Methodologic Issues in Doubly Labeled Water Measurements of Energy Expenditure

During Very Low-Carbohydrate Diets

Abstract

Background: Very low-carbohydrate diets have been reported to substantially increase human energy expenditure as measured by doubly labeled water (DLW) but not by respiratory chambers. Do the DLW data reflect true physiological differences that are undetected by respiratory chambers? Alternatively, are the apparent DLW energy expenditure a consequence of failure to fully account for respiratory quotient (RQ) differences between diets?

Objective: To examine energy expenditure differences between diets varying drastically in carbohydrate and to quantitatively compare DLW data with respiratory chamber and body composition measurements within an energy balance framework.

Design: DLW measurements were obtained during the final two weeks of month-long baseline (BD; 50% carbohydrate, 35% fat, 15% protein) and isocaloric ketogenic diets (KD; 5% carbohydrate, 80% fat, 15% protein) in 17 men with BMI 25-35 kg/m². Subjects resided 2d/week in respiratory chambers to measure energy expenditure (EEchamber). DLW expenditure was calculated using chamber-determined respiratory quotients (RQ) either unadjusted (EE_{DLW}) or adjusted (EE_{DLW\Delta RQ}) for net energy imbalance using diet-specific coefficients. Accelerometers measured physical activity. Body composition changes were measured by dual-energy X-ray absorptiometry which were combined with energy intake measurements to calculate energy expenditure by balance (EE_{bal}).

Results: After transitioning from BD to KD, neither EE_{chamber} nor EE_{bal} were significantly changed (\Delta EE_{chamber}=24\pm30 \text{ kcal/d}; p=0.43 and \Delta EE_{bal}=-141\pm118 \text{ kcal/d}; p=0.25). Similarly, physical activity (-5.1\pm4.8\% ; p=0.3) and exercise efficiency (-1.6\pm2.4\% ; p=0.52) were not significantly changed. However, EE_{DLW} was 209\pm83 \text{ kcal/d} higher during the KD (p=0.023) but was not significantly increased when adjusted for energy balance (EE_{DLW\Delta RQ} =139\pm89 \text{ kcal/d};
p=0.14). After removing 2 outliers whose EE\textsubscript{DLW} were incompatible with other data, EE\textsubscript{DLW} and EE\textsubscript{DLWΔRQ} were marginally increased during the KD by 126±62 kcal/d (p=0.063) and 46±65 kcal/d (p=0.49), respectively.

**Conclusions:** DLW calculations failing to account for diet-specific energy imbalance effects on RQ erroneously suggest that very low carbohydrate diets substantially increase energy expenditure.
Introduction

There is a great deal of interest in whether very low-carbohydrate diets offer a “metabolic advantage” for weight loss by increasing total energy expenditure (1, 2) – a phenomenon predicted by the carbohydrate-insulin model of obesity (3, 4). In support of this concept, a highly-cited controlled feeding study in humans using the doubly labeled water (DLW) method found a substantial increase in average daily energy expenditure during a very low-carbohydrate diet compared with an isocaloric high-carbohydrate diet (5). However, such results are inconsistent with several controlled feeding studies employing respiratory chambers that failed to detect important energy expenditure differences between isocaloric diets varying in carbohydrate content (6-8).

Our recent controlled feeding inpatient study was the first to compare daily energy expenditure between isocaloric diets widely varying in carbohydrate content using both respiratory chambers and DLW (9). Our primary result was a small but statistically significant increase daily energy expenditure as measured by respiratory chamber (EE\textsubscript{chamber}) of 57 ± 13 kcal/d (P = 0.0004) after 17 men (25<BMI<35 kg/m\textsuperscript{2}) transitioned from a one-month inpatient run-in period consuming a moderate-carbohydrate baseline diet (BD) (50% carbohydrate, 35% fat, 15% protein) to a subsequent month-long inpatient period consuming an isocaloric ketogenic diet (KD) (5% carbohydrate, 80% fat, 15% protein). An exploratory aim of our study was to measure changes in average daily energy expenditure by the DLW method (EE\textsubscript{DLW}) and we reported a more substantial increase of 151 ± 63 kcal/d (P = 0.03 uncorrected for multiple comparisons) following the KD (9).
Some investigators who promote the carbohydrate-insulin model of obesity have discounted these EE\textsubscript{chamber} results and have reinterpreted our exploratory EE\textsubscript{DLW} data as underestimating the true physiological effect of very low carbohydrate diets which have been suggested to increase energy expenditure by 200-300 kcal/d (10, 11). However, there are methodological reasons why the energy expenditure calculated by the DLW method is impacted by dietary carbohydrate content that do not reflect true physiological differences. Specifically, the DLW method requires an estimate of the overall metabolic fuel utilization of the body as quantified by the average daily respiratory quotient (RQ). While it is widely known that RQ depends on the composition of the diet as well as the overall state of energy balance, it is less well appreciated that the energy imbalance adjustment of RQ also depends on dietary carbohydrate (12) and such adjustments are rarely employed in DLW calculations.

Here, we reanalyzed our DLW data taking account of the diet-specific energy imbalance adjustments of RQ used in the DLW method and highlight some key challenges to interpreting DLW data when comparing energy expenditure differences between diets varying in carbohydrate.

**Methods**

Details of the study and its approval by the Institutional Review Boards were reported previously (9). Briefly, 17 men with BMI between 25-35 kg/m\textsuperscript{2} provided informed consent and were admitted as inpatients to metabolic wards where they consumed a standard baseline diet (BD) composed of 50% energy from carbohydrate, 35% fat, and 15% protein for 4 weeks immediately followed by 4 weeks of an isocaloric very low-carbohydrate, ketogenic diet (KD) composed of...
5% carbohydrate, 80% fat, 15% protein. Body weight and height were measured to the nearest 0.1 kg and 0.1 cm, respectively, with subjects wearing a hospital gown and undergarments and following an overnight fast. Body fat was measured using dual-energy X-ray absorptiometry (DXA) scanners (Lunar iDXA, GE Healthcare, Madison, WI, USA).

Subjects spent two consecutive days each week residing in respiratory chambers to measure energy expenditure (EE_{chamber}). As described previously (9), during the BD period, the daily energy expenditure was calculated as follows:

\[
EE_{chamber} (\text{kcal}) = 3.88 \times VO_2 (\text{L}) + 1.08 \times VCO_2 (\text{L}) - 1.57 \times N (\text{g})
\]

where \(VO_2\) and \(VCO_2\) were the volumes of oxygen consumed and carbon dioxide produced, respectively, and \(N\) was the 24hr urinary nitrogen excretion measured by chemiluminescence (Antek MultiTek Analyzer, PAC, Houston, TX). During the KD period, the equations were adjusted to account for 24-hour urinary ketone excretion, \(K_{excr}\):

\[
EE_{chamber} (\text{kcal}) = 3.88 \times [VO_2 (\text{L}) - 0.32 (\text{L/g}) \times K_{excr} (\text{g})] + 1.08 \times VCO_2 (\text{L}) - 1.57 \times N (\text{g}) + 1.39 \times K_{excr} (\text{g})
\]

Energy efficiency of physical activity was measured in the respiratory chamber with subjects exercising at a constant, self-selected, level of moderate-intensity cycle ergometry.

Energy expenditure was calculated by energy balance (EE_{bal}) using the daily metabolizable energy intake (EI) and the measured rates of change of the body energy storage pools determined from measurements of fat mass (FM) and fat-free mass (FFM) by DXA at the beginning and end of each two-week BD and KD period coincident with the DLW measurements as follows:

\[
EE_{bal} = EI - \rho_{FFM} \frac{dFFM}{dt} - \rho_{FM} \frac{dFM}{dt}
\]
where $\rho_{FM} = 9300$ kcal/kg is the energy density of body fat mass, $\rho_{FFM} = 1100$ kcal/kg is the energy density of fat-free mass.

Energy expenditure was measured by DLW during the final two weeks of the BD and KD periods to allow sufficient time for fluid shifts as subjects adjusted to each diet. Subjects drank from a stock solution of $^2$H$_2$O and H$_2^{18}$O water in which 1 g of $^2$H$_2$O (99.99% enrichment) was mixed with 19 g of H$_2^{18}$O (10% enrichment). An aliquot of the stock solution was saved for dilution to be analyzed along with each set of urine samples. The water was weighed to the nearest 0.1 g into the dosing container. The prescribed dose was 1.0 g per kg body weight and the actual dose amounts were entered in the dose log. Spot urine samples were collected daily.

Isotopic enrichments of urine samples were measured by isotope ratio mass spectrometry. The average CO$_2$ production rate ($r$CO$_2$) was corrected for previously administered isotope doses (13), can be estimated from the rate constants describing the exponential disappearances of the labeled $^{18}$O and deuterated water isotopes ($k_O$ and $k_D$) in repeated spot urine samples collected over several days. We used the parameters of Racette et al. (14) with the weighted dilution space calculation, $R_{dil}$, proposed by Speakman (15):

$$rCO_2 = \left(\frac{N}{2.078}\right)(1.007k_O - 1.007R_{dil}k_D) - 0.0246r_{GF}$$

$$r_{GF} = 1.05(1.007k_O - 1.007R_{dil}k_D)$$

$$R_{dil} = \left[\left(\frac{N_D}{N_O}\right)_{ave} \times n + 1.034 \times 255\right]/(n + 255)$$

where $r_{GF}$ accounts for the fractionation of the isotopes and $(N_D/N_O)_{ave}$ is the mean of the $N_D/N_O$ values from the $n=17$ subjects.
In our previous report (9), we used the 24hr respiratory quotient, RQ, measured during the respiratory chamber stays to calculate energy expenditure (EE\textsubscript{DLW}) during the baseline period

was calculated as:

\[ EE_{DLW} (\text{kcal}) = \left[ \frac{3.85}{RQ} + 1.07 \right] \times rCO_2 (L) \]

During the KD period, EE\textsubscript{DLW} was calculated as:

\[ EE_{DLW} (\text{kcal}) = \left[ \frac{3.85}{RQ} + 1.07 \right] \times rCO_2 (L) - \left[ 3.85 \times 0.32 + 1.39 \right] \times K_{\text{exc}} (g) \]

However, because the energy expended outside the chamber was significantly greater than inside the chamber (9), the chamber RQ values did not accurately represent the overall RQ values during the DLW period. In other words, the relative magnitude of energy imbalance (EB) during the DLW period was different than the energy imbalance (EI-EE\textsubscript{chamber}) measured during the chamber stays. Therefore, we used the overall energy imbalance during the DLW period, defined by the rate of change of body energy stores, to adjust the chamber RQ measurements by an amount \( \Delta \text{RQ} \) as described in the Online Supplemental Materials:

\[ \Delta \text{RQ} = \lambda \times EB \]

where \( \lambda = 5.28 \times 10^{-5} \text{d/kcal} \) for the BD and \( \lambda = 9.17 \times 10^{-6} \text{d/kcal} \) for the KD.

Importantly, the value of \( \lambda \) is affected by dietary carbohydrate content, and, consequently, the energy equivalence of CO\textsubscript{2} produced in the DLW calculations differs between diets varying in carbohydrate for the same degree of energy imbalance.
Thus, the $\Delta RQ$ adjustment for each individual’s diet-specific state of energy imbalance results in the following calculation of DLW energy expenditure ($EE_{DLW\Delta RQ}$) during the baseline period:

$$EE_{DLW\Delta RQ} (\text{kcal}) = \left[ \frac{3.85}{(RQ + \Delta RQ)} + 1.07 \right] \times rCO_2 (L)$$

During the KD period, $EE_{DLW\Delta RQ}$ was calculated as:

$$EE_{DLW\Delta RQ} (\text{kcal}) = \left[ \frac{3.85}{(RQ + \Delta RQ)} + 1.07 \right] \times rCO_2 (L) - \left[ 3.85 \times 0.32 + 1.39 \right] \times K_{extr} (g)$$

As opposed to our previous study (9) that reported results during the entire six-week period when EI was held constant (i.e. the last two weeks of the BD phase and the entirety of the KD phase), we now report results based upon data obtained only during the two-week DLW phase of both BD and KD periods. In addition to allowing direct comparison with the coincident DLW measures, focusing on the last two weeks of each diet allowed for two weeks to adapt to the BD from the usual diet as well as to the KD from BD.

Statistical analysis was performed using a paired, two-sided t-test with significance declared at the p<0.05 threshold. The data are reported as mean±SE.

**Results**

During the final two weeks of the BD, EI was 2738±107 kcal/d which was significantly higher than $EE_{chamber} = 2626\pm104$ kcal/d (p<0.0001). $EE_{DLW}$ was 2964±126 kcal/d and significantly higher than EI (p=0.011). After adjusting for the energy imbalance, $EE_{DLW\Delta RQ} = 3045\pm135$ kcal/d was significantly greater than $EE_{DLW}$ (p=0.0003). Energy expenditure calculated using EI
and the changes in body energy stores was \( \text{EE}_{\text{bal}} = 3136\pm171 \text{ kcal/d} \) and was not significantly different from \( \text{EE}_{\text{DLW}} \) (\( p=0.23 \)) or \( \text{EE}_{\text{DLW}} \Delta \text{RQ} \) (\( p=0.47 \)). Compared to \( \text{EE}_{\text{chamber}} \), \( \text{EE}_{\text{DLW}} \) was 338\( \pm \)77 kcal/d higher (\( p=0.0005 \)), \( \text{EE}_{\text{DLW}} \Delta \text{RQ} \) was 419\( \pm \)76 kcal/d higher (\( p<0.0001 \)), and \( \text{EE}_{\text{bal}} \) was 509\( \pm \)100 kcal/d higher (\( p<0.0001 \)) indicating that subjects expended significantly more energy outside the chamber during the BD phase.

During the final two weeks of the KD phase, EI was 2730\( \pm \)110 kcal/d which, by design, was not significantly different from the BD phase (\( p=0.16 \)). Whereas we previously reported a transient increase in \( \text{EE}_{\text{chamber}} \) during the first two weeks after introducing the KD (9), neither \( \text{EE}_{\text{chamber}} \) (2650\( \pm \)89 kcal/d; \( p=0.43 \)) nor \( \text{EE}_{\text{bal}} \) (2995\( \pm \)160 kcal/d; \( p=0.25 \)) were significantly different during the last two weeks of the KD compared to the last two weeks of the BD coincident with the DLW measurement periods (Figure 1A). Likewise, physical activity measured using an accelerometer mounted on the hip was not significantly different (KD relative to BD, -5.1\( \pm \)4.8%; \( p=0.3 \)); and energy efficiency of physical activity measured in the respiratory chamber with subjects exercising at a constant level of moderate-intensity cycle ergometry was not significantly different (-1.6\( \pm \)2.4%; \( p=0.52 \)) between the BD and KD phases.

Despite no significant differences in EI, \( \text{EE}_{\text{chamber}} \), \( \text{EE}_{\text{bal}} \), physical activity, or exercise efficiency between the KD and BD phases (Figure 1B), \( \text{EE}_{\text{DLW}} \) was 209\( \pm \)83 kcal/d higher during the KD phase (\( p=0.023 \)). The transition from the BD to KD coincided with increases in \( \text{EE}_{\text{DLW}} \) that were in the opposite direction to \( \text{EE}_{\text{bal}} \), indicating that the DLW calculations during the KD were incommensurate with the changes in body weight and fat mass. After adjusting for the degree of energy imbalance, \( \text{EE}_{\text{DLW}} \Delta \text{RQ} \) was 139\( \pm \)89 kcal/d higher during the KD, but this difference was
no longer significant (p=0.14) and was still in a direction opposite to the changes in body energy
stores.

There were two clear DLW outliers. The first outlier, “subject A”, had an $EE_{DLW}$ that was 1220
kcal/d greater than EI during the BD, and was 1751 kcal/d greater than EI during the KD despite
slight body weight and fat mass gains during these periods. In contrast, the $EE_{chamber}$
measurements for this subject were 173 kcal/d less than EI during the BD, and 65 kcal/d less
than EI during the KD. The second outlier, “subject B”, had an $EE_{DLW}$ during the BD that was
only 123 kcal/d higher than $EE_{chamber}$, but during the KD his $EE_{DLW}$ increased by 1136 kcal/d
which was ~3 standard deviations greater than the mean increase in $EE_{DLW}$, suggesting severe
negative energy balance despite the subject gaining weight during this period and an $EE_{chamber}$
increasing by only 72 kcal/d. Tables S1-S4 in the Online Supplemental Materials provide
summary data on the energy expenditure comparisons between BD and KD phases with and
without the exclusion of these subjects. After excluding these subjects, the increase in $EE_{DLW}$
during the KD was 126±62 kcal/d (p=0.063) and $EE_{DLW} \Delta RQ$ increased by only 46±65 kcal/d
(p=0.49), neither of which were significant (Table S4)

Discussion

As previously reported (9), our inpatient isocaloric feeding study showed that four days of
respiratory chamber measurements that were coincident with each two-week DLW period did
not detect significant changes in energy expenditure that were attributable to diet composition.
However, the increase in $EE_{DLW}$ after transitioning to the KD was substantially greater than
could be accounted for by changes in body energy stores. In the present analysis, after employing
diet-specific RQ adjustments in the DLW calculations to account for energy imbalance (12), we found that the calculated increase in DLW energy expenditure during the KD was significantly attenuated and was no longer statistically significant. After removal of two clear DLW outliers, the RQ-adjusted increase in DLW energy expenditure was further reduced to a marginal ~50 kcal/d higher during the KD.

We previously hypothesized that the discrepancy between the respiratory chamber and DLW measurements was due to increased physical activity outside the respiratory chamber during the KD (9). However, this potential explanation does not agree with the lack of increase in objectively measured physical activity. Also, the energy expended to perform the same low-intensity exercise in the respiratory chamber was not significantly changed by the KD, making it unlikely that the energy efficiency of skeletal muscle contraction had been altered after transitioning to the KD. Thus, the $\text{EE}_{DLW}$ measurements were discordant with several independent measures indicating that the KD did not result in significant energy expenditure changes. The appropriately adjusted RQ values resulted in DLW data more commensurate with the other data, especially after removing the pair of outliers.

Another methodological concern with the DLW method is the theoretical possibility that CO$_2$ production rates can be influenced by the fluxes through biosynthetic pathways that likely vary substantially depending on the carbohydrate content of the diet, especially the de novo lipogenesis pathway (16-18). However, the magnitude of this potential bias in humans is thought to be relatively small, amounting to an energy expenditure difference of only about 30-60 kcal/d (see Online Supplemental Materials). Interestingly, even this small systematic bias would have
been sufficient to nullify the statistical significance of the observed increased EE_{DLW} in our study
and the effect size was similar to the nonsignificant increase in the EE_{DLW\Delta RQ} difference after
removal of the outliers. Individual variability of de novo lipogenesis changes after transitioning
to the KD might explain the diminished correlations during the KD between the DLW
measurements with EE_{chamber} and EE_{bal}. To directly address this question, we need a validation
study in humans with several days of simultaneous respiratory chamber and DLW measurements
high- and low-carbohydrate diets, ideally with simultaneous measurements of de novo
lipogenesis.

Ebbeling et al. (5) reported significant ~200-300 kcal/d differences in EE_{DLW} during the last two
weeks in each of three consecutive month-long periods during which outpatient subjects
consumed a very low-carbohydrate diet (10% of energy) compared to isocaloric diets with
moderate (40% of energy) or high (60% of energy) carbohydrate in random order. However,
resting energy expenditure differences were much smaller (~29-67 kcal/d) and objectively
measured physical activity was not significantly different among the diets. Despite claims of
weight stability, reported energy intake was several hundred calories below the measured EE_{DLW}
but RQ was estimated without adjustment for the subjects’ state of energy balance. Therefore,
similar to the current study, the diet specific effects of energy imbalance on RQ likely
contributed to the observed differences in EE_{DLW}. Thus, the data of Ebbeling et al. could be
interpreted as supporting the possibility that the EE_{DLW} calculations using RQ values unadjusted
for energy imbalance in a diet-specific way were systematically biased such that the isocaloric
very low-carbohydrate diet resulted in systematically increased EE_{DLW}. 
In contrast, Bandini et al. (19) found in an outpatient study that EEDLW was lower during the very low-carbohydrate diet (~7% of energy) as compared to a high-carbohydrate diet (~83% of energy), but this reduction was attributed to decreased physical activity because the subjects reported nausea and lethargy on the low-carbohydrate diet. No significant differences in REE were found. Stubbs et al. (20) found no significant difference between EEDLW using a narrower range of diets with 29-67% of energy as carbohydrate. But the diets were fed ad libitum and energy intake on the low-carbohydrate diet was greater than the moderate-carbohydrate diet which was greater than the high-carbohydrate diet. Thus, the variation in total carbohydrate content of the test diets was attenuated such that daily carbohydrate intake varied by only ~22% of the mean energy intake between diets which may not have been a sufficient range to observe a systematic bias of the DLW method. Furthermore, the positive energy balance with the low-carbohydrate diet increased RQ whereas the negative energy balance with the high-carbohydrate diet decreased RQ. Thus, the RQ differences during consumption of these diets were attenuated by the differences in energy balance.

It is important to emphasize that our study was not intended to be a DLW validation study and there were several limitations. The DLW measurements were not pre-specified as either primary or secondary endpoints of the study. Whereas respiratory chamber measurements have high-precision, with an intrasubject coefficient of variation of EE_{chamber} ~2-3% (21), the DLW method is less precise, with an intrasubject coefficient of variation of energy expenditure of ~ 8-15% (22). Therefore, the relatively large inherent variability of the DLW method may have led to an apparent increase in EE_{DLW} during the KD simply by chance (type-1 error). However, we cannot definitively exclude the possibility of a real increase in energy expenditure, especially at an
effect size of ~50-140 kcal/d after excluding two likely DLW outliers or using diet-specific
adjustments of the DLW calculations to account for the energy imbalance.

The DLW method has been validated during 30% caloric restriction with a 55% carbohydrate
diet (23) and agrees with our result that $\text{EE}_{\text{DLW}}$ and $\text{EE}_{\text{DLW,ARQ}}$ were not significantly different
from $\text{EE}_{\text{bal}}$ during the BD diet phase. Nevertheless, the calculated $\text{EE}_{\text{bal}}$ values are somewhat
uncertain because DXA has a limited ability to precisely and accurately detect small changes in
body energy stores (24). We cannot rule out the possibility that the KD resulted in undetected
increases in activity-related energy expenditure that were undetected by accelerometers. Finally,
the order of the diets was not randomized, and it is possible that the elevated $\text{EE}_{\text{DLW}}$ occurred
simply because the KD followed the BD. Indeed, others have reported a greater metabolic rate
during a low-carbohydrate diet when it followed a high-carbohydrate diet as compared with the
reverse order (25).

In summary, our data illustrate the challenges of using the DLW method to estimate energy
expenditure differences between diets varying widely in the proportion of carbohydrate. We urge
cautions when interpreting such data, especially if the DLW calculations do not appropriately
adjust RQ for energy imbalance or if the DLW results are not corroborated by quantitatively
commensurate observations of energy intake and body composition change.
