Role of interaction network topology in controlling microbial population in consortia

Xining Ren   Richard M. Murray

Abstract—Engineering microbial consortia is an important new frontier for synthetic biology given its efficiency in performing complex tasks and endurance to environmental uncertainty. Most synthetic circuits regulate populational behaviors via cell-to-cell interactions, which are affected by spatially heterogeneous environments. Therefore, it is important to understand the limits on controlling system dynamics and provide a control strategy for engineering consortia under spatial structures. Here, we build a network model for a fractional population control circuit in two-strain consortia, and characterize the cell-to-cell interaction network by topological properties, such as symmetry, locality and connectivity. Using linear network control theory, we relate the network topology to system output's tracking performance. We analytically and numerically demonstrate that the minimum network control cost for good tracking depends on locality difference between two cell population's spatial distributions and how strongly the controller node contributes to interaction strength. To realize a robust consortia, we can manipulate the environment to form a strongly connected network. Our results ground the expected cell population dynamics in its spatially organized interaction network, and inspire directions in cooperative control in microbial consortia.

I. INTRODUCTION

Synthetic biology provides biotechnologies to engineer cells and organisms with pre-specified functions. Interest has recently emerged in designing synthetic circuits for collective behaviors in consortia, which include metabolites trading for mutualism in co-culture [1], programmed predation and rescue in prey-predator systems [2], and other competition or coordination in sender-receiver systems [3]. Multiple populations communicate with each other, divide labor and perform subtasks so that the overall control goal can be achieved in consortia. Therefore, engineering microbial consortia will enrich the potential of synthetic gene circuits in gene therapy, biofuel and other applications [4], [5].

Realizing proposed behaviors of multiple interacting strains on diverse temporal or spatial scales relies on two perspectives. First, synthetic gene circuits need to be engineered in each population to exhibit certain functions. Second, it is essential to engineer cell-to-cell interaction to construct consortia. Bacteria have evolved interactions by producing, exporting and sensing autoinducers that are mostly small and diffusible signaling molecules. This phenomenon is called quorum sensing, where the accumulation of autoinducers in environment provides a good measure of cell population density and can quantitatively affect a cell's gene expression or trigger a differentiation process [6]. Existing work in ecology demonstrate that the cooperative behaviors in consortia rely on the spatial distribution of multiple cell agents and the structure of their interaction [7]. Efforts in network science provide a good approach to define this spatial cell-to-cell interaction as a network graph, to describe the consortia as an integrated system and to analyze population level performance and robustness by graph metrics [8]. As multiple cell populations are usually spatially organized and form heterogeneous consortia, understanding the relationship between cell-to-cell interaction network topology and cooperative dynamics in consortia is particular useful for system-level controller design in synthetic biology. By linking the interaction network topology to populational behaviors, one can optimize control objectives by rearranging the spatial distribution of cell agents, rewiring intercellular quorum sensing pathways, reweighting interaction signaling strengths and turning on or off the synthetic circuits in certain cell agents via external chemical stimulations.

Recent research on engineering microbial consortia mainly focuses on intracellular circuit design [9], [10]. These papers assume that cell populations are well-mixed, because it is elusive how structured network properties enhance control potentials in spatial-organized consortia. Here, we propose a network control strategy of existing synthetic circuits and take different spatial distributions of cell agents and their interaction structures into consideration. Although the principles derived here are based on a specific synthetic circuit that regulates cell population via toxin/antitoxin mechanism, they can be applied to a more general design framework, where the autoinducers in quorum sensing and their regulated products are included in a feedback controller at DNA, transcriptional and translational levels.

This paper is organized as follow. In Section II, we give an overview of the biological design of the synthetic circuit. It performs as a fractional population controller in E.coli [11], [12]. In Section III, we construct a reaction-diffusion model under spatial settings to describe the full dynamics of the system. In Section IV, we derive a reduced network model and define network topology properties such as symmetry, locality and connectivity. In Section V, we use linear network control theory to obtain a mathematical approximation of the closed-form solution for system steady state. Our results include a computational simulation and a mathematical proof relating the interaction network topology properties to steady state cell populations. The results also include a graph representation of network topologies that are robust to perturbations. We summarize the main findings of the paper discuss future work in Section VI.

population control circuit. Two cell populations communicate via two quorum sensing signals $S_1$ and $S_2$. In Cell1, $S_1$ activates toxin $T$ and $S_2$ activates antitoxin $A$ production to further regulate cell death and rescue processes through $T$ and $A$ sequestration. Similar reactions occur in Cell2, (b) describes the spatial setting of microcolonies cultured on an agar plate. Two cell populations are grown in separate wells where quorum sensing signals can diffuse and accumulate in environment to form a certain concentration distribution on 2D space. (c) describes the diffusion of AHL molecules and the color shades represent AHL concentration levels. Cell microcolonies are represented as point sources of AHLs and the concentration of AHLs decreases along distance to the source following the diffusion law. The colored lines between microcolonies represent inter-strain or intra-strain interactions.

Our proposed model consists of $2N$ sets of ODEs of intracellular chemical reactions and 2 sets of PDEs describing AHL diffusion and degradation in the environment. Species and reactions are shown in Table I. The model is written as

$$\frac{dc_i^{(1)}}{dt} = k_c \left(1 - \frac{c_i^{(1)}}{C_{\text{max}}} \right) c_i^{(1)} - dc T_i^{(1)} C_i^{(1)} - p c_i^{(1)}$$

$$\frac{dT_i^{(1)}}{dt} = k_r \left(\frac{S_i^{(1)}}{\left|r_i^{(1)}\right|} \right)^2 - k^+ T_i^{(1)} A_i^{(1)} - d_r T_i^{(1)}$$

$$\frac{dA_i^{(1)}}{dt} = k_A \left(\frac{S_i^{(2)}}{\left|r_i^{(1)}\right|} \right)^2 - k^+ T_i^{(1)} A_i^{(1)} - d_A A_i^{(1)}$$

$$\frac{dS_i^{(1)}}{dt} = \sum_{p=1}^N \frac{k_S C_p^{(1)}}{r_{i_0}^{(1)}} \left(r_{i_0}^{(1)}\right) + k_{\text{diff}} \nabla^2 S_i^{(1)}(r,t)$$

$$0 \leq |r| \leq L, S_i^{(1)}(r,0) = 0, S_i^{(1)} \left(L \frac{r}{|r|}, t\right) = 0$$

$$\frac{dS_i^{(2)}}{dt} = \sum_{q=1}^N k_{S_i C_q^{(2)}} \left(r_{i_0}^{(1)}\right) + k_{\text{diff}} \nabla^2 S_i^{(2)}(r,t)$$

$$0 \leq |r| \leq L, S_i^{(2)}(r,0) = 0, S_i^{(2)} \left(L \frac{r}{|r|}, t\right) = 0.$$

For well-mixed consortia, shown in Fig. 2(a), the reaction-diffusion model reduces to ODEs by setting the distance between wells to be value 0 and having identical dynamics of all cells of the same strain. Fig. 2(b) shows that the steady state of the relative ratio between two populations matches reference with nearly zero error.

For spatially distributed consortia, we can reduce the full model into a simplified one that captures intra/inter-strain interactions. We first reduce the PDEs using quasi-steady state assumptions, and then reduce the ODEs by linearization. AHL molecules diffuse fast on an agar plate [17] so the timescale of AHL dynamics is smaller than cell growth dynamics. We assume the spatial distribution of AHL reaches a quasi-steady state. Since AHL molecules only affect cell growth when they get absorbed and react with intracellular chemicals, we solve for AHL quasi-steady state at each $Cell_1$ microcolony center as

$$S^{(1)}_j(r) = \frac{K_{diff}}{r_y} \sum_{p=1}^{N} f \left( r^{(1)}_p - r^{(1)}_j \right) C^{(1)}_p,$$

$$S^{(2)}_j(r) = \frac{K_{diff}}{r_y} \sum_{q=1}^{N} f \left( r^{(2)}_q - r^{(1)}_j \right) C^{(2)}_q,$$

where $K_{diff} = \frac{k_S}{2\sqrt{d_{diff}(d_y + Y)}}$.

The cell population is regulated via toxin and antitoxin. Since the toxin-antitoxin pair performs strong sequestration, there is a timescale separation of toxin dynamics from cell growth [18]. By performing quasi-steady state approximation and linearization on ODEs in equation (1), we obtain the linearized model in forms of

$$\frac{dC^{(1)}_i}{dt} = k_T d_C \left( -\frac{1}{r_y} S^{(1)}_i \left( r^{(1)}_i \right) + S^{(2)}_i \left( r^{(1)}_i \right) \right),$$

$$\frac{dC^{(2)}_j}{dt} = k_T d_C \left( \frac{1}{r_y} S^{(1)}_j \left( r^{(2)}_j \right) - S^{(2)}_j \left( r^{(2)}_j \right) \right).$$

We plug equation (2) into equation (3), and obtain the simplified model as

$$\frac{dC^{(1)}_i}{dt} = K_C \left( -\frac{1}{r_y} \sum_{p=1}^{N} f \left( r^{(1)}_p - r^{(1)}_i \right) C^{(1)}_p \right),$$

$$\frac{dC^{(2)}_j}{dt} = K_C \left( \frac{1}{r_y} \sum_{p=1}^{N} f \left( r^{(1)}_p - r^{(2)}_j \right) C^{(1)}_p - \sum_{q=1}^{N} f \left( r^{(2)}_q - r^{(2)}_j \right) C^{(2)}_q \right),$$

where $K_C = \frac{K_{diff} k_T d_C}{d_T}$.

Equation (4) only contains cell population at discrete well positions as variables. $K_C$ is a lumped parameter characterizing cell growth rate. In both $Cell_1$ and $Cell_2$ dynamics, there is a negative term representing intra-strain interaction because cells of the same strain would activate self-killing to avoid growth explosion; there is a positive term representing inter-strain interaction because cells get rescue from the other strain to keep growing. All interaction strengths are functions of the distance between involved microcolonies, so that the model can be derived into a spatial network formula.

IV. NETWORK MODEL AND TOPOLOGY PROPERTIES

We represent a network model for spatially distributed consortia via a fully connected graph $G = \{V,E\}$ where $V = \{1,2,\ldots,2N\}$ and $E \subseteq V \times V$ are sets of vertices and edges. The vertices are microcolonies and edges are cell-to-cell interactions via quorum sensing. We define the weighted adjacency matrix $D = [d_{ij}] \in \mathbb{R}^{2N \times 2N}$. The element $d_{ij}$ represents the interaction strength associated with the corresponding edge in $E$.

The network graph can be partitioned into four subnetwork graphs: $G_{11}$, $G_{22}$ containing microcolonies of one cell strain as nodes and interaction edges among nodes, and $G_{12}$, $G_{21}$ containing microcolonies of both strains as nodes but only interaction edges between different strains. The matrix $D$
can be partitioned into four blocks and they are referred as intra-strain interaction strength matrix \(-D_{11}, -D_{22}\), and inter-strain interaction strength matrix \(D_{12}, D_{21}\). We associate a set of real values of cell population densities of each microcolony as system states, denoted as \(C_{i}^{(1)}, C_{j}^{(2)}, i, j = 1, 2, \ldots, N\), and combine these states into a big network state vector \(X = [X^{(1)}, X^{(2)}]^T = [C_{1}^{(1)}, \ldots, C_{N}^{(1)}, C_{1}^{(2)}, \ldots, C_{N}^{(2)}]^T \in \mathbb{R}^{2N}\). The output \(y\) is the relative ratio between two cell population densities. We use \(l_2\) norm for all following discussions.

We identify the element \(d_{ij}\) of matrix \(D\) as \(K_{Ci} f (r_j - r_i)\) according to equation (4) and derive the network state dynamics as in

\[
\begin{align*}
\frac{d}{dt} \begin{bmatrix} X^{(1)} \\ X^{(2)} \end{bmatrix} &= \begin{bmatrix} -\frac{1}{r_i} D_{11} & D_{12} \\ \frac{1}{r_i} D_{21} & -D_{22} \end{bmatrix} \begin{bmatrix} X^{(1)} \\ X^{(2)} \end{bmatrix} + \begin{bmatrix} -D_{11} \\ D_{21} \end{bmatrix} u, \\
y &= \begin{bmatrix} X^{(1)} \\ X^{(2)} \end{bmatrix}
\end{align*}
\]

(5)

Our control goal is to set the output to track an external reference \(r_y\), set by relative IPTG inducer level. We add a network control input \(u \in \mathbb{R}_+^N\) into the system, and it is implemented as an extra production of AHL1 in each Cell1 well. Therefore, the coefficient matrix of \(D\) depends on \(D_{11}\) and \(D_{22}\) because they represent interactions activated by Cell1. When two cell populations are grown on a plate, the spatially structured interaction network may require a control input \(u\) to steer the system to the steady state that satisfies the reference \(r_y\), We define the control cost of \(u\) as

\[EN(u) = \sum_{i=1}^{N} u_i,\]

where \(u_i\) are elements of \(u\), \(i = 1, 2, \ldots, N\).

Consider a network \(G = \bigcup G_{ij}, i, j = 1, 2\) with adjacency matrix \(D = \begin{bmatrix} -D_{11} & D_{12} \\ D_{21} & -D_{22} \end{bmatrix}\). We define properties such as symmetry, locality and connectivity in the context of quorum sensing in microbial consortia.

**Definition 1.** If \(D_{11} = D_{22}, D_{12} = D_{21}\), then \(G\) is a symmetrical network.

**Remark.** Given the assumption that two AHLs diffuse and get degraded at the same rate, the geometric symmetry of spatially distributed consortia is equivalent to network topology symmetry.

**Definition 2.** The locality of a subnetwork \(G_{ii}\) is defined as \(\|D_{ii}\|, i = 1, 2\).

**Remark.** Locality measures the intra-strain interaction strength. If microcolonies are grown closer on the plate, they form a more localized community.

**Definition 3.** The connectivity of a subnetwork \(G_{ij}\) is defined as \(\|D_{ij}\|, i, j = 1, 2, i \neq j\). Connectivity of a network \(G\) is defined as \(\|D_{ij}\| + \|D_{ji}\|, i, j = 1, 2, i \neq j\).

**Remark.** Connectivity represents the inter-strain interaction strength. If two cell populations are more isolated than isolated, the network is strongly connected with large connectivity. Otherwise, the network is weakly connected.

V. RELATIONSHIP BETWEEN TOPOLOGY AND SYSTEM BEHAVIORS

The proposed synthetic circuit ensures good performance in regulating relative ratio of cell population for well-mixed consortia. The results in Fig. 2(b) and from previous work shows that the output \(y\) matches the reference \(r_y\) with negligible error [11]. However, The output’s accurate tracking performance does not maintain for spatially distributed consortia and an extra network control input is needed. By designing the interaction network topology, we can minimize the cost to achieve population control by solving the following problem.

\[
\begin{align*}
\text{minimize} & \quad EN(u) \\
\text{subject to} & \quad G \in \{G\}, \\
& \quad y_w \to r_y, t \to \infty \\
& \quad u = [1, \ldots, 1]^T u.
\end{align*}
\]

We first set the network control input \(u\) to be zero and solve for output dynamics of all potential network topologies to see the limits on performing good tracking. Secondly, we look for certain topologies that need small control efforts by solving equation (6). Then we can show how network properties of symmetry, locality and connectivity contribute to the minimum required network control cost.

Given a fixed network topology, there usually exist cost
favorable nodes that require less control effort than other nodes to achieve good tracking. It could help us efficiently selecting microcolonies to induce extra AHL production as control input by solving the following equation.

\[
\begin{align*}
\text{minimize} & \quad EN(\mathbf{u}) \\
\text{subject to} & \quad G = \{V,E\} \text{ with } D = \begin{bmatrix} -D_{11} & D_{12} \\ D_{21} & -D_{22} \end{bmatrix} \\
& \quad y_{\infty} \rightarrow r_y, t \rightarrow \infty \\
& \quad \mathbf{u} = [0, \ldots, 0, 1, 0, \ldots, 0]^T. 
\end{align*}
\]  

(7)

In this section, we present propositions, and give math proof sketch and simulation results. To better demonstrate, we assume the inter-strain interaction strength between adjacent microcolonies from Cell1 to Cell2 is equal to the strength from Cell2 to Cell1, in other words, \(D_{12} = D_{21}\); all microcolonies have fixed position within the 2N wells, so we have \(|D| = \text{const}|; there is an unique steady state solution for all network topologies, denoted as \(X_{\infty}\) and \(y_{\infty}\).

**A. Network symmetry determines system tracking accuracy**

**Proposition 1.** If network G is symmetrical, then the system in equation (5) requires no network control cost to achieve good tracking of reference.

**Proof** Since \(G\) is symmetrical, we have \(D_{11} = D_{22}, D_{12} = D_{21}\). Let \(\mathbf{u} = \mathbf{0}\), the system dynamics is reduced to

\[
\frac{d}{dt} \begin{bmatrix} X^{(1)} \\ X^{(2)} \end{bmatrix} = \begin{bmatrix} -\frac{1}{r_y} D_{11} & D_{12} \\ \frac{1}{r_y} D_{21} & -D_{22} \end{bmatrix} \begin{bmatrix} X^{(1)} \\ X^{(2)} \end{bmatrix}. 
\]  

(8)

By subtraction of \(X^{(1)}\) and \(X^{(2)}\) dynamics in equation (8), we can obtain the dynamics of \(\Delta X = X^{(1)} - X^{(2)}\) as

\[
\frac{d(\Delta X)}{dt} = (D_{11} + D_{12}) \left( X^{(1)} - \frac{1}{r_y} X^{(1)} \right). 
\]  

(9)

The steady state is solved and it matches the reference.

\[
y_{\infty} = \frac{\|X^{(1)}_{\infty}\|}{\|X^{(2)}_{\infty}\|} = r_y 
\]  

(10)

**Simulation** We run simulations on the full reaction-diffusion model in equation (1). We set \(N = 4, r_y = 1\) and \(\mathbf{u} = \mathbf{0}\). We present three different network topologies that are symmetrical, labeled as sym1, sym2 and sym3 in graph representations and show the system state values (cell population densities on 2D space) at steady state in Fig. 3(a)-3(c). Fig. 4(a) shows the output’s dynamics. Computational results verify the proposition where the output converges to value 1 without extra network control cost.

**B. Locality identifies topology that requires minimum control cost**

**Proposition 2.** Given a network \(G\), the minimal network control cost for system in equation (5) is achieved by topologies with minimal locality difference between subnetworks \(G_{11}\) and \(G_{22}\).

\[
\arg\min_{\mathbf{u}} EN(\mathbf{u}) = \arg\min_{\mathbf{u}} \|D_{22} - D_{11}\| 
\]  

(11)

**Proof** Let \(\mathbf{u} = [1, \ldots, 1]^T.\) By subtraction of \(X^{(1)}\) and \(X^{(2)}\) dynamics in equation (5), we can obtain

\[
\frac{d(\Delta X)}{dt} = -(D_{11} + D_{21}) \left( \frac{1}{r_y} X^{(1)} + u \right) + (D_{12} + D_{22}) X^{(2)}. 
\]  

(12)

Since there exist a unique solution at steady state, we have \(D_{11} + D_{21}\) is invertible and solve for the steady state.

\[
X^{(1)}_{\infty} = r_y (D_{11} + D_{21})^{-1} (D_{12} + D_{22}) X^{(2)}_{\infty} - r_y u 
\]  

(13)

To achieve reference, we let \(y_{\infty} = r_y\) and solve for the minimum required control input cost by giving inequalities.

\[
EN(\mathbf{u}) = N \|\mathbf{u}\| \geq 2N \frac{\|X^{(2)}_{\infty}\|}{\|D\|} ||D_{22}|| - ||D_{11}|| 
\]  

(14)

When \(||D_{22}|| - ||D_{11}|| = 0\), one special case is discussed in Proposition 1 and we have \(EN(\mathbf{u}) = 0 \geq 0\). We can minimized the control cost by minimizing network locality difference.

**Simulation** We present three different network topologies that are asymmetrical, labeled as asym1, asym2 and asym3 in Fig. 3(d)-3(f). For all these topologies, \(G_{22}\) are more locally distributed than \(G_{11}\), which satisfy \(||D_{22}|| - ||D_{11}|| > 0\). Fig. 3(d)-3(f) demonstrate the system state values (cell population densities on 2D space) at steady state without network control input \(\mathbf{u}\). They show \(G_{22}\) population occupies a lower fraction than \(G_{11}\), in other words, \(y_{\infty} > r_y\). We then run simulations with network control input added to the systems and compare the output dynamics in Fig. 4(b). All three systems perform good tracking of the reference with different levels of control cost. We analyze all potential topologies for \(N = 4\) spatial settings and plot the relationship between locality difference and steady state output without control input \(\mathbf{u}\) in Fig. 4(c), and the relationship between locality difference and minimum required control cost in Fig. 4(d). We altered the absolute distance unit values between adjacent wells and the relationships maintain.

**C. Locality and connectivity contribution identifies energetically favorable controller node**

**Proposition 3.** Given a network \(G\), the selection of the most cost favorable node depends on the node’s contribution to locality and connectivity.

\[
\arg\min_{i} EN(\mathbf{v}_i^{(1)}) = \max_{i} (D_{11} + D_{21}) \left[ 0, \ldots, 0, 1_{i=th}, 0, \ldots, 0 \right]^T 
\]  

(15)

**Proof** Let \(\mathbf{u} = [0, \ldots, 0, 1_{i=th}, 0, \ldots, 0]^T.\) Let \(v_i^{(1)}\) and \(v_i^{(2)}\) denote the \(i^{th}\) column of \(D_{11}\) and \(D_{21}\) as

\[
\begin{align*}
& v_i^{(1)} = D_{11} \left[ 0, \ldots, 0, 1_{i=th}, 0, \ldots, 0 \right]^T, \\
& v_i^{(2)} = D_{21} \left[ 0, \ldots, 0, 1_{i=th}, 0, \ldots, 0 \right]^T. 
\end{align*}
\]  

(16)

By subtraction of \(X^{(1)}\) and \(X^{(2)}\) dynamics in equation (5), we can obtain the dynamics of \(\Delta X = X^{(1)} - X^{(2)}\) as
To achieve reference, we let locality difference require more control effort to track reference. Required network control cost and the difference between interaction network localities of two cell populations. The dots are simulated data from all potential topologies of consortia cultured in $2N=2 \times 4$ wells, and the dashed lines are fitted linear functions. Different colors represent results for different physical distance unit values between two adjacent wells. The plot shows that more localized cell population tends to occupy a lower population fraction. (d) describes the relationship between minimum required network control cost and the difference between interaction network localities of two cell populations. The plot shows networks that have large locality difference require more control effort to track reference.

$$
\frac{d(X)}{dr} = -(D_{11} + D_{21}) \frac{1}{r_1} X^{(1)} + (D_{12} + D_{22}) X^{(2)} - \left( v^{(1)}_i + v^{(2)}_i \right) u
$$

(17)

We can solve for the solution as

$$
X^{(1)}_{\infty} = r_1 (D_{11} + D_{21})^{-1} (D_{12} + D_{22}) X^{(2)}_{\infty} - (D_{11} + D_{21})^{-1} r_2 \left( v^{(1)}_i + v^{(2)}_i \right) u.
$$

(18)

To achieve reference, we let $y_{\infty} = r_1$ and solve for the minimum required control input cost as

$$
EN(u) = \|u\| = \left\| X^{(2)}_{\infty} \right\| \left\| D_{22} \right\| - \left\| D_{11} \right\| \frac{1}{\left| v^{(1)}_i + v^{(2)}_i \right|}.
$$

(19)

Given a network topology, $D$ is fixed and we can minimize the control cost by picking one favorable node that contributes most to locality and connectivity.

Simulation We demonstrate the proposition by adding a constant network control input onto each node of a fixed network topology, and measure the control cost required for steering the system output to track the reference. Fig. 5 shows an example of asym1 network topology. The results show that the maximizer and minimizer of function $\left\| (D_{11} + D_{21}) \left[ 0, \cdots, 0, 1, -r_1, 0, \cdots, 0 \right]^T \right\|$ are the most and least cost favorable nodes. The data show the worst selection of control nodes can result in 20% more of cost burden.

D. Connectivity improves network robustness

In microbial consortia, fluctuations of chemicals in environment can cause uncertainly and noises in cell growth. To investigate the robustness of our synthetic circuit and interaction network, we introduce a metabolic burden change as a disturbance to cell growth, and assess system output’s adaptation as a measure of robustness. For all potential network topologies, we decrease the growth rate of Cell$_1$ populations after the system achieves some steady states, and measure the output recovery error when the systems achieves steady states again. Fig. 6(a) shows that topologies of large connectivity are more adaptive to perturbations. Fig. 6(b) shows that the most robust network topology is sym3 where all Cell$_1$ and Cell$_2$ microcolonies are strongly connected, and the least robust network topology describes consortia that contain two rather isolated populations.

From an ecological perspective, our proposed population regulation circuit performs a similar mutualistic symbiosis. Research has shown that mixed consortia are more robust to environmental perturbations and more resistant to invaders [7]. Our model captures such property by relating interaction network connectivity to robustness. In network graph representation, it is clear to see strongly connected topologies correspond to mixed consortia and weakly connected topologies correspond to isolated consortia.

VI. DISCUSSION

In this paper, we propose a network control strategy to achieve population regulation for spatially distributed microbial consortia. Given an intracellular synthetic circuit, we focus on a physically meaningful understanding of how cell-to-cell interaction network topology governs control potential. We build a network model based on reaction-diffusion equations, map system behaviors to topology properties and formulate the network control question as optimization...
problems. The propositions inform links from topology to dynamics analytically and numerically, and provide network level design guidance for better performance with less control efforts in synthetic biology problems.

We note that our work is based on a specific synthetic circuit, but the theory and analysis can be adopted to a more generalized problem in synthetic biology. For any functional intracellular circuit that requires cell-to-cell interaction, our approach is useful for finding out constraints on spatial-temporal dynamics. It is important to discuss about such theoretical limitations on population level synthetic system design, such as biofilm formation. For future work, we would like to gain more intuition about the role of topology in complex networks by applying our results to other systems in microbial consortia.
