Running title: *Biomphalaria glabrata* snail microbiota dysbiosis
**Summary**

Host-associated microbiota can affect the fitness of its host in a number of ways, including the modification of host-parasite interactions and thus the outcome of disease. *Biomphalaria glabrata* is the vector snail of the trematode *Schistosoma mansoni*, the agent of human schistosomiasis, causing hundreds of thousands of deaths every year. Here, we present the first study of the snail bacterial microbiota in response to *Schistosoma* infection. To examine the interplay between *B. glabrata*, *S. mansoni* and snail microbiota, snails were infected and the microbiota composition was analysed by massive 16S rDNA amplicon sequencing approach. We characterized the *Biomphalaria* bacterial microbiota at the individual level in both naïve and infected snails. Sympatric and allopatric strains of parasites were used for infections and re-infections to analyse the modification or dysbiosis of snail microbiota in different host-parasite co-evolutionary contexts. Concomitantly, using RNAseq data, we investigated the link between bacterial microbiota dysbiosis and snail anti-microbial peptide immune response. This work paves the way for a better understanding of snail/schistosome interaction, and would have critical consequences in terms of snail control strategies for fighting schistosomiasis disease in the field.

**Key words:** microbiota; bacteria; *Biomphalaria* snail; *Schistosoma* infection; immune response; dysbiosis
**Introduction**

Several studies have shown that the microbiota interacts with pathogens and/or host immunity in invertebrates. For example, the midgut microbiota of the mosquito *Aedes* sp. elicits a basal immune activity of the immune system (Ramirez et al., 2012) mostly by activating Toll pathways (Xi et al., 2008). In *Anopheles gambiae*, some members of its microbiota can limit malaria transmission, by inducing a wide antimicrobial immune response (Gendrin, 2017). More precisely, bacteria of the genus *Enterobacter*, found in the mosquito microbiota, were shown to produce reactive oxygen species (ROS) that inhibit *Plasmodium* development (Cirimotich et al., 2011). Furthermore, the endosymbiotic bacteria *Wolbachia* induce expression of immune genes, like TEP1 (Thioester-containing protein 1), LRIM1 (Leucine-Rich Immune Molecule 1) or defensin 1 (Joshi et al., 2017). In *Drosophila*, the bacterial microbiota is necessary to produce the Pvf2, a PDGF/VEGF-like growth factor that restricts enteric viral infection (Sansone et al., 2015). The microbiota may also play a role in immune priming. For example, in *Anopheles gambiae*, hemocyte priming during the *Plasmodium* infection is naturally induced by the gut microbiota, whose absence results in more severe infections and re-infections (Rodrigues et al., 2010). Similarly, the gut microbiota is necessary for immune priming in *Tribolium castaneum* and efficient response against *Bacillus thuringiensis* for *Tenebrionis* (Futo et al., 2015). Finally, host immunity can influence the tolerance or control the microbiota. In the tick *Ixodes scapularis*, the protein PIXR, secreted by the tick’s gut, inhibits the bacterial biofilm formation and supports gut eubiosis (healthy gut microbiota), its inactivation leading to dysbiosis. This change in gut microbiota facilitates the colonization by *Borrelia burgdorferi*, the Lyme disease agent (Narasimhan et al., 2017). In *Drosophila*, for example, the intestinal homeobox gene Caudal regulates the commensal-gut mutualism by repressing nuclear factor kappa B-
dependent antimicrobial peptide genes (Ryu et al., 2008). In Hydra, the innate immune sensors and effectors protect not only against pathogens but also control microbiota homeostasis (Augustin et al., 2010). Moreover, host specific antimicrobial peptides (Fraune et al., 2010; Franzenburg et al., 2012) and a rich repertoire of pattern recognition receptors (Bosch, 2013) are involved in maintaining homeostasis between the host and the resident microbiota. Similarly, bactericidal permeability-increasing proteins (BPIs) shape bacterial communities in the light organ of the squid Euprymna scolopes and prevent their spill over to other tissues (Chen et al., 2017).

_Biomphalaria glabrata_ is a freshwater snail (Lophotrochozoa, Planoridae), living in intertropical regions of Latin America, in rivers, ponds, waterways and other freshwater environments. _B. glabrata_ snails have important medical and epidemiological impacts due to their role as the main vector of Schistosoma mansoni (Lophotrochozoa, Platyhelminthes, Trematoda), the agent of intestinal schistosomiasis. Schistosomiasis is the second most widespread human parasitic disease after malaria, affecting over 200 million people worldwide and causing 200,000 deaths annually (WHO, 2002). The _Schistosoma_ adult parasites mate in the human host venous system. Female worms produce eggs that cross endothelial mesenteric vessels and intestinal epithelium to reach faeces and finally the aquatic environment. Once in the water, eggs hatch and release miracidia, the free-living snail-infective parasite stage. At the following step of the life cycle, the miracidium needs to infect the freshwater snail _B. glabrata_. Intensive asexual multiplication in the snail tissues leads to the continuous production of hundreds of generations of cercariae, the free-living human-infective parasite stage. At present, there is no effective vaccine against schistosomiasis and the treatment relies on a single chemotherapeutic treatment, the Praziquantel (Doenhoff et al., 2009), against which
resistance has been observed (Fallon and Doenhoff, 1994). Mollusicides have been also used
to impair *Schistosoma* transmission in the field. However, the dramatic effects of mollusicides
on natural environments prompt us to seek new ways to prevent and/or control this disease in
the field (Tenessen et al., 2015). We propose that a better understanding of ecological
interactions between, *Schistosoma mansoni, Biomphalaria glabrata* snails and its associated
microbiota might represent an interesting approach in search for alternative control strategies.

In this context, we have conducted numerous studies on immunological interactions
between the snail and the parasite (Mitta et al., 2005; Bouchut et al., 2008; Moné et al., 2011;
Coustau et al., 2015; Galinier et al., 2017; Mitta et al., 2017). We have demonstrated that the
nature of the snail immune response depends on the strain/species of host or of parasite
considered. Depending on both the host and the parasite intrinsic capacities, parasites either
develop normally in snail tissue (compatible interaction) or are encapsulated by hemocytes (the
snail immune cells) (incompatible interaction) (Moné et al., 2010; Mitta et al., 2012; Coustau et
al., 2015) (Fig. 1). Depending on the ecological context, totally different immunobiological
interactions have been described in *B. glabrata/S. mansoni* interactions. If immunosuppression
occurs during a sympatric interaction, an activation of the immune response is observed during
an allopatric interaction (Portet et al., 2019). Moreover, following primo-infection and
successive challenges, a shift from a cellular immune response toward a humoral immune
response has been described (Pinaud et al., 2016) (Fig. 1).

However, in the present host-parasite model, only few studies examined the bacterial
microbiota of *Biomphalaria glabrata* so far (Ducklow et al., 1979; Silva et al., 2013). The study
of aerobic heterotrophic cultivable flora of 200 snails (Ducklow et al., 1979) revealed five
predominant bacterial genera including *Pseudomonas, Acinetobacter, Aeromonas, Vibrio* and
Enterobacter. In a more recent study, the *Biomphalaria glabrata* bacterial microbiota has been characterized using 16S rRNA sequences (Silva et al., 2013) of cultured isolates, identifying six additional bacteria genera: *Citrobacter, Cupriavidus, Rhizobium, Stenotrophomonas, Klebsiella* and *Sphingomonas*. In addition, diversity and composition of bacterial microbiota differed between resistant and susceptible *Biomphalaria* phenotypes, with differences in relative abundances of *Gemmata montana* and *Micavibrio aeruginosavorus*. This observation supports the potential link between the resistance against *Schistosoma* parasite and the structure of snail-associated microbiota (Allan et al., 2018). However, no studies have examined changes in bacterial microbiota of *Biomphalaria* snails by culture-independent methods nor following *Schistosoma* infections so far.

Taking into account all the peculiarities of this system, the aim of the present study was to investigate variation of microbiota in snail populations as well as to assess the influence of varying immune response against *Schistosoma* on the host microbiota composition and dynamics. To reach this goal, we first characterized the bacterial microbiota of naive *Biomphalaria glabrata* snails using 16S rDNA metabarcoding. Then, we analysed changes in microbiota composition following, (i) primo-infections with sympatric and allopatric *S. mansoni* parasite isolates displaying the same prevalence and intensity phenotypes and, (ii) subsequent secondary challenges with homologous or heterologous parasite strains. As snail immune response strongly differs between such diverse snail/parasite combinations, we concomitantly analysed the snail immune response using a massive sequencing transcriptomic approach (RNAseq) in order to link it with the observed changes in the composition and diversity of the microbiota.
Results

Characterization of healthy B. glabrata microbiota

To examine the stability of naive BgBRE snail microbiota, we first inspected the microbiota diversity and composition in the control naive snails at day 0 and 25 of the experiment. We found no significant differences between the B0 and B25 snails in any of the alpha diversity indices (Table S3, Table S4).

Naive snails showed little inter-individual variability and a stable composition at the phylum level over time (Fig. 2A, Table S3, Table S4), with Proteobacteria, Bacteroidetes, Cyanobacteria and Planctomycetes phyla being the most represented (Fig 2A). Moreover, the bacterial microbiota of naïve BgBRE snails displayed a considerable temporal and inter-individual stability at the family level (Fig. 2B). The stability of naïve snail microbiota composition over time (Fig. 2) could be related to the laboratory rearing conditions and laboratory environmental abiotic variables (water composition, temperature, pH, food) that were tidily controlled and that did thus not result in changes in host snail physiology or metabolism.

In terms of composition, we observed that 67 (69%) and 86 (89%) out of 97 identified families were shared by all individuals of B0 or B25 naïve snails respectively (Fig. 2B). Those results were used to determine the core microbiota. We defined core microbiota as the families that were present in 100% of the naïve snails. Applying this definition, we identified 62 out of 97 families found in all naïve individual snails (B0 and B25 altogether), and thus constituting the B. glabrata core-microbiota (Table S7 and S8).

Microbiota dynamics following B. glabrata infections by S. mansoni
After establishing the stability of naive *Biomphalaria* bacterial microbiota, we investigated whether *Schistosoma mansoni* infections affected the microbiota structure and dynamics.

To investigate the influence of parasite infections on the bacterial microbiota, we analysed microbiota dynamics following sympatric or allopatric primo-infections and homologous or heterologous challenges (Fig. 1).

We did not observe any significant changes in alpha diversity during the course of primo-infection compared to naive snails, excepted a decrease in the Shannon's *H* diversity index at the fourth day after sympatric infection (Fig. 3, Table S3, Mann-Whitney U test: Table S4).

Conversely, all indices changed significantly following homologous or heterologous challenges (Fig. 3, Table S3, Table S4). Indeed, the observed species richness (Mann-Whitney U test, *p*=0.002), the Chao 1 richness index (Mann-Whitney U test, *p*=0.006), Shannon diversity index (*p*=0.0004) and Pielou evenness index (Mann-Whitney U test, *p*=0.009) were significantly reduced following homologous or heterologous challenges compared to naive and primo-infected snails (Fig. 3, Table S3, Table S4). However, the observed drop in alpha diversity disappeared by the fourth day after heterologous challenge (Fig. 3, Table S4). In addition, alpha diversity was mainly affected by the challenge, regardless of its type (homologous or heterologous). The primo-infection did not significantly affect alpha diversity except for the sympatric combination at day 4 after infection (Table S4).

Regarding the beta diversity, Principal Coordinate Analysis (PCoA) of Bray-Curtis dissimilarities revealed that BB25 samples grouped together with the naive snail samples (B0 and B25) and were separated from the infected-snail samples along both axes (Fig. 4A, Table S5). However, the BB25 samples were significantly different from the naive snail samples (Table S5). The fact
that, BB25 grouped with naive snails rather than with infected-snail samples suggests that the
snail microbiota is resilient to infection, with a tendency to recover between day 4 and day 25
after the primo-infection (Fig. 4A). Analysis of Bray-Curtis dissimilarity index revealed a
significant difference between naive and primo-infected samples (p=0.001) and also between
naive and challenged samples (p=0.001) (Table S5). Concerning the infected-snail samples, all
experimental samples were significantly different from each other with the exception of BB1
versus BB4 and BBB1 versus BBV1 (Table S5).
In addition, the second PCoA axis separated the samples according to the course of infection
(i.e. the day 1 from the day 4 samples) (Fig. 4A), whereas the day 1 after-challenge (BBB1,
BBV1), the day 1 after-primo-infection (BB1, BV1) and all of the day 4 infection samples (BB4,
BV4, BBB4, BBV4) were separated along the first axis (Fig. 4A). Interestingly, day 1 after-
challenge samples (BBB1, BBV1) were more different from the naive microbial communities
than the day 1 primo-infection samples (BB1, BV1). Moreover, the second axis separated the
sympatric primo-infection (BB1) from the allopatric primo-infection (BV1) (Fig. 4A). Finally, all
day 4 samples grouped together reflecting the similarity between these samples regardless of
experimental infection conditions (Fig. 4A). Even if the day of infection appears as the main
explaining factor, these results indicate that the snail microbiota response to the infection also
depends on the type of infection (sympatric vs. allopatric or primo-infection vs. challenge) and
suggest the existence of predictable dynamics.

We further investigated the microbial community dynamics following infection, and we
observed some consistent changes in response to experimental infection type (Fig. 4B). The
relative abundance of Tenericutes increased after infection, particularly at day 1 after challenge

Increase in Verrucomicrobia following allopatric primo-infection (BB25 vs BBV1, student T test P = 0.0114; BB25 vs BBV1 student T test P = 0.0209). Increase in Verrucomicrobia following allopatric primo-infection (BO/B25 vs BV4, student T test P = 6.53 e-06) and homologous / heterologous challenge (BO/B25 vs BBB4/BBV4, student T test P = 0.0012) was most prominent at day 4 after infection (Fig. 4B). Interestingly, high relative abundance of Verrucomicrobia in BB25 represents the main difference with naive snail microbial community composition (BO/B25 vs BB25, student T test P = 1.83 e-05) (Fig. 4B). We further observed decrease in Planctomycetes following sympatric primo-infection (BO/B25 vs BB1/BB4, student T test P = 5.7 e-07) and a decrease in Cyanobacteria following allopatric primo-infection (BO/B25 vs BV1/BV4, student T test P = 0.00254). Interestingly, the relative abundance of both phyla decreased following the challenge regardless of the challenge type (Planctomycetes BO/B25/BB25 vs BBB1/BBB4/BBV1/BBV4, student T test P = 0.0017 and Cyanobacteria BO/B25/BB25 vs BBB1/BBB4/BBV1/BBV4, student T test P = 0.000568) (Fig. 4B). Bacteroidetes decreased 25 days after sympatric primo-infection (BO/B25 vs BB25, student T test P = 0.0467) but increased 4 days after heterologous challenge (BB25 vs BBV4, student T test P = 0.00577). To conclude, depending on the phylum, we observed the largest modifications in microbiota composition at day 1 or 4 after primo-infections and challenges. Whereas the microbiota responded differently to sympatric and allopatric primo-infections, we found no significant differences between the homologous or heterologous challenge (see BBB1 vs BBV1, Fig. 4) (Table S5).

Finally, we examined the core microbiota dynamics during infection. Similarly, to the complete microbiota, the core-microbiota, consisting of 62 families, was affected by the type of infection (naive vs primo-infection (p=0.003) and naive vs challenge (p=0.003)), by the time of infection.
(early (1 day) vs late (4 days)) (p=0.006) and also by the strain of parasite used for primo-infection (SmBRE vs SmVEN) (p=0.016) (Table S6). Principal Coordinate Analysis (PCoA) based on Bray-Curtis dissimilarities between the core microbiotas (Fig. S1) yielded very similar results to those based on the entire dataset (Fig. 4A).

In addition, we observed that 69.4% (43) of the core microbiota families were significantly affected by infection. Among those, 6.5% (4 families) were affected regardless of the infection type (Table S7). Interestingly, these families belong to the most abundant ones (Table S8). Nineteen families (30.6%) were never affected by infection (Table S7). Those families belong to the less represented ones, with the exception of Xanthomonadaceae, which was the 7th most represented family (see Table S8). Further 32.6% (14 families) of the core microbiota responded solely to the primo-infection and 4.7% (2 families) to the challenge (Table S7). Similarly, 20.9% (9 families) of the core microbiota was affected early after infection (1 day) and 7% later (3 families, day 4). Finally, 23.3% (10 families) were affected by the SmBRE infection and 9.3% (4 families) by the SmVEN infection (Table S7).

Link between the microbiota dysbiosis and B. glabrata antimicrobial immune response

The expression level of transcripts encoding antimicrobial peptides and antimicrobial proteins (AMP) was investigated following sympatric or allopatric primo-infection and homologous or heterologous challenges using RNAseq data (Fig. 5 and Fig. S2). Two achacin genes, 5 lipopolysaccharide-binding protein / bactericidal permeability-increasing protein (LBP/PBI) genes, and 5 biomphamacin genes were selected based on the Biomphalaria glabrata genome annotation (Adema et al., 2017). In comparison with the naive snails, the LBP/BPI 3.1 and 3.2 were over-expressed at day 25 after infection and following the challenges, while all other
genes of this family were under-expressed in all conditions (Fig. S2). The achacins were under-expressed following primo-infection in the sympatric combination only, and at day 25 after primo-infection and following both challenges (Fig. S2). No changes in expression were observed following allopatric primo-infection compared to the naive snails (Fig. S2). Finally, the AMP biomphamacins 1, 4, 5 and 6 were over-expressed throughout the infection stages, except for BV1 and BB25 (Fig. 6). The biomphamacin 3 was mainly under-expressed except at BV4 and BBB, where no differential expressions have been detected compared with naive snails (Fig. 5).

Based on our observations of microbial community shifts, changes in expression of antimicrobial molecules were expected to occur following primo-infections and challenges and not for BB25, where resilience of microbial communities has been observed (Fig. 4 and Fig. S1). In this context, the LBP/BPI and achacin seem not to be linked with dysbiosis, as both remained highly down regulated even at BB25 when communities had already recovered (Fig. S2). All biomphamacins, except the biomphamacin 3, were over-expressed after infection, from day 1 in BB infection and day 4 in BV infection and for homologous or heterologous challenges (BBB and BBV). Finally, only a subset of biomphamacins (1, 4, 5, 6) changed in the course of infection but were not differentially expressed at BB25 compared with the naive snails (Fig. 5), suggesting their possible link with dysbiosis.

Discussion

Fine-tuned interactions between microbiota, host immunity and pathogens have been observed in many vertebrate and invertebrate models (Rodrigues et al., 2010; Ramirez et al., 2012; Futo et al., 2015; Sansone et al., 2015; Chen et al., 2017). Following an infection by a
pathogen, a host displays an innate or adaptive immune response against the intruder. The activation of such immune response may in turn affect the microbial community structure. Herein, we investigated the interactions between the host immune system, parasite and the bacterial microbiota in an invertebrate model - the gastropod snail Biomphalaria glabrata and its trematode parasite Schistosoma mansoni. Depending on the past evolutionary history between snails and schistosomes, different immune responses against S. mansoni have been observed. We showed recently that in a sympatric interaction, the parasite that coevolved with its host induced a strong immunosuppression, whereas allopatric interaction resulted in a strong host cellular immune response (Portet et al., 2019). Moreover, a cellular immune response was observed following primo-infection, but a humoral immune response was observed following homologous or heterologous challenges (Pinaud et al., 2016). So using appropriate parasite-host combinations, we have the opportunity to modulate the host immune response type and to test changes in bacterial community composition and diversity (dysbiosis). First, studying the global bacterial microbiota community of Biomphalaria snails, we showed that the bacterial alpha diversity was not modified following primo-infection whatever the parasite strain or the time point of infection (Fig. 3, S3 Table). A decrease in alpha diversity is observed exclusively following challenge infections, as reflected by multiple indices (Fig. 3, S3 Table). Conversely, primo-infection and challenge strongly affected the bacterial OTU composition (Fig. 4). Moreover, differences in immunobiological interactions (immunosuppression, immune cellular response or immune humoral response) resulted in different microbiota dysbiosis reflected by specific changes in the snail microbial community (Fig. 4). Interestingly, homologous and heterologous challenges activated similar humoral immune response (Pinaud et al., 2016; Portet et al., 2019) that resulted in a similar change of
microbiota alpha diversity and composition (Fig. 3, S3 Table, Fig. 4). Then, four days after infection, regardless of its type, the microbiota was still very different from the one in the naïve snails, but the differences between the primo-infection and challenge disappeared, as apparent from the grouping of BB4, BV4, B BB4 and BBV4 in the PCoA (see Fig. 4). Furthermore, most of the OTUs affected by the primo-infection, returned to their initial state by the day 25, indicating that the snail microbiota is resilient against the infection (Fig. 4). However, some differences persisted: the Verrucomicrobia phylum remained highly represented in the infected snails at day 25 after primo-infection (Fig. 4B). Interestingly, some Verrucomicrobia species have been recently proposed as a hallmark of healthy gut due to its anti-inflammatory and immune-stimulant properties and its ability to improve gut barrier function (Fujio-Vejar et al., 2017). High abundance of Verrucomicrobia in the recovered snails could thus potentially reflect their role in community restoration (Fig. 4). Moreover, the expansion of a Verrucomicrobia species *Akkermania muciniphila* has been demonstrated in the gut of *S. mansoni*-infected mice, suggesting a potentially functional role of Verrucomicrobia in *Schistosoma* infection processes in both final and intermediate hosts (Jenkins et al., 2018). We also paid a particular attention to the core-microbiota. Given the various ways to define core microbiota, we considered exclusively the persistent occurrence in the bacterial community in naïve *Biomphalaria glabrata* snails (Astudillo-García et al., 2017). Similarly, to the entire microbiota, the core microbiota was affected by the type of infection (naïve vs challenge), by the time of infection (day 1 vs day 4) as well as by the parasite strain (SmBRE vs SmVEN) (Table S6). Core microbiota seemed to be affected by immunosuppression or the activation of the immune response in a similar way than the whole microbiota (Fig. S1 and Fig. 4A). Understanding the shifts in core microbiota following infection is important as the long-term stability and persistent occurrence of
beneficial microbes and their associated functions may contribute to host health and well-being to maintain host functionality and fitness toward changing ecological environment or environmental stress (Nyholm and McFall-Ngai, 2004; Lozupone et al., 2012; McFall-Ngai et al., 2013).

Given that infections affect the total and core microbiota structure, we explored the antimicrobial immune response following infection to find potential molecular mechanisms involved in the observed microbiota dysbiosis (Fig. 5 and Fig. S2). We analysed antimicrobial peptides (AMP) and antimicrobial proteins and our results suggest that only the AMP belonging to biomphamacin family may potentially affect the microbial communities in response to *Schistosoma* infection. Indeed, even though antimicrobial families can be involved in complex process of regulation or of control of microbiota communities, solely the biomphamacins AMP family members specifically displayed an expression pattern that can be linked with the observed dysbiosis of *Biomphalaria* bacterial communities (Fig. 5). Even if AMPs is often considered as the main immune pathway responsible for microbiota regulation (Onchuru and Kaltenpoth, 2019), an overall modification of the immune system may also be considered as a cause of dysbiosis. The potential role of immune recognition or ROS/NOS pathways as to be considered (Wang et al., 2014; Budachetri and Karim, 2015; Yang et al., 2015; Yang et al., 2016) and this will deserve further investigations in the present biological experimental model.

It has been shown that the immune system is a key determinant of host-associated bacterial communities in many biological systems. Two mechanisms have been proposed to explain host-microbiota interactions through crosstalk with the host innate immune system. The first one proposes that the host immune system exerts constant pressure on the microbiota in order to maintain homeostasis (Hooper et al., 2012), the host immune system can thus control the
composition of the resident microbiota (Zhang et al., 2015). According to this hypothesis, any changes in host immune response to infection would potentially affect the resident microbiota diversity and composition. The second mechanism proposes that the immune system would be tolerant to weak and continuous antigenic immune stimulations experienced during a lifespan (Pradeu and Eric, 2014), and thus that host immune system would not exert any pressure on the resident microbiota. In this case, any changes in host immune response to infection would potentially not affect the resident microbiota diversity and composition.

Interestingly, numerous studies demonstrate a direct control of microbial communities by the host immune system. As an example, species-specific antimicrobial peptides can shape species-specific bacterial associations in Hydra (Franzenburg et al., 2013). Other immune pathways have been also demonstrated to regulate or control the microbiota communities, like the intestinal homeo-box gene Caudal in Drosophila (Ryu et al., 2008), or neuropeptides with antibacterial activity which are secreted to shape the microbiome on the body surface of Hydra (Augustin et al., 2017), even host lectins were demonstrated to stabilize microbiota communities (Dinh et al., 2018).

Thus, if biotic stress (i.e. an infection) modifies the expression of antimicrobial peptides or other immune related pathways, an effect on the microbial communities can be expected. Our results indicate that bacterial communities could indeed be shaped by the immune system of B. glabrata. Based on the hypothesis proposed by Hooper and collaborators (Hooper and Macpherson, 2010; Hooper et al., 2012; Dinh et al., 2018), it seems that the immune system of B. glabrata snails maintains or controls the microbial communities permanently. Therefore, following an infection, the immune system is diverted from its function of managing the microbiota and consequently the bacterial communities evade its regulation, resulting in
changes of their composition and diversity. When the immune response returns to a basal level, the microbiota is again under-control and the microbiota shows its resilience by returning to its “healthy” state (Hooper and Macpherson, 2010; Hooper et al., 2012), as observed in the present study (Fig. 4). In other words, the immune system is likely no longer able to maintain the microbiota homeostasis after infection (resulting in dysbiosis), which, may in turn affect host homeostasis or fitness (Contijoch et al., 2019; Warne et al., 2019) (Contijoch, Britton et al. 2019, Warne, Kirschman et al. 2019).

Changes in microbiota composition may result from shifts in the abundance of specific bacterial groups participating in anti-pathogen response, or just be a collateral effect of the immune response activation against metazoan parasite infection. This question will deserve further investigation, by testing S. mansoni prevalence and intensity in experimental infections of Biomphalaria glabrata snails following antibiotic treatment or microbiota transplantation.

In order to fully understand Schistosomiasis transmission and to develop new ways to control the expansion of this widespread human parasitic disease in the field, it will be crucial to determine if the snail-associated bacterial communities affect the parasite transmission. For example, expanding knowledge on Biomphalaria snail microbiota is an essential step for developing paratransgenetic solutions to the spread of Schistosomiasis, involving the use of transgenic bacteria expressing foreign gene products (i.e., schistosomicidal compounds) that can reduce host competence and block pathogen development or transmission when introduced into the microbiota of vector snail field populations (Aksoy et al., 2008; Coutinho-Abreu et al., 2010; Gilbert et al., 2016).
Experimental procedures

Ethical statements

Our laboratory holds permit # A66040 for experiments on animals, which was obtained from the French Ministry of Agriculture and Fisheries and the French Ministry of National Education, Research, and Technology. The housing, breeding and care of the utilized animals followed the ethical requirements of our country. The experimenter possesses an official certificate for animal experimentation from both of the above-listed French ministries (Decree # 87-848, October 19, 1987). The various protocols used in this study have been approved by the French veterinary agency of the DRAAF Languedoc-Roussillon (Direction Régionale de l'Alimentation, de l'Agriculture et de la Forêt), Montpellier, France (authorization # 007083).

Biological material

In this study, we used a single strain of the host snail, the albino Brazilian strain of Biomphalaria glabrata (BgBRE) and two strains of the trematode parasite Schistosoma mansoni: a Brazilian strain (SmBRE, for sympatric infection) and a Venezuelan strain (SmVEN, for allopatric infection). BgBRE and SmBRE strains originate from the locality of Recife, Brazil; the SmVEN parasite strain was recovered from the locality of Guacara, Venezuela. All host and parasite strains were maintained in the laboratory on their respective sympatric snail hosts (SmBRE on BgBRE and SmVEN on BgVEN). The snails were reared at constant temperature of 26°C and fed only with washed salad every 3 days.

Experimental Infections (Fig. 1)

In order to decipher the inter-individual structure of snail microbiota as well as investigate the
influence of different snail immune stimulations on its microbiota structure and dynamics, we applied a two-step experimental infection protocol (Fig. 1).

Briefly, BgBRE snails were primo-infected with one of the two parasite strains (SmBRE sympatric or SmVEN allopatric). The snails were then sampled 1 and 4 days following primo-infection by both parasite strains and 25 days after primo-infection for SmBRE infection condition. Then, the BgBRE snails primo-infected with SmBRE were challenged (25 days after the primo-infection) with SmBRE or SmVEN parasite strains for homologous or heterologous challenges respectively. The challenged snails were then sampled 1 and 4 days following challenge (Fig. 1). For all experimental infections, the snails were individually exposed for 12h to 10 miracidia in 5mL of pond water, thereafter snails were returned to the water tanks and separated according to the parasite strain and infection conditions.

Infections and sampling for microbiota analysis

We performed a primo-infection of 63 BgBRE snails with either SmBRE (sympatric, 49 snails) or SmVEN (allopatric, 14 snails) strains. Then, 25 days after the primo-infection, we challenged a subset (28 snails) of SmBRE-primo-infected snails with either SmBRE (14 snails) (homologous challenge) or SmVEN (14 snails) (heterologous challenge).

To examine the effect of primo-infection on the snail microbiota, we sampled 7 whole snails for each infection combination on day one (named BB1 and BV1; the first letter refers to the Biomphalaria strain BgBRE and the second letter refers to the origin of S. mansoni strains used for primo-infection, SmBRE or SmVEN), on day four (BB4 and BV4), and on day twenty-five (BB25, no SmVEN-infected snails were sampled on day 25) after the primo-infection. This BB25 sample is used as control for microbiota changes observed following challenge infections. Thus
then, we sampled 7 whole-snails on day one after the challenge (BBB1 and BBV1; the third letter refers to the origin of the *S. mansoni* strain used for the challenge, SmBRE or SmVEN) and on day four (BBB4 and BBV4) after the challenge. In addition, we used 6 naive snails collected at the beginning of the experiment (B0) and 6 naive snails collected at the time of challenge (i.e. day 25, named B25) as controls to assess the variability and stability of the BgBRE snail’s bacterial communities in our breeding and rearing laboratory conditions. Snails were not fed 24 hours before the DNA extraction for metabarcoding analysis.

**Infection and sampling for host antimicrobial immune response**

We performed a primo-infection of 180 BgBRE snails with either SmBRE (sympatric, 140 snails) or SmVEN (allopatric, 40 snails). Then, 25 days after infection, we challenged a subset (80 snails) of SmBRE-infected snails with either SmBRE (40 snails) (homologous challenge) or SmVEN (40 snails) (heterologous challenge) (Portet et al., 2019).

To study the primo-infection transcriptomic immune response of the snail, we took 20 snails pooled for each infection type on day one (BB1 and BV1), four (BB4 and BV4), and twenty-five (BB25). After the challenge with SmBRE or SmVEN, we sampled 20 snails in each condition at days 1 and 4. Then samples of day 1 and day 4 were mixed together into a single sample referring to BBB or BBV. In addition, we used 2 pools of 30 naive snails (B0.1 and B0.2) to establish the basal snail transcriptomic activity (Portet et al., 2019).

**Extraction and sequencing**

**DNA extraction and 16S rDNA sequencing**
Immediately after sampling, snail shells were cleaned with alcohol and removed, whole snails were then frozen in liquid nitrogen and grounded. The total DNA was extracted with DNeasy Blood and Tissue Kit (Qiagen) according to the manufacturer's protocol. The DNA quantification was performed by Qubit 2.0 Fluorometer, using dsRNA BR Assay kit. Individual 16S rDNA amplicon libraries were generated using the 341F (CCTACGGGNGGCWGCAG) and 805R (GACTACHVGGGTATCTAATCC) primers targeting the variable V3-V4 loops (Klindworth et al., 2013). Paired-end sequencing with 250 bp read length was performed on the Illumina MiSeq sequencing system (Genome Québec, Montréal, Québec, Canada) using the v2 chemistry according to the manufacturer's protocol.

RNA extraction and transcriptomic sequencing

Immediately after sampling, snail shells were cleaned with alcohol and removed, then snails were pooled according to infection type. Total RNA was extracted using TRIZOL (Sigma Life Science, USA) according to the manufacturer's instructions. For BBB and BBV equimolar amounts of RNA extracted from molluscs challenged at both 1 and 4 days were mixed together into a single sample. mRNAs were sequenced in paired-end 72-bp read lengths, using the mRNA-Seq kit for transcriptome sequencing on Illumina Genome Analyzer II (MGX-Montpellier GenomiX, Montpellier, France).

Microbiota analysis

Data analysis of 16S sequences

The FROGS pipeline (Find Rapidly OTU with Galaxy Solution) implemented on a galaxy instance (http://sigenae-workbench.toulouse.inra.fr/galaxy/) was used for data processing (Escudie et
al., 2017). Briefly, paired reads were merged using FLASH (Magoc and Salzberg, 2011). After
denoising and primer/adapters removal (Didion et al., 2017), de novo clustering was done using
SWARM, which uses a local clustering threshold, with aggregation distance d=3 after denoising.
Chimeras were removed using VSEARCH (Rognes et al., 2016). We filtered out the singletons
and performed taxonomic assignment using Blast+ against the Silva database (release 128).

All statistical analyses were done using R v3.3.1 (R: a language and environment for
statistical computing, 2008; R Development Core Team, R Foundation for Statistical Computing,
Vienna, Austria [http://www.R-project.org]). We used the phyloseq R package for community
composition analysis (McMurdie and Holmes, 2013) to infer alpha diversity metrics as well as
beta diversity (between sample distance). Beta diversity was examined by Principal Coordinate
Analysis (PCoA) using the Bray-Curtis distance matrices. We performed a Mann Whitney U test
(p<0.05) to compare alpha diversity and one-way PERMANOVA with a Benjamini & Hochberg
post-hoc to analyze beta diversity between the experimental groups. For all analyses, the
threshold significance level was set at 0.05.

Analysis of core-microbiota

We defined the core-microbiota as the set of bacterial families that were present in 100% of
the naive individuals excluding unknown or multi-affiliations at lower taxonomic ranks (Table
S1). We then used the abundances of OTUs belonging to these families to examine the
composition of the core-microbiota.

To check if the core-microbiota is affected by infection, we compared the abundance of core
families between infected snails and naive conditions with a one-way PERMANOVA with a
Benjamini & Hochberg post-hoc correction. Moreover, a frequency test was performed to
determine which specific families were affected during infection. The number of significantly
differentially represented families at each sampling day (1, 4 and 25 days after primo infections and 1, 4 days after challenges) was calculated to assess the temporal variability during the course of infection.

Transcriptome analysis of antimicrobial immune response

Antimicrobial response

An antimicrobial transcriptome was built from transcripts known to be involved in *Biomphalaria* immune response against bacteria (antimicrobial peptides: biomphamacin or antimicrobial proteins: LBP/BPI and achacin; see Table S2 for details). The full-length sequences of these transcripts were recovered from GenBank and the *Biomphalaria* genome (Adema et al., 2017) and joined in a subset that represents the antimicrobial transcriptome of *B. glabrata*. This antimicrobial transcriptome was then concatenated with a de-novo assembled transcriptome of *Biomphalaria* available in our laboratory (see (Dheilly et al., 2015; Pinaud et al., 2016; Galinier et al., 2017) for details) and uploaded on the Galaxy server. Before concatenation, a blastn (70% identity and 90% coverage) was conducted to identify redundant transcripts across the transcriptomes. Redundant transcripts were then discarded using CDhitEst to avoid mapping errors and bias in read counts when using Bowtie2 package.

Differential expression analysis

High-quality reads (Phred score >29) were aligned to the concatenated transcriptome using Bowtie2 (v.2.0.2), which was run locally on a Galaxy server. The DESeq2 (v2.12) R package was used to identify differential expression levels between uninfected (B0.1 and B0.2) and infected conditions (p value < 0.05).

Legends to Figures

Fig. 1: Experimental protocol

Fig. 2: *Biomphalaria glabrata* microbiota characterization

Characterisation of the *Biomphalaria* bacterial microbiota of six naive snails recovered at the start of experimentation (B0.1; B0.2; B0.3; B0.4; B0.5 and B0.6) and 6 naive snails recovered 25 days after the start of experimentation (B25.1; B25.2; B25.3; B25.4; B25.5 and B25.6). A. Phylum level composition of the 20 most abundant OTUs phyla among the 12 naive snails. B. The Venn diagram represents the number of the 97 OTUs families which shared between the 6 naive snails at B0 (left Venn diagram), and between the 6 naive snails at B25 (right Venn diagram).

Fig. 3: Microbiota alpha Diversity

Boxplots of Chao1 and Shannon indices for all samples. For the Naive condition, B0 and B25 snails were pooled; BB: primo infection of BgBRE by SmBRE; BV: primo infection of BgBRE by SmVEN; BBB: primo infection of BgBRE by SmBRE and challenge by SmBRE; BBV: primo infection of BgBRE by SmBRE and challenge by SmVEN. The time point is mentioned with 1, 4 or 25 corresponding to the day after primo-infection or challenge. The differences between naive and infected conditions were tested with a Mann-Whitney U test and significant differences mentioned with “*”.

Fig. 4: Beta diversity and bacterial communities following *Biomphalaria* infection
Dynamics of the bacterial microbiota of *Biomphalaria glabrata* following *Schistosoma* primo-infection and challenge. A. Functional diversity comparisons of *Biomphalaria* microbiota along infection. Principal coordinate analysis of pairwise Bray-Curtis distances between all infection type and time samples. Axes represent the two synthetic variables explaining the greatest proportion of variation in the data set. The sample name indicated in the figure corresponds to the centroid of all the biological replicates points of the respective experimental sample. B. Phylum level composition of the 20 most abundant OTUs among all points of the kinetic. In this representation, the replicate naive snails were pooled for more readability.

**Fig. 5: Differential gene expression of Biomphamacin antimicrobial peptides**

Log2FC (fold change) of antimicrobial immune transcripts between naive and infected snails inferred from previous RNAseq analysis on the same experiment. A positive Log2 fold-change indicates over-expression in infected snails compared to the naive snails. Antimicrobial peptide families included 6 Biomphamacins (macin-like AMPs) consisting of 6 genes (shade of green).

**Fig. S1: Core Microbiota analysis**

Modifications of the bacterial core microbiota of *Biomphalaria glabrata* following *Schistosoma* primo-infection and challenge. After a one-way Permanova with a Benjamini & Hochberg post-hoc, a frequency test was realised to determine which specific families were affected during infection. A. Proportion of OTU Families affected by infection are represented by colour circles. The Venn diagram shows more precisely the specific impact of infections on the OTU families partially influenced. B. Heatmap corresponding to all core microbiota with clustering on Family.
modification patterns between conditions. The scale of red correspond to ratio between naïve condition and each point of infection.

**Fig. S2: Differential gene expression of LBP/BPI and Achacin antimicrobial protein families**

Log2FC (fold change) of antimicrobial immune transcripts between naïve and infected snails inferred from previous RNAseq analysis on the same experiment. A positive Log2 fold-change indicates over-expression in infected snails compared to the naïve snails. Antimicrobial protein families: LBP/BPIs (*Lipopolysaccharide-binding protein / Bactericidal Permeability-Increasing protein*) consisting of 5 genes (in blue) and achacins consisting of 2 genes (in orange).
