, we assessed the contribution of MTC firing to the patterns of oscillatory activity

259   in OB by performing extracellular recordings of LFP and MUA in OB of P8-10 R26-

260   heterozygous cre-positive (n=12) and cre-negative (n=11) Tbet-cre;ArchT-EGFP mice. Upon

261   *in vivo* light stimulation (Fig 3A), the majority (64.58%, 31/48) of MTCs responded with a

262   pronounced firing rate decrease from a median of 1.2 Hz (iqr 0.66-2.26) before to 0.45 Hz

263   (iqr 0.13-0.99) during light exposure. None of the units augmented the firing during

264   illumination and only few units (4.14%, 2/48) showed a post-stimulus firing increase (Fig 3D).

265   Some units (31.25%, 15/48), most likely non-MTCs located close to the mitral cell layer, did

266   not respond to light stimulation. Local silencing of MTCs modified the coordinated activity of

267   OB. The properties of RR and theta bursts (theta burst power: p=0.23, Wilcoxon rank-sum

268   test) were largely similar in cre-negative and cre-positive mice under control conditions (i.e.

269   no light stimulation). Only the power of RR activity was slightly different (RR power: p=0.03,

270   Wilcoxon rank-sum test). Upon light stimulation the RR power in cre-positive pups did not

271   change (pre stimulus: median 92.27 µV^2, iqr 80.12-122.36; during stimulus: median 86.99

272   µV^2, iqr 71.96-100.06, p=0.2324, Wilcoxon signed-rank test, one outlier removed). In

273   contrast, theta power in cre-positive pups significantly decreased during light stimulation (pre

274   stimulus: median 89.73 µV^2, iqr 57.28-100.73; during stimulus: median 70.58 µV^2, iqr 45.70-

275   87.91, p=0.0049, Wilcoxon signed-rank test, one outlier removed). The theta responses to

276   light differed between cre-positive (median 0.84 µV^2, iqr 0.81-0.89) and cre-negative pups

277   (median 0.99 µV^2, iqr 0.93-1.20, p=0.0024, Wilcoxon rank-sum test, 3 outliers from

278   expression group removed), whereas for RR during light stimulus was similar in the two

279   groups (cre-positive, median 0.91, iqr 0.82-1.0; cre-negative pups median 0.96, iqr 0.93-1.05,

280   p= 0.3447, Wilcoxon rank-sum test, 1 outlier from control group, 2 outliers from expression

281   group removed) (Fig 3E, F).

282   These data show that RR and theta bursts in the neonatal OB have different origin.

283   While RR critically depends on nasal air flow, MTC activity is necessary for the entrainment

284   of OB in theta bursts.

285   ***Theta bursts in OB drive discontinuous oscillations and time the firing in the neonatal***

286   ***LEC***

287   The presence of both direct axonal MTC-to-LEC projections and early patterns of oscillatory

288   activity in OB led to the question of their relevance for the emergence of functional

289   assemblies in the neonatal LEC. In contrast to the documented relevance of entorhinal

290   output for developing limbic circuits (11), the role of sensory inputs for the functional

291   maturation of LEC is still unknown.

292   Multi-site extracellular recordings of LFP and MUA from the layer II/III of LEC from

293   P8-10 mice *in vivo* (n=11) (Fig 4A) confirmed the previously reported presence of

294   discontinuous theta bursts with large amplitude (median 154.14 µV, iqr 101.10-191.65) and a

295   duration of 5.15 s (iqr 4.13-8.48) (Fig 4B-D). They appear superimposed on a slow rhythm

296   (2-4 Hz) that continuously entrains the neonatal LEC and has been overlooked in previous

297   investigations. This slow pattern of activity that was present both during theta bursts (median

298   area power 526.25 µV^2, iqr 307.68-1171.85) and "silent" periods (median area power 86.57

299   µV^2, iqr 52.55-344.43), temporally correlated with the simultaneously recorded respiration

300   and was therefore, classified as entorhinal RR. These results demonstrate that the

301   respiration-entrained brain rhythms, a powerful mechanism of long-range coupling (46),

302   emerge early during development. Beside oscillatory patterns, neonatal LEC generates

303   prominent firing concentrated during theta bursts (median 0.42 Hz, iqr 0.22-0.86 vs. non-

304   bursting periods median 0.07 Hz, iqr 0.04 – 0.19, p=1.72x10^{-10}, Wilcoxon signed-rank test,

305   n=54 cells from 11 mice) (Fig 4E). We next assessed the coupling strength between firing

306   and oscillatory activity. Similar fractions of entorhinal neurons were phase-locked to RR

11

307   (75.93%, 41/54 units) and theta bursts (61.11%, 33/54 units, p=0.1, $\chi^2(1)$=2.7472). The

308   strength of coupling assessed by PPC was also stronger for RR (median: 0.21, iqr: 0.20-

309   0.22) and theta (median: 0.21, iqr: 0.20-0.21, p=2.98×10^{-4}, Wilcoxon rank-sum test, 4 outliers

310   removed, n=50 units), with most cells being locked to the trough of RR and theta oscillation

311   (Fig 4F).

312   Simultaneous recordings from OB and LEC (n=9) of neonatal mice gave first insights

313   into their dynamic coupling (Fig 5A). While both areas showed similar oscillatory activity, their

314   power significantly differed. Both RR power (OB: median 143.62 μV^2, iqr 78.03-247.78; LEC:

315   median 109.91, iqr: 26.72-110.51, p=0.0499, Wilcoxon signed-rank test, 1 outlier removed)

316   and theta power (OB: median 193.39 μV^2, iqr 97.47-262.01, LEC: median 112.37 μV^2, iqr

317   43.38-127.36, p= 0.0273) were higher in OB as compared to LEC (Fig 5B). Analysis of the

318   temporal correspondence of theta bursts in OB and LEC revealed that 48.70% of them co-

319   occurred with more than 60% temporal overlap. The coupling strength assessed by

320   imaginary spectral coherence, which excludes synchrony effects due to volume conductance

321   (47), revealed that the OB-LEC coupling is evident in both slow frequencies (i.e RR) and

322   theta band (i.e. theta bursts) (Fig 5C). In line with anatomical data, we detected no

323   differences in the coupling of dorsal and ventral OB with LEC. Both relative occurrence of co-

324   occurring events (dorsal: median 27.04 %, iqr 20.08–33.98 %; ventral: median 21.83 %, iqr

325   15.66-35.14 %; p=0.67, Wilcoxon rank-sum test) and mean imaginary coherence in both RR

326   (dorsal: median 0.11 Hz, iqr 0.09-0.14 Hz; ventral: median 0.08 Hz, iqr 0.05-0.10 Hz; p=0.13,

327   Wilcoxon rank-sum test) and theta frequency range (dorsal: median 0.07 Hz, iqr 0.06-0.11

328   Hz; ventral: median 0.06 Hz, iqr 0.06- 0.09 Hz; p=0.54, Wilcoxon rank-sum test) were similar

329   for dorsal and ventral OB in relationship to LEC (S1 Fig). These data are in line with

330   anatomical investigations in adult mice (48) as well as with our tracing data (Fig 1), showing

331   that, FG injections into neonatal LEC leads to homogenous MTC labeling throughout the OB.

332   To assess the influence of anesthesia on entorhinal activity patterns and coupling

333   between LEC and OB, we recorded both areas in mouse pups before and after urethane i.p.

334   injection (n=18). Urethane did not change the overall spectral distribution of activity patterns

335   in LEC. As in the non-anesthetized state, RR and theta bursts were the main patterns of

336   entorhinal activity, yet the RR power decreased and theta power augmented under urethane

337   action (S4A Fig, S1 Table). Urethane affected the duration of theta bursts and slightly

338   increased their occurrence (S4B Fig). The synchrony between OB and LEC varied in

339   magnitude, but not frequency distribution. The imaginary coherence peaked at 2-4 Hz and at

340   5 to 20 Hz, corresponding to RR and theta-beta frequencies, respectively. While mean RR

341   coherence did not differ between states (p=0.17, Wilcoxon rank-sum test, 2 outliers

342   removed), theta coherence was higher in the presence of urethane (p=0.0034).

343   These data indicate that, independent of brain state and anatomical subdivision, OB

344   and LEC couple tightly, both being synchronized in continuous RR and discontinuous theta

345   oscillations at neonatal age.

346   Since feed-forward projections from MTCs to LEC are dense, whereas feed-back

347   projections from LEC to OB are rather sparse, we asked whether the functional coupling

348   between the two areas is directed, and if so, whether directionality is frequency-specific. To

349   estimate the directionality of OB-LEC coupling, we used two approaches. First, we assessed

350   the phase lag between LFP in OB and LEC. While the phase lag for continuous RR was

351   centered to 0, it peaked in negative range for theta bursts, indicating that OB theta bursts

352   most likely drive LEC theta oscillations (Fig 5D). Second, we analyzed the temporal

353   relationship between spiking activity in one area and either LFP or spiking in the other area.

354   For RR, a similar number of clustered units in OB and LEC were phase-locked to RR in LEC

355   (31.48%, 17/54) and OB (25.27%, 23/91 p=0.54, $\chi^2(1)=0.38$, χ^2 test of proportions),

356   respectively and their coupling strengths were comparable (p=0.35, Wilcoxon rank-sum test,

357   OB cells to LEC RR: median 0.21, iqr 0.19-0.23; LEC cells to OB RR: median 0.22, iqr 0.19-

358   0.28, Fig 5E). In contrast, a significantly higher fraction of LEC neurons were phase-locked to

359   theta bursts in OB (42.47%, 31/73) when compared to OB neurons timed by entorhinal theta

360   phase (10.20%, 5/49, p=1.28x10-4, $\chi^2(1)=14.67$, χ^2 test of proportions, Fig 5E). The coupling

361   strengths of these neuronal populations, however, were comparable (p=0.44, Wilcoxon rank-

362   sum test, OB cells to LEC theta: median: 0.22, iqr: 0.19-0.24; LEC cells to OB theta: median:

13

363   0.23, iqr: 0.20-0.26, one outlier removed from OB theta-LEC units group). Notably, MTCs

364   preferentially fire during the trough of RR activity and theta bursts in OB, whereas LEC cells

365   preferentially fire on the rising phase after the trough of OB rhythms, indicating that MTC

366   firing precedes LEC cell firing by about a third of a cycle (Fig 5F, G).

367   Together, these data suggest that the continuous RR rhythm is not involved in

368   directed information flow within OB-LEC circuits, whereas theta bursts in OB drive the

369   oscillatory entrainment of LEC.

370   ***Pharmacological blockade of OB firing diminishes the slow and fast oscillatory***

371   ***activity but not the coupling of OB-LEC circuits***

372   To confirm the functional long-range coupling between OB and LEC, we pharmacologically

373   abolished the neuronal activity by unilateral pressure-injection of the voltage-dependent

374   sodium channel (hence action potential) blocker lidocaine (4% in sterile saline) into OB.

375   Extracellular recordings of LFP and MUA were performed simultaneously from OB and LEC

376   of mice (n=8) before and after lidocaine injection *in vivo* (Fig 6A). The injected lidocaine

377   volume of 4 µl was proven to not spread across the borders of OB (Fig 6B). Lidocaine

378   abolished OB firing within ten minutes of injection from a median baseline firing rate of 1.97

379   Hz (iqr: 0.77-2.80) to 0.00 Hz (iqr: 0.00-0.02). A partial recovery was observed after 30-40

380   min (χ^2(7)=45.04, p=1.34x10^{-7}, Friedman test, with Wilcoxon signed-rank post hoc test with

381   Bonferroni correction) (Fig 6D). The firing of entorhinal neurons was also significantly

382   reduced after lidocaine treatment in OB from a median baseline firing rate of 2.4 Hz (iqr 1.46-

383   3.60) to 0.52 Hz (iqr 0.32-1.09) within the first 10 minutes after injection (χ^2 (7)=135.50,

384   p=4.45x10^{-26}, Friedman test, with Wilcoxon signed-rank post-hoc test with Bonferroni

385   correction). The decrease of firing rates in both areas was accompanied by changes of

386   oscillatory network activity. In OB, the power of RR (baseline: median 91.05 µV^2; iqr 70.66-

387   224.40; lidocaine: median 8.88, iqr 3.90-20.16; p=0.0078, Wilcoxon signed-rank test) as well

388   as the occurrence (baseline: median 4.76 bursts/min, iqr 3.58-5.93; lidocaine: 1.03

389   bursts/min, iqr 0.76-1.56, p=0.0234, Wilcoxon signed-rank test), duration (baseline: median

390   4.41 s, iqr 3.78-4.77; lidocaine: median 2.35, iqr 1.89-2.88, p=0.0078, Wilcoxon signed-rank

391   test) and power (baseline: median 202.07 μV^2, iqr 163.62-261.95; lidocaine: median 33.19,

392   iqr 24.14-109.00. p=0.0156, Wilcoxon signed-rank test) of theta bursts were reduced. In LEC,

393   the power of RR (baseline: median 55.88 μV^2, iqr 42.48-134.05; lidocaine: median 17.71, iqr

394   9.07-53.80, p=0.0391, Wilcoxon signed-rank test) as well as the duration (baseline: median

395   4.41 s, iqr 3.74-4.58; lidocaine: median 3.24, iqr 3.14-3.56, p=0.0156, Wilcoxon signed-rank

396   test, one outlier removed) and power (baseline: median 148.11 μV^2, iqr 115.76-191.62;

397   lidocaine: median 75.50, iqr 65.99-116.63, p=0.0313, Wilcoxon signed-rank test, 2 outliers

398   removed) of theta bursts were decreased after blockade of OB firing. While the coordinated

399   activity substantially diminished in OB and LEC, the coupling between both areas was not

400   affected by lidocaine. Coherence neither changed in slow frequencies (baseline: median

401   0.08, iqr 0.05-0.11; lidocaine: median 0.14, iqr 0.08-0.24, p=0.25, Wilcoxon signed-rank test)

402   nor in theta frequency band (baseline: median 0.11, iqr 0.07-0.16; lidocaine: median 0.14, iqr

403   0.10-0.18, p=0.54, Wilcoxon signed-rank test) after blocking OB firing (Fig 6E).

404   These data indicate that blocking of neuronal firing in OB causes massive

405   diminishment of coordinated activity in both OB and LEC but does not change the coupling

406   strength between the two regions.

407   ***Odors boost the oscillatory activity in neonatal OB and LEC and augment their fast***

408   ***frequency coupling***

409   In contrast to other sensory systems that lack peripheral sensitivity for environmental stimuli

410   during early postnatal development, the olfactory system is functional at birth. Therefore, the

411   characterized coordinated patterns of oscillatory activity, RR and theta bursts, might have a

412   dual origin, i.e. resulting from both spontaneous and/or stimulus-evoked activation of OB

413   neurons. To gain first insights into the relevance of environmental stimuli on oscillatory

414   activity and long-range entrainment of OB and LEC, we exposed P8-10 mouse pups to

415   different odors. Prominent oscillatory discharge with slow and fast frequencies as well as

416   MUA were induced in OB by olfactometer-controlled exposure to odors, such as octanal

417   (10%) (Fig 7A). Intriguingly, we observed odor-evoked responses also in LEC, albeit at lower

418   magnitude. Compared to theta bursts recorded in absence of stimuli (i.e baseline) and to

419 responses to saline, these octanal-evoked responses had a higher amplitude of slow

420 oscillations corresponding to RR both in OB (χ^2 (2)= 36.05, p=1.49x10^{-8}, Kruskal-Wallis test,

421 Wilcoxon rank-sum test with Bonferroni correction as post-hoc test) and LEC (χ^2 (2)= 13.80,

422 p=0.001, Kruskal-Wallis test, Wilcoxon rank-sum test with Bonferroni correction as post-hoc

423 test). Similarly, octanal augmented the amplitude of theta bursts in both regions (OB: χ^2(2)=

424 36.30, p=1.31x10^{-8}, Kruskal-Wallis test, Wilcoxon rank-sum test with Bonferroni correction as

425 post-hoc test, LEC: χ^2(2)= 20.52, p=0.000035, Kruskal-Wallis test, Wilcoxon rank-sum test

426 with Bonferroni correction as post-hoc test) (Fig 7B, C, Table 1). In contrast to coordinated

427 theta burst activity recorded in the absence of olfactory stimulation, evoked responses

428 included beta band (15-30 Hz) activity. The amplitude of beta activity was significantly higher

429 in the presence of octanal than during baseline or saline exposure both in OB (χ^2(2)= 56.52,

430 p=5.33x10^{-13}, Kruskal-Wallis test, Wilcoxon rank-sum test with Bonferroni correction as post-

431 hoc test) and LEC (χ^2(2)= 31.94, p=1.16x10^{-7}, Kruskal-Wallis test, Wilcoxon rank-sum test

432 with Bonferroni correction as post-hoc test) (Fig 7B, C, Table 1). The presence of odor-driven

433 OB activity confirms the maturity of receptor cells and odor-processing mechanisms in the

434 olfactory system at early postnatal age. Moreover, the presence of odor-driven LEC activity

435 indicates that coordinated activity from OB drives the oscillatory entrainment of LEC. To

436 determine which oscillatory patterns are mainly involved in these directed OB-LEC

437 interactions, we calculated the imaginary coherence between the two areas upon exposure

438 to either saline or octanal. While the coherence in the slow frequency band (i.e. RR) was

439 higher for odor-triggered events as compared to baseline events, it was similar for saline and

440 octanal (χ^2(2)= 23.22, p=9.06x10^{-6}, Kruskal-Wallis test, Wilcoxon rank-sum test with

441 Bonferroni correction as post-hoc test, Fig 7D, Table 1). In contrast, the coherence in fast

442 frequencies significantly augmented in the presence of octanal when compared to saline-

443 evoked or baseline events (theta: χ^2(2)= 43.99, p=2.81x10^{-10}, Kruskal-Wallis test, Wilcoxon

444 rank-sum test with Bonferroni correction as post-hoc test, beta: χ^2(2)= 48.48, p=2.98x10^{-11},

445 Kruskal-Wallis test, Wilcoxon rank-sum test with Bonferroni correction as post-hoc test) (Fig

446 7D, Table 1). These data suggest that discontinuous bursts, either spontaneous or odor-

16

447   induced, facilitate the long range OB-LEC coupling and boost local entrainment in beta band

448   of entorhinal circuits.

449

450
451 **Table 1 (related to Figure 7). Quantification of odor-responses in neonatal OB-LEC networks.**

	OB amplitude (relative change)				LEC amplitude (relative change)				OB-LEC coherence (relative change)			
	No odor	**Saline**	**Octanal**	**p**	**No odor**	**Saline**	**Octanal**	**p**	**No odor**	**Saline**	**Octanal**	**p**
RR	1.34 1.00-1.61	2.78 1.17 - 3.20	3.41 2.41 - 4.50	<0.001	1.59 1.17-3.31	2.27 1.29 -4.45	5.38 2.21 - 8.94	=0.001	0.69 0.50-1.0	1.18 0.76 - 1.49	1.38 0.90 - 1.73	<0.001

452
453
454 The values are given as median and inter-quartile ranges and p-values (Kruskal-Wallis H test) for odor-evoked changes in oscillatory activity in

455 RR, theta and beta band in OB and LEC, as well as OB-LEC coherence, when compared to baseline events are included.

456
457

458   **DISCUSSION**

459   Assembling of neurons into functional networks during development is the pre-requisite for

460   behavioral performance in adults. Entrainment of neurons into coordinated oscillatory

461   rhythms represents a powerful assembling principle that has been initially identified to control

462   the topographic organization of sensory systems (6, 8, 49, 50). More recently, patterns of

463   coordinated activity have been characterized in developing limbic systems (9, 14, 15, 51, 52).

464   However, it is still unclear whether sensory and limbic circuits adhere to similar assembling

465   principles and how they interact during early development. In the present study, we tested

466   the hypothesis that coordinated activity patterns of neuronal assemblies in neonatal OB

467   contribute to the oscillatory entrainment of LEC, the gatekeeper of limbic circuits during

468   development. Combining *in vivo* electrophysiology, optogenetics and pharmacology with

469   anatomical tracing of projections, we demonstrate that (i) two major patterns of coordinated

470   activity entrain the neonatal OB: continuous slow frequency oscillations temporally related to

471   respiration and discontinuous theta band oscillations critically depending on MTC activity; (ii)

472   both rhythms temporally couple the neonatal OB and LEC via dense direct axonal

473   projections, with OB theta bursts boosting the oscillatory entrainment of entorhinal circuits;

474   and (iii) olfactory stimuli augment oscillatory power, induce activity in fast frequency bands,

475   and strengthen the coupling within OB-LEC circuits (Fig 8). These data reveal that

476   endogenously-generated and stimulus-driven activities in OB control the oscillatory

477   entrainment of LEC.

478   Brain development has been extensively investigated in rodents because they

479   enable insights into a time window that remains inaccessible in humans. As altricial species,

480   rodents are born at an immature stage of brain development. They are blind, deaf, do not

481   whisker and have limited motor abilities during the first postnatal days. Before the onset of

482   the ability to actively respond to sensory stimuli, coordinated activity patterns, typically

483   characterized by rhythmic burst discharge separated by periods of quiescence, emerge

484   endogenously. Such patterns have been described in developing somatosensory, visual and

485   auditory systems. Their onset, properties, and underlying mechanisms are relatively well

486   understood. For example, retinal waves emerge before the onset of light-sensitivity and

487   vision as local patterns of coordinated activity mediated by gap junctions, cholinergic and

488   glutamatergic circuits (53, 54). Retinal waves synaptically propagate along the visual tract to

489   primary visual cortex (35, 55, 56) and are mandatory for the refinement of visual maps (57).

490   Similarly, cochlear burst activity emerges before the onset of hearing as a result of

491   coordinated firing and propagates along auditory pathways (58, 59). These cochlear bursts

492   are crucial for the establishment of precise tonotopic maps (5, 49). The precision of whisker

493   maps in the primary somatosensory cortex seems to be equally controlled by coordinated

494   activity evolving during postnatal development (8, 60). In the absence of a sensory periphery

495   with bursting activity before the onset of whisking, passive activation of whiskers is replayed

496   within thalamo-cortical circuits and contributes to refinement of topographic maps (6).

497   At the same postnatal age, the olfactory system is considered to be fully mature, the

498   sense of smell being of particular relevance for pup survival. This early maturity poses the

499   question, whether the mechanisms of organization differ between developing olfactory

500   pathways and other sensory systems. The present data indicate that, similar to retina or

501   cochlea, OB generates discontinuous patterns of oscillatory activity peaking in theta

502   frequency range. MTCs are critical mediators of theta bursts. These bursts are

503   complemented by the continuous RR that is timed by respiration/air flow and largely

504   independent of neuronal firing in OB. While endogenously generated discontinuous theta

505   bursts are a common activity pattern in peripheral sensory structures, independent of system

506   maturity (OB *versus* retina, cochlea), the continuous RR was not reported for other sensory

507   systems. The frequency structure of network activity in neonatal OB was largely independent

508   of the brain state. Anesthesia augmented theta but not RR power, suggesting that MTC

509   activity is enhanced. Similarly, in adult OB, MTCs augmented odor-evoked activity, thus

510   broadening their odor tuning under anesthesia (45, 61).

511   Overall, bursting OB activity during development profoundly differs from the

512   oscillatory activity in adults. Supporting previous observations *in vitro* (62), we showed that

513   neonatal MTCs are not only preferentially attuned to theta band activity but also contribute to

514   its generation. In adult mice, network activity in theta band emerges from respiration-coupled

515   sensory input in the glomerular layer (63) and MTCs are mainly involved in the generation of

516   fast oscillatory activity in gamma band (64-67). Similarly, fast rhythms are absent in the

517   developing OB (68) and only in the presence of odors beta band activity was induced. The

518   protracted emergence of fast oscillations has been hypothesized to result from late

519   integration of OB interneurons into local circuits and from age-dependent intrinsic biophysical

520   properties of MTCs. As a consequence, it has been postulated that the developing OB

521   encodes only first-order (e.g. odor identity) but not second-order sensory information (e.g.

522   odor context) (45, 69).

523   The presence of both stimulus-related and endogenous network activity raises the

524   question, whether and, if so, how both activity types either concurrently or independently

525   shape the maturation of the olfactory system. Already the role of spontaneous activity

526   endogenously generated in the sensory periphery has been subject of debate. As shown for

527   network activity in the immature retina and cochlea, discontinuous OB bursts in neonatal

528   mice are likely to have a permissive role in the establishment of precise connectivity that is

529   inherent in an olfactory map (70). However, it remains unclear how the spontaneous and

530   stimulus-evoked activities create a coherent sensory representation lacking mutual

531   perturbations. This is a unique feature of the developing OB. Spontaneous retinal waves and

532   cochlear bursts diminish and disappear with the onset of light sensitivity and hearing.

533   Therefore, they do not interfere with stimulus-evoked activity. Understanding the

534   mechanisms of theta bursts and RR during early development, as initiated in the present

535   study, will enable us to disentangle their function(s) along the olfactory pathway.

536   In sharp contrast to most sensory pathways, the olfactory system bypasses a

537   thalamic relay and directly conveys information from OB to cortical areas. Much research

538   focused on the PIR, where the bulbar topography is largely discarded and dense inputs from

539   OB are integrated to form odor percepts (16, 71-73). MTC axons also target LEC and in fact

540   these axons represent the main input that rodent LEC receives (74). LEC neurons respond to

541   odors (75, 76) and have been proposed to act as a modulator of olfactory coding through

542　interactions with the PIR (24, 77, 78). The present results show that already at neonatal age

543　a tight coupling links the OB with LEC. MTC axons target layer I of neonatal LEC as

544　previously shown for adults (17, 79). These projections mediate the coupling by synchrony

545　between the two areas as well as the early drive from OB to LEC. Remarkably, the neonatal

546　LEC and OB show similar patterns of oscillatory activity, RR and theta bursts, albeit with

547　lower power in LEC. The coupling by synchrony between the two areas peaked within the

548　same frequency bands, 2-4 Hz and 4-10 Hz. Given the measures used for the assessment of

549　synchrony it is unlikely that similarities result from volume conduction. Reflecting the more

550　pronounced OB-to-LEC innervation as compared with *vice versa* projections, the entorhinal

551　firing was stronger timed by the phase of RR and theta bursts in the OB than the OB firing

552　was driven by the entorhinal activity. Interestingly, lidocaine blockade of MTC firing did not

553　abolish the coupling between OB and LEC, suggesting that alternative pathways might

554　contribute to the synchrony between the two areas.

555　　　　While feedback projections from LEC to OB (and piriform cortex, not shown) emerge

556　early in life, their function seems to mature postnatally to reach the anticipatory top-down

557　modulation and optimal input discrimination that have been identified at adult stage (80).

558　Recent findings revealed that the cellular substrate of feedforward and feedback interactions

559　between OB, LEC and PIR of adult mice are highly complex (24). We hypothesize that,

560　under the influence of excitatory inputs from OB, the local entorhinal circuitry is activated.

561　The MTC target neurons in LEC are mainly glutamatergic, suggesting that coordinated OB

562　activity causes an overall excitation in LEC that might facilitate the formation and refinement

563　of local circuits.

564　　　　Olfactory information reaches the adult HP (CA1 and dentate gyrus) via reelin-

565　positive neurons in LEC (24, 81). Along these axonal projections, the oscillatory activity is

566　synchronized and enables directed functional interactions between OB, LEC and HP. In turn,

567　HP unidirectionally projects to PFC. At the functional level, the communication across areas

568　involves oscillatory activity that temporally coordinates the neuronal assemblies. For

569　example, respiration-related slow activity, even if subject to debate regarding its relationship

570   to previously described slow rhythms (82), has recently been found to occur simultaneously

571   with theta oscillations (83) and moreover entrain faster beta and gamma oscillations in LEC,

572   HP, and PFC (46, 84, 85). Taking into account the role of HP and PFC for cognitive

573   processing (86), the OB activity that directly entrains the limbic circuit via LEC activation

574   might represent a powerful control mechanisms of memory and executive performance of

575   adult (87, 88).

576   It is tempting to speculate about the potential functions of OB-driven entrainment of

577   LEC during neonatal development, before the emergence of cognitive abilities. Our previous

578   results demonstrated that LEC acts as gatekeeper of prefrontal-hippocampal interactions

579   shortly after birth (11). Discontinuous theta bursts in LEC drive the oscillatory entrainment

580   and time the firing of both prelimbic subdivision of PFC and CA1 area of the

581   intermediate/ventral HP. Here we show that MTC-dependent theta activity of neonatal OB

582   boosts RR and theta bursts in LEC. On the other hand, olfactory stimuli elicit even faster

583   entrainment of OB-LEC circuitry, with beta band oscillations being only detectable in the

584   presence of odors, such as octanal. An important issue that remains to be elucidated is

585   whether specific scents that the pups naturally encounter during development, such as

586   maternal odors, shape the network function even stronger than "artificial" odors. The effects

587   of maternal odor on physical, neuroendocrine, and behavioral development of pups has been

588   extensively investigated (27, 89, 90), yet very little is known about the underlying cellular and

589   circuit mechanisms. We propose that endogenously generated and odor-evoked OB activity,

590   especially as a result of maternal odor, might increase the level of excitability within

591   entorhinal-prelimbic-hippocampal networks and strengthen their wiring. By these means, the

592   olfactory system could facilitate the postnatal maturation of limbic circuitry and, ultimately, the

593   emergence of cognitive abilities.

594

595   **MATERIALS AND METHODS**

596   ***Ethics statement.*** All experiments were performed in compliance with the German laws and

597   the guidelines of the European Union for the use of animals in research and were approved

598   by the local ethical committee (15/17).

599   ***Experimental model and subject details***

600   *Mice.* Timed-pregnant C57Bl/6J and Tbet-cre mice from the animal facility of the University

601   Medical Center Hamburg-Eppendorf as well as B6.Cg-*Gt(ROSA)26Sor*$^{tm40.1(CAG-aop3/EGFP)Hze}$/J

602   mice (Ai40(RCL-ArchT-EGFP)-D, Jackson Laboratory, stock no: 02118), and Tbet-cre;ArchT-

603   EGFP mice (bred by the animal facility of the University Medical Center Hamburg-Eppendorf)

604   were housed individually in breeding cages at a 12 h light / 12 h dark cycle and fed *ad*

605   *libitum*. Mouse lines used for CLARITY experiments (Tbet-cre mice, B6.Cg-

606   *Gt(ROSA)26Sor*$^{tm9(CAG-tdTomato)Hze}$/J (Ai9(RCL-tdT), Jackson Laboratory, stock no: 007909 and

607   Tbet-cre;tdT mice) were bred in the animal facility at RWTH Aachen University under similar

608   conditions. The day of vaginal plug detection was defined E0.5, while the day of birth was

609   assigned as P0. Male mice underwent sensory manipulation, light stimulation,

610   pharmacological treatment and multi-site electrophysiological recordings at P8-10. For

611   CLARITY experiments, male and female mice were used. Genotypes were determined using

612   genomic DNA and following primer sequence (Metabion, Planegg/Steinkirchen, Germany: for

613   Cre   in   Ai40(RCL-ArchT-EGFP)-D   mice: PCR   forward   primer   5'-

614   ATCCGAAAAGAAAACGTTGA-3' and reverse primer 5'-ATCCAGGTTACGGATATAGT-3';

615   for ROSA26-wt PCR forward primer 5'-AAAGTCGCTCTGAGTTGTTAT-3' and reverse

616   primer 5'-GGAGCGGGAGAAATGGATATG-3'; for GFP-tg PCR forward primer 5'-

617   CTGGTCGAGCTGGACGGCGACG-3'   and   reverse   primer   5'-

618   GTAGGTCAGGGTGGTCACGAG-3'; for Cre in Ai9(RCL-tdT) mice: forward primer 5'

619   CATGTCCATCAGGTTCTTGC 3' and reverse primer 5' AGAGAAAGCCCAGGAGCAG 3'; for

620   tdTomato forward primer 5' GGCATTAAAGCAGCGTATCC 3' and reverse primer 5'

621   CTGTTCCTGTACGGCATGG 3'. The PCR reactions were as follows: 10 min at 95°C, 30

622   cycles of 45 s at 95°C, 90 s at 54°C, 90 s at 72°C, followed by a final extension step of 10

623   min at 72°C (Cre-tg and ROSA26-wt), 10 min at 95°C, 30 cycles of 45 s at 95°C, 90 s at

624   68°C, 90 s at 72°C, followed by a final extension step of 10 min at 72°C (GFP-tg). In addition

625   to genotyping, EGFP expression in OB prior to surgery was detected using a dual fluorescent

626   protein flashlight (Electron microscopy sciences, PA, US).

627   ***Surgical procedures***

628   *Surgical preparation for electrophysiology and light delivery in vitro.* For patch-clamp

629   recordings, pups were decapitated and brains were sliced in 300 μm-thick coronal sections.

630   Slices were incubated in oxygenated ACSF containing (in mM) 119 NaCl, 2.5 KCl, 1

631   NaH_2PO_4, 26.2 $NaHCO_3$, 11 glucose, 1.3 $MgSO_4$ (320 mOsm) at 37 °C. Prior to recordings,

632   slices were maintained at room temperature and superfused with oxygenated ACSF.

633   *Surgical preparation for electrophysiology and light delivery in vivo.* For recordings in non-

634   anesthetized state, 0.5% bupivacain / 1% lidocaine was locally applied on the neck muscles.

635   For recordings under anesthesia, mice were injected i.p. with urethane (1 mg/g body weight;

636   Sigma-Aldrich, MO, USA) prior to surgery. For both groups, under isoflurane anesthesia

637   (induction: 5%, maintenance: 2.5%) the head of the pup was fixed into a stereotaxic

638   apparatus as previously reported (9).

639   The surgery protocols are described in detail in Supplemental Information.

640   ***Electrophysiology***

641   *Electrophysiological recordings in vivo.* One-shank electrodes (NeuroNexus, MI, USA) with

642   16 recording sites were inserted into dorsal (depth 0.5-1.2 mm, angle 0°) or ventral OB (1.4-

643   1.8 mm, angle 0°) as well as in LEC (depth: 2 mm, angle: 10° from the vertical plane). Two-

644   shank optoelectrodes (Buzsaki16-OA16LP, NeuroNexus, MI, USA) with 8 recordings sites on

645   each shank aligned with an optical fiber ending 40 μm above the top recording site were

646   inserted into ventral OB. Extracellular signals were band-pass filtered (0.1 Hz – 9 kHz) and

647   digitized (32 kHz) by a multichannel amplifier (Digital Lynx SX; Neuralynx, Bozeman, MO;

648   USA) and Cheetah acquisition software (Neuralynx).

649   *Electrophysiological recordings in vitro.* Whole-cell patch-clamp recordings were performed

650   from MTCs identified by their location in the mitral cell layer and visualized by membrane-

651   bound EGFP. All recordings were performed at room temperature. Recording electrodes (4-9

652   MΩ) were filled with K-gluconate based solution containing (in mM): 130 K-gluconate, 10

653   HEPES, 0.5 EGTA, 4 Mg-ATP, 0.3 Na-GTP, 8 NaCl (285 mOsm, pH 7.4) and 0.5% biocytin

654   for post-hoc morphological identification of recorded cells. Recordings were controlled with

655   the Ephus software (91) in the MATLAB environment (The MathWorks, Inc., MA, USA).

656   **Morphological investigation**

657   *CLARITY.* Brains from neonatal mice of both sexes were sliced in 1 mm- (for LEC) and 500

658   μm-thick (for OB) coronal sections. To maintain the structural integrity, the tissue was fixed

659   overnight at 4°C in hydrogel fixation solution containing 4% acrylamide, 0.05% bis-

660   acrylamide, 0.25% VA-044 Initiator, 4% PFA in PBS-/-. After polymerization and embedding

661   the nuclear marker DRAQ5 (1:1000) was added to the samples. After washing steps, the

662   samples were incubated for 24 h in RIMS80 containing 80 g Nycodenz, 20 mM PS, 0.1%

663   Tween 20, and 0.01% sodium acid.

664   *Retrograde tracing.* For retrograde tracing, anesthetized P3-4 mice received unilateral

665   Fluorogold (FG) (Fluorochrome, LLC, USA) injections into OB (0.8 mm anterior from the

666   fronto-nasal suture, 0.8 mm from midline) or LEC (1 mm posterior to bregma, 5 mm from

667   midline). After 4-5 days, pups were deeply anesthetized and perfused at P8.

668   All staining protocols are described in detail in Supplemental Information.

669   **Manipulations**

670   *Light stimulation in vitro.* Whole-cell current-clamp recordings were performed from ArchT-

671   EGFP expressing mitral cells in coronal slices of the neonatal Tbet-cre;ArchT mice. Yellow

672   light pulses (595 nm) of different light intensities (0.2 – 2.6 mW) were applied to test the

673   effect on the membrane potential.

674   *Light stimulation in vivo.* Trapezoid light stimulation was applied using a diode pumped solid

675   state (DPSS) laser (Cobolt Mambo, 594 nm, Omicron, Austria), controlled by an Arduino Uno

676   (Arduino, Italy).

677   *Naris occlusion.* One naris was closed using silicon adhesive (Kwik-Sil, World Precision

678   Instruments). After a recovery period of five minutes, the recording was pursued while one

679   naris was sealed.

680   *Pharmacological inactivation.* To block the firing of OB neurons, lidocaine hydrochloride 4%

681   in 0.9% NaCl, pH 7.0 with NaOH) was slowly infused into the OB

682   *Odor stimulation.* An eight channel dilution olfactometer (Aurora Scientific) was used for

683   stimulus delivery.

684   All manipulation protocols are described in detail in Supplemental Information.

685   **Quantification and statistical analysis**

686   *Immunohistochemistry quantification.* Images were analyzed using ImageJ.

687   *Detection of respiration frequency.* Respiration was monitored using a piezo-electric sensor

688   placed under the pup's chest.

689   *LFP analysis.* Data were analyzed offline using custom-written scripts in the MATLAB

690   environment (Version 9, MathWorks, Natick, MA).

691   For details, see Supplemental Information.

692   *Statistics.* Statistical analysis was performed using SPSS Statistics 22 (IBM, NY) or

693   MATLAB. Gaussian distribution of the data was assessed using the Kolmogorov-Smirnov

694   test. None of the data sets were normally distributed. Therefore, data were tested for

695   significance using Wilcoxon signed-rank test (2 related samples), Wilcoxon rank-sum test (2

696   unrelated samples), Friedman test (>2 related samples; Wilcoxon signed-rank post hoc test

697   with Bonferroni correction) and Kruskal-Wallis H test (>2 unrelated samples; Wilcoxon rank-

698   sum test post hoc test with Bonferroni correction). Differences in proportions were tested

699   using χ^2 test. For classification of single unit responses to light stimulation, significant firing

27

700   rate changes were assessed statistically using Wilcoxon signed-rank test. Data are

701   represented as median and inter-quartile range.

938

939   **Figure legends**

940   **Fig 1. Patterns of axonal connectivity between OB and LEC in neonatal mice.**

941   **(A)** Long-range projections of tdTomato fluorescently labeled OB M/T cells (left) when

942   superimposed on a bright-field image showing the ventral (middle) and lateral (right) view of

943   the whole brain of a P10 Tbet-cre;tdTomato mouse. **(B)** Unprocessed (left) and cleared

944   (right) brain of a P10 mouse. **(C)** Cleared 500 µm-thick coronal section containing the OB of

945   a Tbet-cre;tdTomato mouse showing MTCs (red) when counterstained with the nuclear

946   marker DRAQ5 (blue). Inset, tdTomato-stained MTCs displayed at larger magnification. **(D)**

947   MTC axons targeting LEC in a cleared 1 mm-thick coronal brain slice. Inset, axons of

948   tdTomato-expressing MTCs when counter-stained with DRAQ5 (blue) and displayed at larger

949   magnification. **(E)** Photographs of a 100 µm-thick coronal section from a P8 mouse depicting

950   retrogradely labeled neurons in the OB (right) after injection of FG into the LEC (left) at P3.

951   Inset, FG-labeled MTCs displayed at larger magnification. **(F)** Photographs of a 50 µm-thick

952   coronal section from a P8 mouse depicting retrogradely labeled neurons in LEC (right top)

953   after injection of FG into OB (100 µm-thick coronal section, left) at P4 (LEC, lateral entorhinal

954   cortex; PIR, piriform cortex; PMCo, posteromedial cortical amygdaloid nucleus; rf, rhinal

955   fissure; af, amygdaloid fissure). Counterstaining for GABA (red) shows no overlap between

956   GABA positive (red) and FG (white) labeled cell bodies (right bottom).

957   **Fig 2. Continuous and discontinuous patterns of oscillatory activity in the neonatal**

958   **olfactory bulb.**

959   **(A)** Digital photomontage reconstructing the track of the multi-site DiI-labeled recording

960   electrode (red) in a Nissl-stained (green) 100 µm-thick coronal section including the OB from

961   a P9 mouse. The dots (gray) show the position of the 16 recording sites of the silicon probe

962   and the recording channels (white) in the mitral cell layer (MCL) and external plexiform layer

963   (EPL) that were used for spike and LFP analysis, respectively. **(B)** LFP recording of the

964   oscillatory activity in the OB of a P10 mouse displayed band-pass filtered in different

965   frequency bands and accompanied by the wavelet spectrogram (white line represents time-

966   averaged power of the trace; white arrows point towards peak frequency values) as well as

34

967   simultaneously recorded MUA (high-pass filter >400 Hz) and respiration. **(C)** Characteristic

968   slow continuous oscillatory activity and theta bursts from the trace shown in b when

969   displayed at higher magnification. Insets, continuous oscillatory activity in relationship with

970   respiration (left, blue) and a discontinuous theta burst (right, red). **(D)** Power spectra (mean ±

971   SEM) of LFP in OB during non-burst activity (blue) and discontinuous bursts (red) as well as

972   of theta bursts normalized to non-bursting activity (purple). The respiration frequency was

973   depicted as horizontal bar and expanded at larger scale (top). **(E)** Temporal relationship

974   between neuronal firing and network oscillations in OB. Left, histogram showing the

975   percentage of spikes occurring during theta burst for all clustered units. Right, box plot

976   depicting the firing rates of OB units during non-burst periods and theta burst periods. Gray

977   dots and lines correspond to individual cells (Wilcoxon signed-rank test, ***$p < 0.001$). **(F)**

978   Histograms depicting the phase locking of OB cells to RR (left) and theta activity (right). Only

979   significantly locked cells were used for analysis.

980   **Fig 3. Effects of optogenetic silencing of MTCs on the patterns of oscillatory activity in**

981   **the neonatal OB.**

982   **(A)** Photograph of the brain of a P8 cre-positive Tbet-cre;ArchT-EGFP mouse (left) showing

983   EGFP-fluorescent MTCs cell bodies and their projections. **(B)** Left, photograph of a 100 µm-

984   thick coronal section including the OB from a P8 cre-positive Tbet-cre;ArchT-EGFP mouse.

985   The position of recording sites in MCL and EPL layers is marked by white squares. The light

986   guide ending just above the recording sites is shown in gray. The iso-contour lines of light

987   spreading calculated using Monte Carlo simulation are shown in yellow. Right, propagation of

988   light intensity in the brain as predicted by Monte Carlo simulation. Yellow lines correspond to

989   the iso-contour lines for light power of 1 and 10 mW/mm^2, respectively. **(C)** Neuronal firing

990   (SUA) and LFP band-pass filtered for different frequency bands (broad 1-100 Hz, RR 2-4 Hz,

991   theta 4-12 Hz) in response to light (yellow, 594 nm) stimulation of MTCs in a P8 cre-positive

992   Tbet-cre;ArchT-EGFP mouse. Traces are accompanied by the color-coded wavelet

993   spectrogram of LFP shown at identical timescale. **(D)** Raster plots and peri-stimulus time

994   histograms displaying the firing of MTCs in response to light stimulation. The color-coded bar

995   (bottom) displays the fraction of cells that responded with a firing decrease during stimulus

996   (red), constant firing during stimulus but a firing increase post-stimulus (blue) and unchanged

997   firing rate (white). **(E)** Box plots displaying the absolute power before and during light

998   stimulation in cre-positive pups (left) and the relative change of RR activity in neonatal OB of

999   cre-positive and cre-negative mice (right). Gray dots and lines correspond to individual

1000   animals. **(F)** Same as E for discontinuous theta bursts (**p < 0.01, left: signed-rank test, right:

1001   rank-sum test).

1002   **Fig 4. Continuous and discontinuous patterns of oscillatory activity in the neonatal**

1003   **LEC.**

1004   **(A)** Digital photomontage reconstructing the track of the multi-site DiI-labeled recording

1005   electrode (red) in a Nissl-stained (green) 100 µm-thick coronal section including LEC from a

1006   P9 mouse. The gray dots show the position of the 16 recording sites. (PRh, perirhinal cortex;

1007   LEC, lateral entorhinal cortex; PIR, piriform cortex; rf, rhinal fissure; af, amygdaloid fissure).

1008   **(B)** LFP recording of the oscillatory activity in LEC of a P10 mouse displayed band-pass

1009   filtered in different frequency bands and accompanied by the wavelet spectrogram (white line

1010   represents time-averaged power of the trace) as well as simultaneously recorded MUA (high-

1011   pass filter >400 Hz) and respiration. **(C)** Characteristic slow continuous oscillatory activity

1012   and theta bursts from the trace shown in B when displayed at higher magnification. **(D)**

1013   Power spectra (mean ± SEM) of LFP in LEC during non-burst activity (blue) and

1014   discontinuous bursts (red) as well as of theta bursts normalized to non-bursting activity

1015   (purple). The respiration frequency was depicted as horizontal bar and expanded at larger

1016   scale (top). **(E)** Temporal relationship between neuronal firing and network oscillations in

1017   LEC. Left, histogram showing the percentage of spikes occurring during theta burst for all

1018   clustered units. Right, box plot depicting the firing rates of LEC units during non-burst periods

1019   and theta burst periods. Gray dots and lines correspond to individual cells (Wilcoxon signed-

1020   rank test, ***p < 0.001). **(F)** Histograms depicting the phase locking of LEC neurons to RR

1021   (left) and theta activity (right). Only significantly locked cells were used for analysis.

1022

Fig 5. Frequency-dependent functional coupling between neonatal OB and LEC.

(A) Characteristic traces of band-pass filtered LFP recorded simultaneously in OB (top) and LEC (bottom) of a P9 mouse, displayed together with wavelet spectrograms showing the frequency content. Note the temporal correlation between discontinuous theta bursts in both areas. **(B)** Boxplots displaying RR power (top, green) and theta burst power (bottom, purple) in OB and LEC. Gray lines and dots correspond to individual pups. (*p<0.05, Wilcoxon signed-rank test). **(C)** Plot of imaginary part of coherence between OB and LEC showing prominent peaks in RR and theta band. The gray line corresponds to the significance threshold as assessed by Monte Carlo simulation. **(D)** Histograms of phase differences between RR (left, green) and theta (right, purple) activity recorded simultaneously in OB and LEC. **(E)** Left, bar diagram displaying the percentage of OB units coupled to the RR (green) and theta bursts (purple) in LEC and the percentage of LEC units coupled to the RR (green) and theta bursts (purple) in OB. Right, box plot showing the coupling strength of OB cells significantly locked to LEC oscillations (green: RR, purple: theta bursts) and of LEC cells significantly locked to OB oscillations (green: RR, purple: theta bursts). Gray dots correspond to individual cells (χ^2 test of proportions ***p < 0.001). **(F)** Histograms showing the distribution of preferred phases of LEC cells significantly locked to RR (left) and OB theta bursts (right) in neonatal OB. For comparison, histograms of OB cells locked to the respective OB rhythm are plotted as white bars. **(G)** Histograms showing the distribution of preferred phases of OB cells significantly locked to RR (left) and theta bursts (right) in neonatal LEC. For comparison, histograms of LEC cells locked to the respective LEC rhythm are plotted as white bars.

Fig 6. Effects of pharmacological blockade of neuronal firing in OB on patterns of oscillatory activity in OB-LEC circuits.

(A) Schematic drawing of experimental protocol. **(B)** Photograph of the brain of a P10 mouse showing the confinement of injections to one hemisphere of the OB. For visualization, the same volume of methylene blue was used. **(C)** Characteristic LFP traces (black, filtered 1-100 Hz) recorded in OB (top) and LEC (bottom) of a P9 mouse before (left) and after (right)

1051   lidocaine infusion, displayed together with the wavelet spectrograms of the LFP and

1052   simultaneously recorded MUA. **(D)** Top, mean MUA firing rate in OB (left) and LEC (right)

1053   before and after lidocaine infusion. The time of infusion is considered 0. Bottom, box plots

1054   displaying the mean MUA in OB (left) and LEC (right) before and after lidocaine infusion

1055   (Friedmann test, Wilxocon signed-rank test with Bonferroni correction for post-hoc

1056   comparison, *p<0.0071). **(E)** Box plots displaying the power of RR activity in OB and LEC as

1057   well as the mean OB-LEC coherence in the RR band before and after lidocaine infusion.

1058   Gray dots and lines correspond to individual animals (Wilcoxon signed-rank test, *p < 0.05;

1059   **p < 0.01). **(F)** Same as E for the theta burst activity in neonatal OB and LEC.

1060   **Fig 7. Odor-triggered activity patterns in OB of neonatal mouse.**

1061   **(A)** Characteristic LFP traces (band-pass filtered 1-100 Hz) recorded in OB (top) and LEC

1062   (bottom) of a P9 mouse before (baseline, left) and after application of odors (saline, middle;

1063   octanal, right) displayed together with simultaneously recorded MUA. **(B)** Box plots showing

1064   odor-evoked changes in the amplitude of RR (left), theta (middle) and beta (right) activity in

1065   OB when normalized to baseline. **(C)** Same as B for LEC. **(D)** Odor-evoked relative changes

1066   in OB-LEC coherence in RR (left), theta (middle) and beta (right) band when normalized to

1067   baseline. Gray dots correspond to individual trials. (Kruskal-Wallis H test, Wilcoxon rank-sum

1068   test with Bonferroni correction as post-hoc test, *p<0.0167).

1069   **Fig 8. Schematic diagram of structural and functional coupling within OB-LEC**

1070   **networks of neonatal mice.**

1071   Mutual axonal projections (red) connect neonatal OB and LEC. In OB of neonatal mice,

1072   continuous air flow-dependent RR and discontinuous MTC-driven theta bursts represent the

1073   two major patterns of oscillatory activity. They are augmented by olfactory stimuli (blue) that

1074   additionally evoke beta oscillations. OB activity boosts the oscillatory entrainment of neonatal

1075   LEC that, in turn, might drive the limbic circuits during development.
