29   **Abstract**

30   To prevent erroneous actions, individuals must often inhibit prepared behavioral

31   responses. The right inferior frontal gyrus (rIFG) and its connectivity patterns are

32   prominently implicated as key to behavioral inhibition. However, previous studies have

33   applied neurostimulation methods with low spatial resolution that impede simultaneous

34   network modeling of neural activity. Therefore, direct evidence for inhibitory control in

35   rIFG is lacking, while the accompanying network mechanisms remain unknown. We

36   addressed this gap using a Stop Signal task and transcranial focused ultrasound

37   (TFUS) to pars opercularis in rIFG. TFUS improved stopping performance by enhancing

38   stopping speed. Electroencephalographic dynamic causal modeling indicated inhibition

39   performance increased by TFUS modulating pars opercularis pyramidal neuron

40   connectivity to subcortex. By combining TFUS and network modeling, our results

41   provide causal evidence that response inhibition is implemented along two pathways

42   originating from a direct rIFG to subcortical pathway and a parallel pathway that

43   modulates pre-SMA inhibition onto subcortical nodes.

44

Introduction

45

46   Behavioral inhibition is necessary to suppress impending actions that become

47   contextually inappropriate (Aron et al., 2014; Baddeley, 1996; Logan and Cowan, 1984).

48   The control over inhibitory capacities is dramatically reduced in pathologies dominated

49   by aberrant impulse control, e.g. ADHD (Bari and Robbins, 2013). The stop-signal task

50   has been widely used as a paradigm for probing inhibition (Logan and Cowan, 1984).

51   This task involves cueing action execution (Go signal) on every trial. On a percentage of

52   trials, individuals are cued (Stop signal) to attempt inhibiting responses at a delay after a

53   Go. This task allows deriving the stop signal reaction time (SSRT), a latent measure of

54   stopping speed.

55   The predominant conceptual framework implicates a right-lateralized prefrontal

56   stopping circuit driving inhibition (Aron, Robbins, and Poldrack, 2014; Chambers et al.,

57   2006), with an anatomical locus in the posterior portion of the right inferior frontal gyrus

58   (rIFG), pars opercularis (Aron and Poldrack, 2006). It has been argued this area directly

59   implement motor braking via projections to subcortical nodes (Aron et al., 2014).

60   Supporting evidence is based on demonstrations that rIFG neural activity is larger in

61   successful compared to failed stopping (Aron et al., 2006; Boehler et al., 2010; Li et al.,

62   2006), and both inhibition and SSRTs being altered in individuals with rIFG lesions

63   (Aron et al., 2003) and ADHD (Morein-Zamir et al., 2014). rIFG is considered a core

64   node for response inhibition, nevertheless successful inhibition also engages a broader

65   network that includes pre-supplementary motor area (pre-SMA; Duann et al., 2009),

66   subthalamic nucleus (STN) and striatum (Aron et al., 2007; Mallet et al., 2016).

67   Although modulation of RIFG activity typically accompanies inhibitory control,

68   several researchers have proposed RIFG's involvement is indirect (Duann et al., 2009;

69   Sharp et al., 2010; Xu et al., 2017). This indirect role involves rIFG registering a stop-

70   signal context, and signaling the context to pre-SMA, which has been argued to

71   explicitly trigger inhibition (Duann et al., 2009; Sharp et al., 2010; Rae et al., 2015). At a

72   network level, this hypothesis has gained support from fMRI connectivity in stop-signal

73   studies wherein pre-SMA alone exhibited modulated connectivity with subcortical

74   structures during successful inhibition (Duann et al., 2009; Rae et al., 2015). However,

75   other connectivity studies have implicated both rIFG and pre-SMA connectivity to STN

76   and striatal pathways as predicting inhibition speed (Jahfari et al., 2011; Xu et al.,

77   2017). Additionally, primate research implies that direct neural projections to the STN

78   originate in both the rIFG and pre-SMA, with the STN acting as an integrator (Haynes

79   and Haber, 2013). These dual-pathway models leave open the possibility that rIFG can

80   directly trigger inhibition in parallel with pre-SMA (Aron et al., 2016).

81   In contrast to the above conclusions, an alternative framework posits that neither

82   rIFG or pre-SMA directly implement inhibition, with inhibition emerging from attentional

83   orienting and biased competition processes (Hampshire and Sharp, 2015; Chatham et

84   al., 2012). This proposition is based on findings indicating sectors of rIFG are

85   equivalently active during stop-signal and other putatively non-inhibitory tasks (Erika-

86   Florence et al., 2014; Hampshire et al., 2010; Xu et al., 2017). For example, rIFG

87   activity scales with stimulus probability (Shulman et al., 2009) and regularly during tasks

88   requiring attentional re-orienting (Vossel et al., 2006; Levy and Wagner, 2011). The

89   claim that attentional orienting drives response inhibition is supported primarily by

90 demonstrating rIFG fMRI activity is equivalent during both stop-signal tasks and other

91 tasks with no apparent inhibitory demands (Sharp et al., 2010). In this framework

92 (reviewed in Hampshire and Sharp, 2015), inhibition could occur through rIFG top-down

93 signals that bias attentional processing through increasing synaptic efficacy of sensory

94 cortices (Hampsire, 2015; Feldman and Friston, 2010).

95 Given the prevalence of findings supporting either a direct or indirect role of rIFG

96 in response inhibition, or the absence of behavioral inhibition processes altogether,

97 delineating between alternative mechanisms has remained inconclusive. For example,

98 an established way to control for attentional demands is comparing neural activity

99 during a stop-signal and putatively non-inhibitory tasks. However, a notable issue with

100 this comparison is that other tasks may still induce unaccounted for cognitive processes

101 or latent inhibitory demands not directly measurable in behavior (Aron et al., 2014).

102 Given the ambiguity introduced by comparing tasks to parcellate neural activity

103 underlying inhibitory versus other cognitive demands, direct approaches are needed to

104 circumvent these issues.

105 Neurostimulation during inhibitory tasks offers a potential in-route to identify how

106 rIFG, and particularly pars opercularis, is causally involved in motor braking, while

107 detailing its role in the broader inhibition network. Respectively, several studies have

108 applied transcranial magnetic (TMS; Cai et al., 2012; Obeso et al., 2013; Verbruggen et

109 al., 2010) or direct current (Jacobson et al., 2011) stimulation during inhibition tasks.

110 Some studies found offline TMS applied to either rIFG or pre-SMA impaired or improved

111 inhibition performance (Chambers et al., 2006; Verbruggen et al., 2010), respectively.

112 However, others have shown pre-SMA TMS can either improve inhibition with no effect

113   on rIFG (Obeso, 2013). Limitations of previous human neurostimulation response

114   inhibition studies include either lack of neural activity measurements or limited spatial

115   accuracy (Opitz et al., 2013). For example, TMS applied to rIFG during inhibition tasks

116   most likely engaged ventral premotor areas involved also in action switching (Buch et

117   al., 2010). The implication is that, if rIFG is potentially involved in attentional orienting,

118   inhibitory control, or both, these neurostimulation approaches likely elicited broad

119   effects on these processes. Therefore, it remains to be causally established that rIFG

120   and, more importantly, pars opercularis, engage an explicit motor inhibition mechanism

121   embedded in its connectivity that operates alongside attentional mechanisms (Munkata

122   et al., 2011; Wiecki and Frank, 2013).

123   Here, we employed MRI-guided, neuronavigated transcranial focused ultrasound

124   stimulation (TFUS) directly to the pars opercularis of the rIFG while humans performed

125   a stop-signal task. TFUS is a stimulation technique with a millimeter spatial resolution

126   (Fini and Tyler, 2017). Neural activity underlying response inhibition was assessed with

127   EEG event-related potentials (ERPs) and source analysis. Using this approach allowed

128   us to delineate the specific role of pars opercularis, while detailing which ERPs and

129   network functions are directly related to inhibition success and its speed (SSRT). TFUS

130   to pars opercularis significantly improved response inhibition through a targeted effect of

131   shortening SSRT. To determine how TFUS altered biophysical mechanisms generating

132   neural activity underlying inhibitory mechanisms, we built dynamic causal models

133   (DCM) of ERPs using microcircuit models. The main network hypothesis was that an

134   explicit rIFG inhibition mechanism would be embodied in direct rIFG-to-subcortical

135   connectivity weighting that directly reflects TFUS-induced changes in stopping efficiency

136   (SSRT). We confirmed this hypothesis by demonstrating TFUS directly altered rIFG

137   connectivity to a hidden subcortical node. In addition, DCM also indicated that only No-

138   TFUS successful versus failed stopping, rather than successful stopping in general,

139   were differentiated by mechanisms linked to network mechanisms associated with

140   attentional modulation, i.e., recurrent synaptic superficial gain of visual cortex.

141   Importantly, these results support the proposal that rIFG is directly involved in

142   implementing an explicit response inhibition function and stopping efficiency.

143   **Methods**

144   **Participants**

145   Participants consisted of healthy adult volunteers and were divided into one of

146   three experimental groups. The main experimental group received transcranial focused

147   ultrasound (TFUS) stimulation to the right inferior frontal gyrus (rIFG) (n = 25; 19 males,

148   mean age 24.1 yrs SD 3.2 yrs). A second group was used as cortical site, active control

149   group. These participants received stimulation to the ipsilateral somatosensory cortex

150   (S1) (n = 23; 15 males, mean age 22.4 yrs. SD = 3.3 yrs). A third group received a

151   sham stimulation near the right temple (n = 15; 8 male, mean age 24.2 yrs SD = 2.8 yrs)

152   and was used as control for possible auditory effects of TFUS over rIFG (sham rIFG).

153   All individuals were right-handed and received financial compensation for participation

154   in the study. Before being enrolled, each subject was screened for neurological

155   disorders and previous history of epilepsy, stroke, or brain injury. Furthermore, a

156   neurologist from the Barrow Neurological Institute (Phoenix, AZ) screened all subjects'

157   T1 scans after structural MRI acquisition, and before participation in the study.

158   **Stop Signal Task and TFUS design**

159   The current study used the conventional Stop Signal Task that involved both 'Go'

160   and 'Stop' trials (Fig. 1A). We presented the experiment using Opensesame (Mathôt et

161   al., 2012). Each trial started with a centrally-located fixation cross on the monitor. In

162   both trial types, the fixation cue was replaced by a green 'Go' circle (3° x 3° visual

163   angle), with an exponentially-distributed time interval (mean: 500 ms; standard

164   deviation: 50 ms). Subjects were instructed "to press the up key as soon as they

165   detected the Go circle" (top panel, Fig. 1A). In 'Go' trials, the circle vanished when the

166   button was pressed or after 800 ms had passed from the fixation cross stimulus. In

167   'Stop' trials, the stop was a red square which appeared around the green circle (middle

168   and bottom panel, Fig. 1A). If the subject successfully inhibited his/her response with

169   respect to the Stop cue within 800 ms, the red square was extinguished, and the trial

170   was considered a successful inhibition. The time required to inhibit a response following

171   the Stop signal is defined as stop signal reaction time (SSRT) (see below). The timing of

172   the Stop cue relative to Go cue, i.e., the stop signal delay (SSD), was presented at one

173   of four fixed, but subject-specific SSDs. The SSDs were designated by having each

174   subject first perform a practice block of 50 Go trials only to determine their baseline Go

175   reaction time (RT). After this block, the 4 SSD levels were set to 25, 35, 75 and 95% of

176   the mean Go RT. These SSDs were fixed throughout the experimental session. Using a

177   set of fixed SSDs allowed us to calculate the SSRT using routines that are less

178   susceptible to low trial numbers (Matzke et al., 2013; see Data processing). Additionally,

179   we sought to determine the effects of online TFUS at different SSDs to estimate the

180   effects of stimulation on neural and behavioral responses at different stages of a Go

181   process predicted by response inhibition models (Verbruggen and Logan, 2009). All

182   trials were separated by an inter-trial interval of 2000 ms (±300 ms randomly drawn

183   jitter).

184   TFUS was delivered either simultaneously with (1) the Go signal in both Go and

185   Stop trials, or (2) the Stop signal (Fig. 1A). The purpose of delivering TFUS during Go

186   trials was to determine the neural and behavioral effects of TFUS to rIFG independent

187   of a stopping signal. Specifically, this allowed us to assess whether any effects of TFUS

188   on stopping behavior are related merely to alteration of the timing of an underlying Go

189   process. Therefore, we used 5 types of trials. The first two consisted of Go trials with no

190   TFUS or with TFUS locked to the Go cue (No-TFUS and Go-TFUS trials, respectively).

191   The other three trials consisted of Stop trials: No-TFUS trials, Go-TFUS, and TFUS

192   locked to the Stop signal (Stop-TFUS). These three types of Stop trials were examined

193   across the four SSDs.

194   TFUS delivery for Stop trials was evenly distributed across the 4 SSD levels. The

195   overall probability of a stop trial was set to 35% of all trials (Fig. 1B). We chose this level

196   to accommodate the need for large amounts of Stop trials required to examine the

197   effects of TFUS on Stop trials across all SSD levels, while still making Go trials more

198   frequent. Each experimental session consisted of 1200 trials distributed across 12

199   blocks. Blocks were segmented into stimulation and no-stimulation blocks; the former

200   containing trials with and without stimulation, and the later containing no stimulation.

201   Trial types (Go and Stop trials) were randomly and evenly distributed throughout the

202   experiment. The trial numbers were chosen to enable the comparison between TFUS

203   and non-stimulation trials across successful and failed inhibition trials, while allowing a

204   reasonable number of trials to be performed without inducing significant fatigue to the

205   participants. The block design, as well as the use of an active-stimulation and sham

206   control groups was chosen to mitigate any possible carry-over effects of the stimulation

207   across trials.

208   **EEG acquisition**

209   EEG was recorded using a 64-channel ActiCap system (BrainVision, Morrisville,

210   NC), with a standard 10–20 layout. Data was recorded at a sampling rate of 5 kHz, with

211   resolution 0.1 µV and bandpass filter of 0.1–100 Hz. Impedances were always kept < 5

212   kΩ. Online recordings utilized a ground at AFz and left mastoid reference. At the

213   beginning of each session, electrode layouts with respect to each individual's head

214   shape were registered using a CapTrak camera system (BrainVision, Morrisville, NC)

215   with the left and right preauricular, and nasion as fiducial landmarks. This allowed for

216   later co-registration with each individuals T1 structural MRI scan and for source-

217   localized analysis (see Data Processing).

218   **Structural MRI acquisition (T1) and processing**

219   For purposes of TFUS neuronavigation and co-registering EEG electrode

220   placement, we obtained a structural T1 MRI scan for each participant. T1 volumes were

221   collected using an 3D MPRAGE sequence (TR = 2300 ms, TE = 4.5 ms, 1 x 1 x 1.1

222   mm^3 voxels, field of view 240 x 256 mm^2, 180 sagittal slices) in a Philips Ingenia 3T

223   scanner with a 32-channel head coil. Brainsuite was used to process T1s, which

224   included cortical extraction sequence and a surface label-registration procedure with the

225   BCI-DNI atlas. After labeling, we checked the locations and created a mask of either

226   pars opercularis (rIFG group) or the centroid of ipsilateral S1 (control group). This

227 volume labeling and mask creation procedure was used for guiding TFUS target

228 identification.

TFUS targeting, setup and parameters

230   All stimulation targets were planned prior to subject arrival. We used a Brainsight

231 neuronavigation system (Rogue industries) with subjects' T1 scans to guide placement

232 of the transducer beam profile with respect to each individual's neuroanatomy. First, we

233 created a subject-specific mask from the cortical atlas registration and projected it into

234 the Montreal Neurologic Institute (MNI) coordinate system (Evans et al., 1994). When

235 planning the TFUS target, we considered both MNI coordinates and individual anatomy.

236 For example, neuroimaging studies (Boehler et al., 2010) and metanalysis (Chikazoe et

237 al., 2009; Levy and Wagner, 2011) have shown specific activation of the pars

238 opercularis (around x=48, y=16, x=18) for contrasts of successful inhibition versus Go

239 trials and successful versus failed inhibition trials. In the case of the RIFG group, we first

240 identified these MNI coordinates. Notably, the pars opercularis is an anatomical

241 definition and is often referred to as ventro-lateral prefrontal cortex in neuroimaging

242 studies focused on localization of activity that is functionally related to response

243 inhibition and cognitive control (Levy and Wagner, 2011). During target planning, we

244 confirmed the identified MNI coordinates were inside the anatomical region of the pars

245 opercularis, identified from registering atlas maps to individual anatomy. We also

246 performed visually confirmation that the TFUS target was indeed rostral to the inferior

247 precentral sulcus, dorsal to the sylvian fissure, caudal to the ascending rhomulus of the

248 syvian fissure, and ventral to the inferior frontal sulcus (Tomaiuolo et al., 1999).

249 Because significant anatomical variation exists in this region, individual anatomy rather

250   than coordinates were prioritized when planning the TFUS focus. For the S1 group,

251   stimulation was targeted near x=-43, y=-29, z=54 and within the left post-central gyrus.

252   Because we used a single element transducer, with a fixed focal depth of 30mm and a

253   5mm silicon spacer, all stimulation was done at a penetration depth of 25mm and

254   normal the surface of the scalp.

255   After EEG setup, we used an infrared optical tracking system (Polars Vicra, NDI

256   Medical) to register the subjects' structural MRI scans in virtual space, with their head

257   and the ultrasound transducer in real space. The alignment and cortical registration

258   were accomplished by registering the individual's T1 derived anatomy using the nasion,

259   tip of the nose, philtrum, and left and right periauricular notch and tragus. To visualize

260   the TFUS target in the cortex, we created a custom design in Solidworks that rendered

261   the transducer housing and ellipsoidal beam profile projection into the registered cortex

262   (Fig. 1C). A 3D printed housing was made for the transducer to hold the optical tracking

263   unit and silicon spacer (ss-6060 Silicon Solutions, Cuyahoga Falls, OH

264   http://siliconesolutions.com/ss-6060.html). Acoustic conductive gel was applied to both

265   the transducer and the scalp. After correct placement of the transducer using the

266   neuronavigation, we recorded the coordinates of the stimulation target. Figure 1C

267   shows the rendering from one subject's T1 and scalp in the rIFG group, along with the

268   3D rendering of the transducer housing (green object) and the pars opercularis mask

269   (white anatomical structure). In the auditory rIFG control group, we employed a sham

270   TFUS (similar to Legon et al., 2018) by placing the gel coated transducer perpendicular

271   to the rIFG target. This sham procedure was done to ensure there was still an auditory

272   effect of the ultrasound (from the pulse repetition frequency) without active stimulation.

273   The TFUS transducer was held flush to the head with a custom-made,

274   lightweight, elastic mesh cap, which did not interfere with EEG recording. To ensure

275   accurate TFUS placement throughout the experimental session, the rotational and

276   cartesian displacement of the beam profile from the cortical target was tracked. The

277   overall accuracy was measured as deviation from the original alignment of the beam

278   with the anatomical target. During the experimental session, we sampled the position of

279   the TFUS transducer during each break. Accuracy was very high, with an average

280   deviation of ±1.5 mm displacement across all subjects and sessions.

281   The setup and parameters used for TFUS in this experiment were nearly

282   identical to those used by Legon et al. (2014). We used a broadband, single-element

283   focused ultrasound transducer with a center frequency of 0.5 MHz, a fixed focal depth of

284   30mm, and a lateral spatial resolution of 4.5 mm^2 and axial spatial resolution of 18mm^2

285   (Blatek, Inc., State College, PA) (Legon et al., 2014). Prior water tank testing through

286   cadaver skull revealed transcranial spatial-peak pulse average intensity (I_{sppa}) of 5.8

287   W/cm^2, and the optimal frequencies for TFUS transmission while minimizing cranial

288   attenuation are 0.2- 0.65 MHz (Hayner and Hynynen, 2001; White et al., 2006).

289   The TFUS waveforms were generated using a two-channel, 2 MHz function

290   generator (BK Precision) (Legon et al, 2014). Channel 1 was triggered by the

291   presentation computer and produced the pulse repetition frequency (PRF) of 1.0 kHz.

292   This was used to trigger channel 2, which produced short burst at the 0.5 MHz acoustic

293   frequency. The result produced a ultrasound waveform with a carrier frequency of 0.5

294   Mhz, PRF of 1.0Khz, and duty cycle 24%. Each stimulation duration was 0.5 s. The

295   transducer power was driven by sending channel 2's output to a 40-W linear RF

296 amplifier (E&I 240L; Electronics and Innovation). The waveforms were triggered in

297 alignment with experimentally-relevant temporal events (see description below and Fig.

298 1A). It has been previously verified that the resulting waveform does not incur any

299 heating of skin or skull bone (Legon et al., 2014).

300 **Computational simulation of TFUS propagation**

301 We quantified peak pressure amplitude, peak intensity and accuracy of the beam

302 distribution with TFUS target to rIFG using the pseudospectral simulation method in K-

303 wave (Treeby and Cox, 2010). Reference peak pressure planes for the simulations

304 were derived from a water tank test and previous data (Legon et al., 2014). Simulation

305 parameters were first validated by simulating the transducer in water to compare the

306 simulation results with those from the water tank test. The max pressure plane at the

307 30-mm focus in the water tank was used as a source input pressure for the transducer

308 during the simulation. The transducer was modeled to have a 30-mm radius of

309 curvature. Water simulations used a homogenously medium of water density (1000

310 kg/m^3) and speed of sound (1482 m/s). We created a computational grid over a 256 x

311 256 x 256 with 1-mm spacing. The points per wavelength were 6, Courant–Friedrichs–

312 Lewy = 0.1, and simulation time was set to 6 pulses (duration = 250 μs) to ensure

313 simulation stability.

314 Simulation of ultrasound through water predicted a max pressure of 1.05 Mpa

315 and spatial peak pulse average intensity (Isppa) of 22.4 W/cm^2 at the focus. This

316 prediction closely aligns with previous studies and simulations (Legon et al., 2014) of

317 the same transducer. Comparison of simulations and water data indicated a 97% match

318 of pressure/intensity at the focus taken over a $5\,mm^3$ voxel section in all 3 planes at the

319 focus. The lateral full-width at half maximum of the max pressure at the beam was 4.39

320 mm in simulation (Fig. 1C).

321   For simulating transcranial US, we extracted 3-dimensional maps of the skull

322 from a CT (1-mm resolution) and brain from T1 MRI scan (1-mm resolution) from three

323 preoperative patients at Barrow Neurological institute. The MRI and CT were both co-

324 registered and normalized to the MNI space in SPM12. To mimic our approach of

325 targeting used in the experiments, we surface registered the gray matter volume to the

326 BCI-DNI atlas and identified the centroid of pars opercularis. This allowed us to map

327 from world coordinates of the scan to MNI coordinates of the target (Fig. 1D). The

328 average stimulation location for these three subjects was x = 48, y = 18, and z = 6.

329 Conversion from Hounsfield units in the CT to sound speed and density were done

330 using the relations described in Aubry et al. (2003). All skull materials were set using

331 these parameters, while other tissues were treated as homogeneous with parameters

332 set to that of water. Attenuation was modeled as a power law with a $\beta = 0.5$ and

333 absorption was also modeled with a $b = 1.08$ (Treeby and Cox, 2010). Results for this

334 simulation are presented in the Results section.

335   **Data processing and experimental variables**

336 **Behavioral variables**

337   The main variables under consideration were the Go trial reaction time (Go RT),

338 percentage of successfully inhibited responses on Stop trials (successful stopping) per

339 SSD, failed inhibition reaction time, and SSRT. The SSRT was estimated using a

340 hierarchical Bayesian parametric approach (Matzke et al., 2013a) that allows estimation

341 of the distribution of SSRTs while assuming an ex-gaussian distribution of SSRTs.

342   Importantly, we chose this approach as Matzke et al. (2013a) showed that it performs

343   well even when there are only a few trials available per SSD level. This SSRT

344   estimation procedure was run separately per group (rIFG and S1) and trial types (No-

345   TFUS Stop trials, Go-TFUS Stop trials, and Stop- TFUS Stop trials). As we report in the

346   Results section, we used combined RTs from Go trials with and without TFUS because

347   stimulation did not alter the Go RT.

348   **EEG artifact removal**

349   Continuous EEG data were first down-sampled to 250 Hz, then high-pass filtered

350   (1 Hz) and re-referenced to the scalp average. Any channels that displayed artifacts for

351   more than 25% of the total session were removed before further processing but were

352   later interpolated after artifact rejection. We removed channels that were designated

353   unsuitable for analysis by visual inspection and absolute temporal standard deviation (>

354   5) across channels. It is important to note that, in each of the stimulation groups, the

355   cortical sites of rIFG and S1 were close to the F8 and CP4 electrodes. Therefore, these

356   electrodes could not be used for EEG recording in their respective groups and were

357   always interpolated after artifact removal. The remaining data processing involved

358   creating epochs from Stop trials locked to stop signal onset (-100 to 500 ms

359   peristimulus) because our analysis focused on this epoch. Individual epochs were then

360   rejected from further analysis if they contained large scalp EMG or rare events (< 8% of

361   all trials). The ERPs baseline corrected by subtracting the activity from -100 ms to the

362   stop signal. Out of the 53 participants, 3 subjects were excluded from analyses due to

363   EEG recording issues (impedance >25 kΩ across channels). The remaining data were

364   bandpass filtered from 1-25 Hz. EOG artifacts related to eye movements and blinks

365   were removed using Independent Components Analysis using eeglab (ICA; Delorme

366   and Makeig, 2004). On average, 3.35 components were removed per participant.

367   Because we later applied a Hanning taper to the edges of the event-related potentials

368   (ERP) before dynamic causal modeling, we applied the same procedure to the ERPs

369   after cleaning using a Hanning taper.

370   **QUANTIFICATION AND STATISTICAL ANALYSIS**

371   **Behavior analysis**

372   To quantify how the probability of response inhibition changed over levels of

373   SSD, P(respond|signal), and across TFUS conditions within and across groups we fit a

374   2-parameter logistic model. This was done to analyze P(respond|signal) as a curve.

375   This was achieved using by fitting the 2-parameter linear mixed-effects model with

376   random intercepts and slopes to obtain subject and condition specific model

377   parameters. P(respond|signal), denoted as p, were converted to a negative logit (log((1-

378   p)/p) before fitting. As our main goal was to estimate the logistic curve slope (β), we ran

379   the mixed-effects model (using LME4 in R) with the full interaction of SSD and

380   stimulation condition (no-TFUS, Go-TFUS, Stop-TFUS). Logistic slopes per subject

381   were estimated by combining fixed and random coefficients. β parameters were

382   analyzed using a mixed-design ANOVA on β with factors of Group (3 levels) and TFUS

383   (3 levels: No, Go, Stop).

384   **Separating neural components of Go-responses and response-inhibition**

385   Our analysis of ERPs was based on the premises of the Independent Horse

386   Race model (Logan and Cowan, 1984) – which posits independent accumulation of Go

387   and Stop activity till one of them reaches threshold. Due to the nature of measuring

388   these processes through EEG and the inhibitory processes, there is overlap of neural

389   processes related to stopping and going during stop trials. Therefore, we removed Go-

390   related activity from both successfully (SS) and unsuccessfully (US) inhibited Stop trials

391   through subtracting the Go ERPs from the Stop ERPs. We used the approach

392   employed by Mattia et al. (2012). On a per-subject basis, we found Go-trial ERPs (No-

393   TFUS and TFUS) that had RTs that were latency-matched to SS trials based on each

394   subject's SSRT. These Go trials had to have RTs either equal to or greater than the

395   SSRT. For US trials, we found latency-matched Go trials with RTs with a different

396   procedure. We first calculated each subject's mean signal-respond RT for each of the

397   two highest SSDs. We then calculated the difference in SSD (ms) and searched for Go

398   RT trials for each SSD that fell within the mean signal-respond RT ± half the difference

399   of the SSD (ms). This was done to prevent overlap of activity from both faster and

400   slower Go RTs and signal-respond RTs. These steps were performed separately for the

401   highest and second highest SSD. This procedure was done separately for SS and US

402   trials for both TFUS conditions. After correcting the SS and US stop trial, the corrected

403   ERPs were averaged across the two highest SSDs per subject (corresponding to the

404   85% and 105% mean Go RT of each subject). These ERPs were used for the remaining

405   analysis.

406   **Analysis of inhibition-related ERP**

407   Our analysis focused on event-related potentials (ERPs) from source-localized

408   analysis and Dynamic Causal Modeling (DCM; David et al., 2006). The primary

409   motivation for these analyses is that previous work has revealed a set of ERPs that

410   often accompany response inhibition following a Stop signal (reviewed in Huster et al.,

411 2013 and Kenemans, 2015). The main ERPs found in inhibitory tasks include a N2/P3

412 complex that has a fronto-central and radial topography. This component has been

413 hypothesized to be generated mainly by the pre-SMA/SMA in the medial frontal cortex

414 (Huster et al., 2013) and has been considered to reflect a critical signature of reactive

415 stopping elicited by stop signal tasks (Kenemans, 2015; Wessel and Aron, 2017).

416 Furthermore, the P300 of this complex has been proposed to be a relevant marker of

417 stopping efficiency, given that it predicts the SSRT (Wessel and Aron, 2015) and

418 successful versus failed inhibition (Kok et al., 2003). The ERP associated with stopping

419 in rIFG is typically associated with a negative amplitude difference comparing

420 successful and failed stopping that emerges around 200 ms (N200; Schmajuk et al.,

421 2006). We examined these ERPs and P/N100 responses which are sometimes elicited

422 over sensory areas, depending on whether the stimuli used for Go and Stop signals are

423 in the same sensory modality (Kenemans, 2015). By combining TFUS and EEG, we can

424 examine some of the issues that are addressed by ongoing debate, i.e., which of these

425 potentials are stopping-relevant, and how their activity is generated by a network model

426 through DCM – all without signal interference induced by stimulation.

427 **Scalp space analysis.**

428   To examine the standard ERP effects typically found in the SST, we first

429 examined activity at the sensor level. This was done using permutation-based

430 dependent samples t-tests. Spatiotemporal activity was examined and multiple-

431 comparison corrected for using a cluster-based p-value correction of $p < 0.01$ and 5000

432 permutations for each contrast considered. The contrasts included comparison of (1)

433 successful stop (SS) – unsuccessful stopp (US) trials over Go-TFUS and Stop-TFUS

434　conditions, a (2) SS (No-TFUS) – SS (Stop-TFUS) contrast, and (3) and interaction

435　contrast comparing SS – US difference between the No-TFUS and Stop-TFUS

436　conditions. The first contrast is typically used to determine which areas exhibit ERPs (or

437　brain areas) that differentiate successful inhibition (Swaan et al., 2012). The third

438　contrast (interaction) was used to determine how the SS-US contrast differed between

439　No-TFUS and Stop-TFUS conditions. The second contrast was the main focus of our

440　analysis and was used to determine which scalp ERPs differentiated successful

441　stopping in the No-TFUS and Stop-TFUS conditions. We anticipated that this contrast

442　would reflect processes that mainly include those responsible for both the success and

443　efficiency of inhibitory processes, e.g., SSRT.

444　**P300 onset and SSRT TFUS effects**

445　　　Recent work has indicated that the frontocentral P300 onset latency is related to

446　the SSRT (Wessel and Aron, 2015). Therefore, we hypothesized that TFUS altered

447　inhibition through the SSRT and expected a shift in this latency as well. We calculated

448　the shift in P300 onset crossings between TFUS conditions in two steps. First, we took

449　the across-subject mean frontocentral ERP waveform in a time-window of ±50 ms

450　around the zero-crossing. To calculate each subject's zero-crossing time, we calculated

451　the dynamic time warping distance from the template mean ERP to the subject's ERP.

452　Second, this distance was added to the median zero-crossing time to obtain an

453　individual subject crossing for both the No-TFUS- and Stop TFUS-locked conditions.

454　**Source localization**

455   To estimate the activity in source space from the sensor recordings, we used a

456   group inversion with the multiple sparse-priors approach as implemented in SPM12.

457   The individual subject data passed to the inversion routine were mean sensor ERPs per

458   condition. We performed the group inversion only for the rIFG groups and analysis

459   because this was the only group to exhibit behavioral effects from TFUS. In this

460   procedure, the individual's recorded electrode locations and individual T1 were warped

461   to the default MNI anatomical brain and cortical mesh provided in SPM. These meshes

462   were used to calculate the forward solution using a boundary element head model. All

463   conditions were used in the group inversion routine. Because the multiple sparse-priors

464   approach attempts to fit the sensor data with respect to the lead-field matrix, we

465   performed the inversion over a window starting from the stop signal up to 500 ms. While

466   narrow windows are considered better for time-resolved estimation, we wanted to

467   estimate overall changes in activity using the same window we would employ later for

468   dynamic causal modeling.

469   **Source analysis: Whole-brain contrasts and regression**

470   Based on examination of the sensor level data, we first identified time windows

471   surrounding the ERPs discussed above (N100, N200, and P300). To balance the

472   number of points contributing to the source estimate used for analysis, we used the

473   same window size for estimating the source activity of each ERP. The time windows

474   were centered around the across-subject mean peak activity of each ERP with a

475   window of ±40 ms. These time windows were used to create 3D source image activity

476   interpolated into MNI voxel space for each subject and condition. The resulting images

477   were spatially smoothed (6 mm full-width half maximum) evoked power from 1-25 Hz.

478   We used evoked power because we were concerned with 'activation' and time window,

479   but not the direction of voltage deflection. This choice was driven by the fact that we

480   already established the canonical inhibition related ERPs at the scalp level. These

481   evoked images were analyzed used a flexible factorial design to implement a repeated-

482   measures ANOVA, including all main effects and interactions. The factors included (1)

483   inhibition success (SS or US trial), and (2) stimulation condition (No-TFUS or Stop

484   TFUS). The resulting statistical parametric maps were analyzed with a threshold set at p

485   < 0.005 (peak-level, uncorrected) and cluster-wise FWE $p < 0.05$. For expositional

486   brevity, these SPMs are presented in the supplementary material except for the

487   conjunction F-contrast showing the overlap of the SS-US and TFUS F-contrasts. This

488   conjunction shown in the main text both confirms the differential SS-US effect in rIFG

489   and the spatially precise impact of TFUS.

490   We also conducted a whole-brain SPM linear regression using the same time

491   windows identified above. We regressed the difference in evoked activity between No-

492   TFUS and Stop-TFUS SS trials against the difference in each subject's SSRT for these

493   conditions. Using this approach, we examined both positive and negative contrasts (t-

494   tests) in each window. This analysis was done to (1) determine prior source locations

495   for the DCM analysis (see below) and (2) identify which areas predicted the change in

496   SSRT due to TFUS. Because a primary goal was determining DCM priors, we used a

497   lenient uncorrected cluster threshold of $P < 0.01$ and a minimum cluster-extant

498   threshold of 20 voxels.

499   **Dynamic Causal Modeling (DCM)**

500   To model the connectivity of the network involved in successful stopping, we

501   used the canonical microcircuit model (Bastos et al., 2012) for all areas except the

502   contralateral motor cortex. For left motor cortex (M1), we used a recently developed

503   version built-off the canonical microcircuit that more closely resembles the agranular

504   structure of M1 (Bhatt et al., 2016). Our sequential model building and analysis focused

505   both on a priori areas of interest that have been well described in response inhibition

506   literature (e.g., Wessel and Aron, 2017) – including rIFG, rpre-SMA, rDLPFC – and

507   those areas that we identified in comparing the effects of Stop TFUS and No-TFUS

508   changes in SSRT on evoked power. Given the typically right-lateralized areas found to

509   be modulated by inhibition, we focused mainly on pathways on the right hemisphere.

510   We used source locations identified in both (1) the regression of change in SSRT and

511   (2) the whole-brain SPM interaction F-contrasts examining locations for which Stop-

512   TFUS and No-TFUS were different for the SS-US comparison. The significant source

513   cluster peaks ($P < 0.01$ threshold) revealed by these analysis were labeled using the

514   AAL atlas labeling toolbox, and used to identify source coordinates in MNI space

515   ([x,y,x]: rIFG [48,28,4]; pre-SMA [6, 24, 54]; rDLPFC [30, 28, 40]; rParietal [10,-74,56];

516   rTemporal [52,-18,-12]; LM1 [-37,-25,-62]; right inferior occipital gyrus (rIOG) [46, -

517   76,10]). These source locations are in general agreement with previous literature in both

518   fMRI, EEG, and MEG studies of SSTs (Aron et al., 2006; Boehler et al., 2010; Rae et

519   al., 2014) and meta-analyses of cortical locations and boundaries (Chikazoe et al.,

520   2009). In building the model, we also included a hidden deep source to model the

521   potential connectivity effects to and from cortical sources. Because the main output of

522   the basal ganglia mediating inhibition and responding is the thalamus, we used a source

523 location [4, -16, -2] identified during a previous fMRI stop signal study (Boehler et al.,

524 2010). This approach of using a deep source node in DCM for EEG has been previously

525 employed by David et al. (2011). In the DCM, we used an equivalent current dipole

526 model and allowed the inversion process to optimize the source locations.

527   To determine the appropriate model connectivity structure, we first examined the

528 grand mean ERP data in SS No-TFUS trials from a window spanning 0 – 500 ms.

529 Recent work has shown that estimating the model structure from grand means (across

530 subjects) is sufficient and provides a close approximation to fixed-effects selection when

531 using ERP data (Litvak et al., 2015) rather than fitting DCMs across all subjects for each

532 variation in connection structures.

533   To optimize the model structure, we performed Bayesian model selection using

534 family-wise fixed effects in several iterations. In the first set of iterations, we inverted 48

535 different models from the grand mean data, and then partitioned it into several families

536 (Penny et al., 2010). These families were based on (1) the structure of the pre-frontal

537 hierarchy (Fig. S1), (2) structure of the lower hierarchy (Fig. S1), (3) whether exogenous

538 inputs were supplied to right inferior occipital gyrus (rIOG), rIFG, or both, and (4)

539 whether the cortical nodes projecting to the hidden deep source were of the forward or

540 backward type. Inputs were modeled as a Gaussian bump with a prior onset of 60 ms.

541 With respect to comparison (4), pulling evidence from previous inhibitory control,

542 primate tracing, and tractography studies and reviews, the areas we examined for

543 different connections projecting to the deep node included rIFG, pre-SMA, right

544 dorsolateral prefrontal cortex (rDLPFC) and rIOG. A backward connection from M1 to

545 the deep node was also included based on putative M1 to basal ganglia connections

546   (Nambu et al., 2002). Because the efferent connections from Thalamus output is

547   excitatory and has been found to target deep pyramidal layers (Yamawaki et al., 2014),

548   the above listed areas all received forward connections from the deep source.

549   In this modeling, we assumed hierarchically connected areas always entailed a

550   backward and forward connection between nodes. Nodes that were lateral in a

551   hierarchy were supplied with both forward and backward nodes (Fig. S1). A final note is

552   on the connections between lower areas and prefrontal areas. Rather than optimize all

553   possible connection permutations, we chose to instantiate connections that reflect the

554   cognitive and attentional control-related differences typically postulated to operate in

555   dorsal and ventral pathways (Corbetta and Shulman, 2001). Both streams received

556   forward input from rIOG. The ventral stream included a forward connection from

557   rTemporal cortex to rIFG. The dorsal stream included forward projections from rParietal

558   to both rDLPFC and pre-SMA.

559   After inversion of each model, we used a fixed-effects Bayesian model selection

560   to perform family inference and calculate the model posterior probability to determine

561   the winning model in each family. The family model probability results from these four

562   different family comparisons are shown in Figure S2. This analysis indicated that,

563   across families, the winning model had (1) a prefrontal hierarchy with laterally

564   connected rDLPFC and rIFG above pre-SMA, (2) a parallel structure of rParietal and

565   rTemporal cortices without a lateral connection, (3) exogenous inputs to both rIOG and

566   rIFG, and (4) backward cortical to deep connections. A diagram of the final model

567   structure is shown in the DCM results section.

568   The next step in model building involved determining which connections were

569   modulated by conditions specific changes between No-TFUS SS and US trials and,

570   primarily, between No-TFUS SS and Stop-TFUS SS trials. For our purposes, this

571   included extrinsic connections between areas and intrinsic gain connections within an

572   area. Instead of testing an expansive set of permutations of condition-specific

573   modulations of extrinsic connections (B matrix in DCM), we a priori opted to use the

574   recently developed Parametric Empirical Bayesian modeling framework for DCM

575   (Friston et al., 2016). As will be explained below, this involves doing Bayesian statistics

576   on full DCMs that will have all condition modulatory parameters of interest entered a

577   hierarchal-general linear model from which hypotheses can be tested. This obviates the

578   need for conventional statistics and model reduction over all extrinsic connections. If a

579   DCM model is referred to as full, this includes condition-driven modulations of all

580   extrinsic connections. Otherwise it includes an explicitly stated set of connections.

581   After determining a model structure, we inverted this model for each subject's

582   ERPs. This inversion was performed twice, using different combinations of trials to

583   assess different hypotheses. The DCM was first inverted using the No-TFUS US and

584   SS trial ERPs. The US trial was set as the baseline. This inversion allowed us to first

585   compare how the network connections were modulated between US and SS trials in a

586   baseline network without the effects of TFUS. Specifically, we wanted to examine how

587   changes in connectivity (DCM B matrix) distinguished between unsuccessful and

588   successful inhibition. Analysis of this general linear model (described below) focused on

589   the B matrix which describes how connections changed between conditions. This

590   comparison was done to mirror the standard comparison of SS and US trials that is

591   typically employed to reveal what inhibitory mechanisms were more potently activated

592   during SS trials (Aron et al, 2014). Furthermore, using this contrast of conditions

593   provides a baseline to ask whether the same connectivity mechanisms were altered

594   when comparing No-TFUS and Stop-TFUS SS trials. Therefore, the second DCM model

595   inversion was applied to the No-TFUS and Stop-TFUS SS trials. The No-TFUS trials

596   were used as a baseline for the fit. Again, this allowed a focus on the connectivity

597   modulation between the two conditions and treated the non-stimulation condition as the

598   baseline network.

599   To analyze the resultant DCM condition-specific changes and the modulation of

600   connectivity parameters by experiment relevant variables (e.g., SSRT), we tested

601   group-level effects using the Parametric Empirical Bayes (PEB) framework. We give a

602   brief overview of PEB (for in-depth discussion, see Friston et al., 2016) for hypothesis

603   testing and connectivity parameter extraction using a PEB. Building a PEB statistical

604   model involves creating a hierarchical model with, in our case, two levels. The lower

605   level is the subject level, which is the results of DCM fits to individual's ERP data. This

606   first level includes the posterior means and uncertainties for each subject's DCM

607   connectivity parameters. The PEB framework statistically models these parameters

608   using a Bayesian general linear model (GLM) at the group level. As is the case with

609   GLMs (and mixed models), the model attempts to explains the connectivity parameters

610   as between-subject and within-subject variability, while allowing for between-subject

611   differences in connectivity parameters to be treated as random effects. The PEB

612   Bayesian GLM allows using subject-based DCM parameters to be examined using a

613   linear model with respect to explanatory variables at the between-subject (group) level.

614 Because the PEB framework yields group-level estimates as empirical priors, this

615 approach also allows changing parameters that were estimated at the subject level by

616 allowing them to be estimates distributed around a group mean effect. This process

617 stands in contrast to the typically used "summary statistic" approach, which often

618 involves applying several t-tests or correlations per connection.

619   For clarity, we built two separate PEB models for the DCMs fit to (1) No-TFUS

620 US and SS trials, and (2) No-TFUS and Stop-TFUS SS trials. The former PEB model

621 was used to test hypotheses regarding mean changes in connectivity between

622 unsuccessful and successful inhibition at baseline (No-TFUS). The latter PEB model

623 was used to address (1) how the inhibition network connectivity changed on average

624 between TFUS conditions (intercept in GLM), and (2) how individual differences in the

625 change in SSRT between TFUS conditions was embedded in changes in connectivity

626 parameters across subjects (covariate). Therefore, in the first model we only used the

627 mean intercept as the explanatory variable to examine mean changes in connectivity

628 between No-TFUS US and SS trials. The mean change parameters represent the gain

629 change in connectivity going from US to SS trials. In the second model, which examined

630 No-TFUS SS and Stop-TFUS SS trials, we used a design matrix of explanatory

631 variables that included an (1) intercept representing mean changes in connectivity

632 (mean TFUS effect), (2) the change in individual subject's SSRT between TFUS

633 conditions, and (3) the TFUS change in individual subject SSRT variability. Before

634 entering the SSRT covariates, they were transformed to a gain change by taking the

635 log-ratio of Stop-TFUS SSRT (mean or variability) over the No-TFUS SSRT (mean or

636   variability). The covariates were then z-scored to have a zero mean and yield

637   standardized PEB model parameters.

638   When initially estimating each of the two PEBs, we always entered in the full

639   model including all extrinsic and intrinsic connection modulatory parameters. Because

640   our hypotheses centered around changes along prefrontal and deep areas, and ventral

641   pathway interactions, we first compared the PEB model with and without dorsal pathway

642   connection parameters. We show in the results that, across both PEBs, the model

643   without dorsal pathway connection changes yielded a better model with respect to the

644   explanatory variables. This allowed a substantial reduction in connectivity parameters

645   needing to be tested.

646   Once the group-level GLM parameters were estimated with respect to

647   modulations of extrinsic and intrinsic connectivity, we used this framework to test

648   several hypotheses regarding mean and SSRT driven changes in connectivity

649   parameters. Hypothesis testing proceeds by Bayesian model reduction of the GLM. This

650   involves turning off/on different connectivity parameters and comparing the free energy

651   of reduced models. Comparing models in this manner is similar to performing classical

652   hypothesis testing via model reduction in mixed models by employing likelihood ratio or

653   F-tests.

654   Hypotheses were tested by designing models with different combinations of

655   parameters on/off. The model space of these hypotheses was defined in a factorial

656   space that focused on 4 factors that could be modulated by mean connectivity changes

657   (PEBs 1 and 2) or connectivity modulation via TFUS induced changes in SSRT (PEB 2).

658   These factor/hypothesis spaces were driven by previous work. The first set of models

659   considered how inhibition is related to pathways the backward connections from rIFG

660   and pre-SMA to the deep (i.e., basal ganglia) nodes. The second factor, driven by work

661   indicating that pre-SMA interacts with rIFG before deep projections (Rae et al., 2009),

662   tested for modulation of their backwards and forwards connections. The third factor was

663   motivated by proposals that differences in inhibition (SS vs. US) might be mediated

664   changes in attentional orienting, which predict changes in intrinsic self-inhibitory gain in

665   either rIFG, rIOG, or both. Therefore, this factor examined for modulation of the

666   superficial pyramidal cell gain across the nodes. Finally, to examine how SS versus US

667   and different TFUS effects on inhibition depend on top-down vs bottom-up processing,

668   our final comparison tested for the inclusion of either backward, forward or both sets of

669   connections along the ventral pathway. Given that each of 4 factors had 3 levels each,

670   plus a null (all zero) model, the first PEB surmounted to testing 3^4+1 (82) models, and

671   PEB model 2 included $2*3^4$+1 (163) models.

672   Rather than summarize these effects as the free energy for each model, which

673   would surmount to a severe reduction in discerning the probability of a winning model,

674   the hypotheses were grouped into families, and model hypotheses were tested at the

675   family level. After using family model comparison on reduced GLMs, we used Bayesian

676   model averaging (BMA) to obtain GLM model estimates of connectivity parameters

677   having a posterior probability >95%. BMA was performed on all families within a factor,

678   weighting the summarized parameters by the probability of the family. For example,

679   BMA parameters for the second PEB mode that includes the mean SSRT as a

680   predictor, for example, should be interpreted as would a linear regression coefficient;

681   similarly, the mean term would represent the mean change in connectivity. These BMA

682   parameters were reported as the final changes in connectivity and should be considered

683   to have a 95% probability of being non-zero.

684   Before conducting our main analysis presented, and to reduce the model space,

685   we first considered whether the best PEB model would include ventral and dorsal

686   pathway projections after fitting to individual subjects. Specifically, we asked if

687   describing the baseline difference of no-TFUS SS and US inhibition involved modulation

688   of either or both the dorsal and ventral pathways. Using the family-based hypothesis

689   comparisons test described above for PEBs, we created factor spaces including the

690   dorsal, ventral, or both pathways. Both sets of pathways included top-down and bottom-

691   up connections that were grouped together. The dorsal pathway included the rParietal

692   and rDLPFC nodes and the ventral pathway included rIFG and rTemporal. Bayesian

693   model comparison (probability = 1) revealed strong evidence in favor of the model with

694   just ventral pathway connection modulations from US to SS trials. Based on this result,

695   we excluded dorsal pathway connections from the rest of our DCM analysis to reduce

696   the space of parameters.

Results

698   Human participants performed a Stop-Signal task with online, trial-by-trial TFUS.

699   Subjects were divided into groups based on receiving one of three stimulation type: (1)

700   active stimulation targeted to right pars opercularis, (2) an active stimulation control site

701   (ipsilateral somatosensory, S1) to account for non-site specific TFUS, and (3) sham

702   stimulation to account for TFUS auditory artifacts. Since TFUS has been demonstrated

703   to illicit immediate effects on ERPs (Lee et al., 2016), stimulation was applied online

704   (see Methods) either at the onset of the go or stop signal cue, during both Go and Stop

705   trials (Figure 1A). We hypothesized that if rIFG implemented motor inhibition, then

706   TFUS behavioral effects would be limited to alteration of stopping but not going. TFUS

707   in the pars opercularis group improved inhibition, while exerting no effects in control

708   groups. TFUS also altered inhibition related ERPs, which were quantified at electrode

709   and source-localized levels, while also assessing TFUS impact on effective network

710   connectivity assessed using DCM.
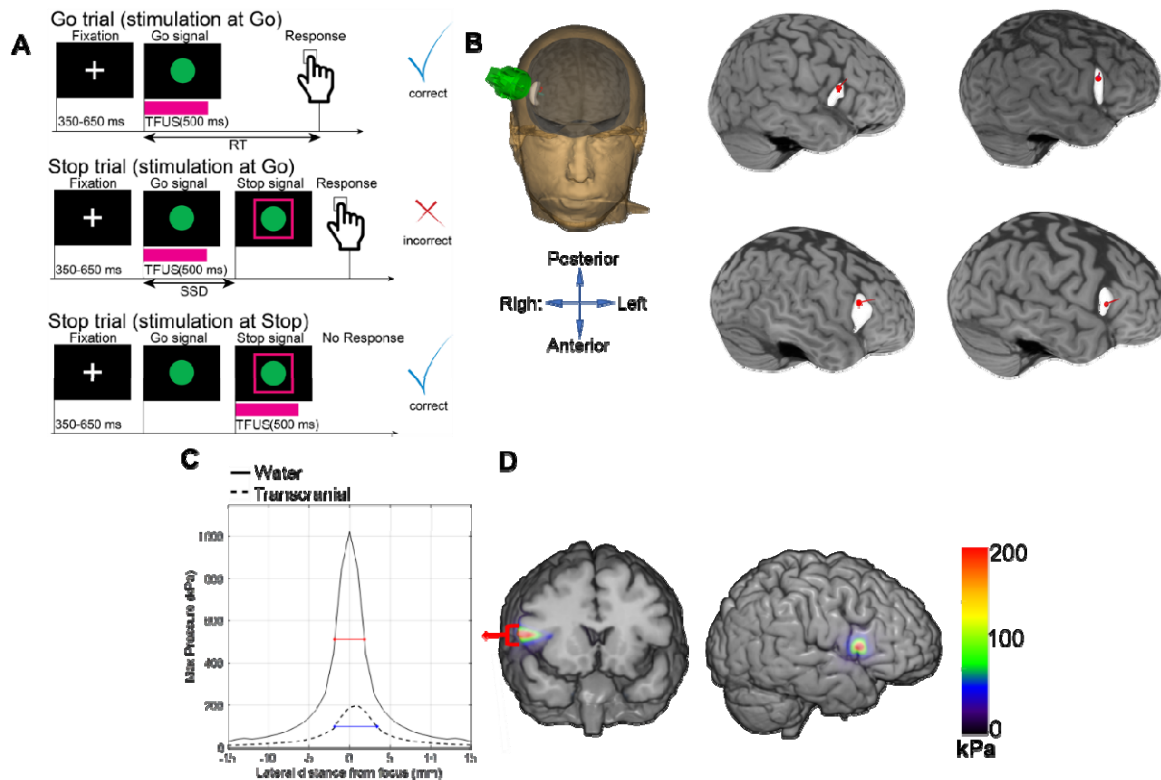

711

712   Figure 1 **A.** visual layout of Stop-Signal task and corresponding times when transcranial focused
713   ultrasound (*TFUS*) was delivered. **B.** The left plot shows the average neuronavigation location of TFUS
714   applied to all MRIs used in the rIFG group. The structural scans on the right show renderings of the
715   targeted TFUS point in pars opercularis in 4 subjects. **C**. Lateral maximum pressure profile obtained at
716   30-mm depth focus in both water and transcranial ultrasound simulation on a CT scan from one patient
717   (solid and dotted lines, respectively). Horizontal red and blue lines denote full-width half maximum of the
718   spatial profile of lateral pressure. **D.** Simulated transcranial pressure profile onto T1 MRI plot shown as a
719   color overlay.

720   **Numerical simulation of TFUS to rIFG**

721   To determine intensity and accuracy of TFUS after skull transmission in the rIFG

722 group, we used numerical simulations based on CT and MRI data from 3 preoperative

723 patients and validated the simulation results using a water tank test. At the focus,

724 modeling of transcranial simulations predicted an average maximum intensity of 2.8

725 W/cm^2. This is in the range of intensity of non-thermal neuromodulation (Legon et al.,

726 2014). Additionally, predicted shifts in peak pressure due to skull transmission was 1.25

727 mm laterally, relative to a water model simulation, and had a lateral full-width half

728 maximum of 5.1 mm (Fig. 1C). These simulations indicate a high spatial precision with

729 >95% of energy limited to pars opercularis (Fig. 1D).

730 **Only TFUS to rIFG alters response inhibition**

731   We first addressed how probability of failing to inhibit responses,

732 P(respond|signal) (Fig. 2A), changed across TFUS conditions within and across groups,

733 by fitting a 2-parameter logistic linear mixed-model to obtain a slope (**β)** of the response

734 inhibition curve across all subjects and TFUS conditions. Modeling indicated a good fit

735 of the logistic curve (mean R^2 = 84%). Analysis of **β** indicated only the rIFG group

736 exhibited a TFUS-altered P(respond|signal). Importantly, behavioral effects of TFUS

737 were not found for either control groups. Anova results indicated a significant Group x

738 TFUS interaction ($F(2,50) = 3.8$, $p = 0.034$, $\eta_p^2 = 0.17$), and an overall effect of TFUS

739 condition ($F(2,50) = 11.74$, $p = 0.002$, $\eta_p^2 = 0.29$). Follow-up one-way ANOVAs across

740 TFUS onsets (e.g., coincident with stop signal), but within-groups, showed only the rIFG

741 group exhibited differences across onsets. Follow-up t-tests in this group showed **β** for

742 Stop-TFUS was lower than No-TFUS and Go-TFUS conditions (both $p < 0.01$: mean **β**'s

743 indicating change in probability for approximately 25% change in normalized SSD: No-

744   TFUS = 0.35 (0.12), Stop-TFUS=0.27 (0.08), Go-TFUS=0.35 (0.11)). These results

745   indicate only the rIFG group was affected by TFUS, as predicted, and only during Stop-

746   TFUS.

747   Figure 2A shows improved inhibition performance during Stop-TFUS for the rIFG

748   group occurred at longer SSDs (65% and 95% SSD). A repeated-measures ANOVA on

749   P(respond|signal) for the rIFG group across all SSD levels and TFUS onsets revealed a

750   significant interaction ($F(6,102) = 8.21$, $p < 0.0001$,   = 0.33). Contrast t-tests between

751   Stop-TFUS and the average of No- and Go-TFUS across all SSDs indicated the

752   interaction resulted from a reduction in P(respond|signal) for Stop-TFUS in the highest

753   two SSDs (all $p < 0.01$; Bonferroni α = 0.0125). These results indicate Stop-TFUS

754   induced improvements of inhibition were more pronounced at later SSDs.
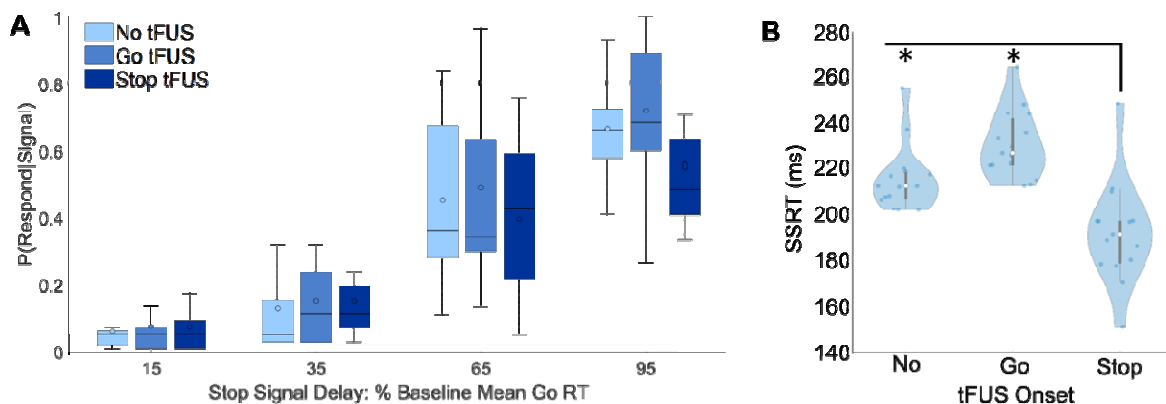

755

756   Figure 2. **A.** Probability of responding across stop signal delays in the rIFG TFUS group for all TFUS
757   onsets. **B.** Violin plots of rIFG group across-subject distribution of stop signal reaction times (SSRT).

758

759   Based on the prediction that rIFG implements an inhibitory process and our

760   finding that TFUS improved inhibition in this group, we hypothesized rIFG TFUS

761   changes to P(respond|signal) should result from a shortening of the stopping speed

762   (i.e., SSRT); notably, TFUS did not affect other behavioral variables (e.g., Go RTs, see

763   Supplementary Material). SSRT analysis in a mixed-design ANOVA indicated a

764   significant Group x TFUS interaction ($F(4,100) = 10.2$, $p < 0.001$, $\eta_p^2 = 0.21$). Follow-up

765   one-way ANOVAs within-groups indicated only rIFG group SSRTs (Fig. 2B) differed

766   between TFUS onsets ($p < 0.05$), with t-tests confirming that SSRTs were indeed

767   shortest and only altered during Stop-TFUS (Fig. 2B). This result, along with the above

768   P(respond|signal), indicate rIFG Stop-TFUS altered inhibition by shortening the stop

769   process (SSRT).

770   **Neural components underlying inhibition**

771   In the rest of the results we focus our analysis on the rIFG group because this

772   was the only group exhibiting behavioral effects of TFUS. Furthermore, we only analyze

773   No-TFUS and Stop-TFUS conditions because Go activity was subtracted from neural

774   data at Stop trials (see Methods).

775   Our first analysis examined sensor-level ERPs across three contrasts using

776   cluster-based permutation t-tests: (1) successful – unsuccessful stopping contrast over

777   both TFUS conditions, (2) successful (No-TFUS) – successful stopping (Stop-TFUS)

778   contrast, and (3) interaction comparing successful – unsuccessful stopping between the

779   No-TFUS and Stop-TFUS conditions. The cluster-based scalp maps show the

780   progression of clusters time-locked to the stop-signal onset (0 ms, Fig. 3A,B).
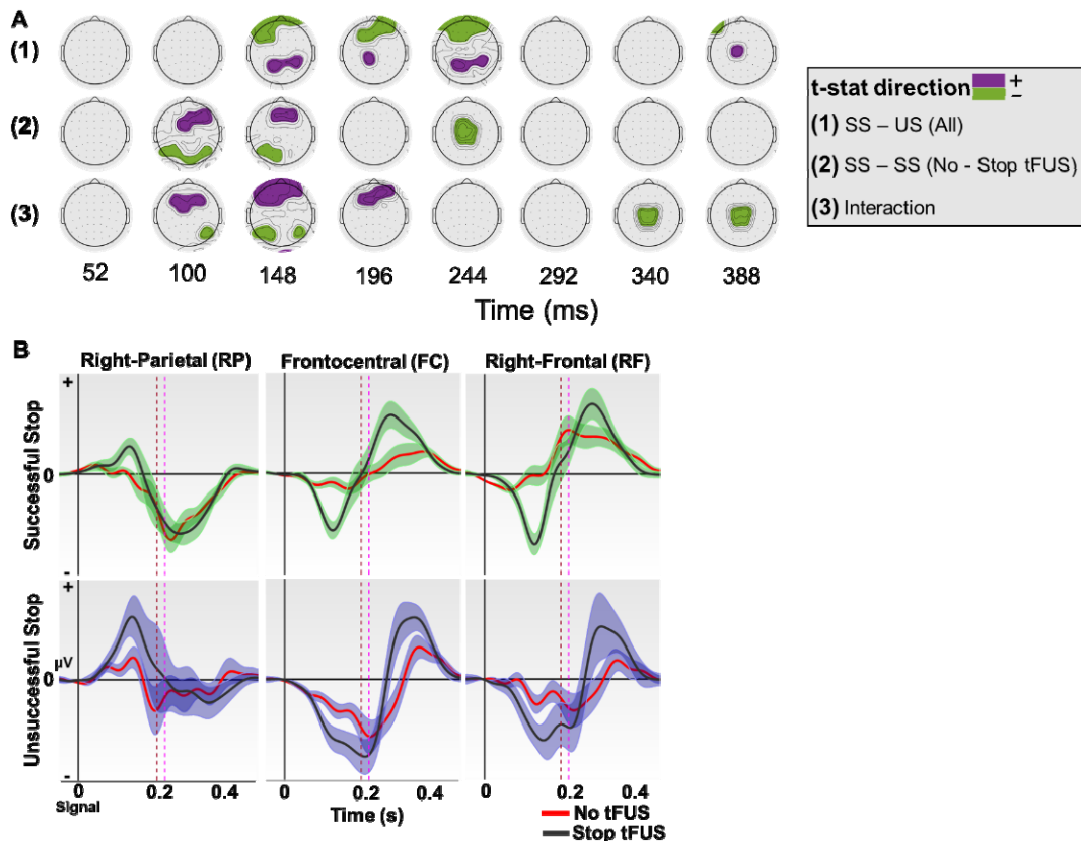

Figure 3. **A.** Scalp plots of cluster-corrected permutation paired t-tests ($p < 0.01$). Colored contours represent significant clusters. (1). Contrast of all SS and US trials. (2). Contrast of TFUS conditions SS. (3). Interaction contrast calculated as SS-US of No-TFUS trials minus SS-US Stop-TFUS trials. **B.** Average ERP time courses of three clusters identified by the permutation testing that were differentiated by statistical contrasts. From left to right, the first cluster (left column) is right-parietal electrodes (CP6, CP4, P6, P8), the second cluster (middle column) is fronto-central electrodes (C1, Cz, C2), and the third cluster (right column) is right-frontal electrodes (F8, F6, F4). The vertical dashed lines represent the stop-signal reaction times for the No-TFUS (magenta) and Stop-TFUS (maroon). Latencies in A and B are expressed relative to stop signal onset (0 ms).

We identified several ERPs that differentiated successful stopping (SS) and unsuccessful stopping (US) trials. The first contrast of SS-US (Figure 3A, row 1) indicated SS trials exhibited a larger ERP centralized over a right-parietal cluster around the time-range typically found for the P100 peak (100-148 ms). The interaction of SS-US and TFUS showed this effect occurred earlier and during the peak onset (80-100 ms) of Stop-TFUS trials. Consideration of the SS-SS contrast (TFUS effect; Figure 3A-

798   2nd row) indicated the largest effect was attributable to the SS TFUS trials, supporting

799   previous conjectures that inhibition and stopping speed is directly related to larger P100

800   parietal responses. This result also aligns with previous studies reporting an enhanced

801   P100 during successful stopping (Boehler et al., 2009).

802   We also examined the N100 in the right-frontal cluster in the 80-120 ms window

803   (Figure 3B). We did not find a difference in the frontal N100 with respect to the overall

804   SS – US contrast (Figure 3A). This result is in line with several other studies noting a

805   non-significant effect of this contrast (Kenemans, 2015). However, we did find the ERP

806   was substantially larger in SS TFUS trials compared to SS No-TFUS trials indicating a

807   direct contribution to stopping efficacy. This increase for SS TFUS suggests this ERP

808   may stem from rIFG and provide an index of stopping speed, rather than success.

809   The ERPs most commonly associated with response is the N200/P300 complex.

810   Notably, the N200 often appears in both right-frontal and fronto-central clusters, while

811   the P300 is more aligned with the fronto-central (Huster et al., 2013; Kenemans, 2015).

812   When examining the N200, which typically only appears during US (Liotti et al., 2010;

813   Wessel et al., 2015), we found an ERP peaking around 200 ms in both clusters that only

814   appeared in US trials (Figure 3B). This N200 emerged during both No- and Stop-TFUS

815   (Figure 3, bottom right), with a larger amplitude during US Stop-TFUS.

816   Of all possible ERPs, the fronto-central P300 has been regarded as the most

817   robust marker of response inhibition and stopping speed (Wessel and Aron, 2015).

818   Accordingly, we found P300 amplitude differed between SS and US trials, with US trials

819   exhibiting a larger amplitude around the peak (290-320 ms) (Figs. 3A-B). However,

820   because P300 peaks occur after the SSRT, this implies it is too temporally protracted to
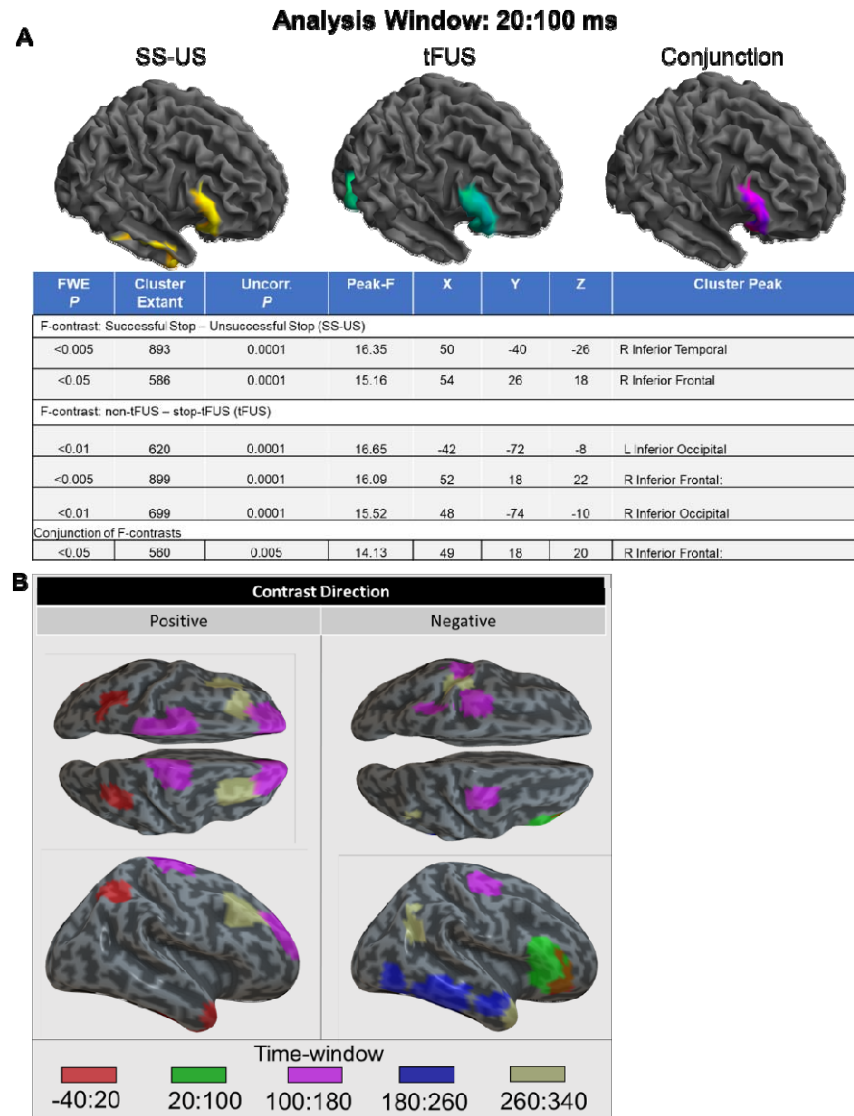

821 reflect inhibition (Huster et al., 2013). Alternatively, others have indicated the P300

822 onset latency is related to inhibition because it scales with individuals SSRTs (Wessel

823 and Aron, 2015). Based on this notion, we considered whether the P300 onset was

824 causally related to the SSRT shortening induced by TFUS. We tested the specific

825 prediction that Stop-TFUS SS trials should exhibit an earlier onset that correlates with

826 individual changes in SSRT. Visually, contrasting waveforms of SS trials across TFUS

827 conditions (Fig. 3B, upper-middle) supports this intuition that P300 onset (zero-crossing

828 in Figure 3B) shifted earlier in alignment with Stop-TFUS induced SSRT shifts. This was

829 quantitatively supported by a significant, across-subject correlation between the TFUS

830 induced in change P300 onset and SSRT (0.61, $p < 0.05$), providing direct support that

831 P300 latencies reflect the timing of inhibition speed.

832 **Whole-brain source SPM and source-based regression analysis**

833 We also examined source-based activity to localize TFUS-induced changes in

834 evoked activity and generating source location priors for DCM. We hypothesized that, if

835 differential rIFG activation indexed SS versus US, then conjunction analysis should

836 reveal an overlap between SS – US and No-TFUS – Stop-TFUS conditions if rIFG

837 activity is related to successful stopping (Aron et al., 2014). As expected, whole-brain

838 SPMs (Fig. 4A) revealed the only area exhibiting an overlap was a pars opercularis-

839 centered rIFG peak during the 20-100 ms time window (results of analysis of other time

840 windows are reported in Supplementary Material).

841 To understand how TFUS altered stopping efficacy, we compared changes in

842 SSRT between Stop-TFUS and No-TFUS SS trials using whole-brain SPM linear

843 regression. In the regression, positive contrasts indicate ΔSSRT (No-TFUS – TFUS) is

844 associated with larger activity in No-TFUS trials. Negative contrasts indicate TFUS SS

845 trials exhibit larger evoked activity predicted by larger changes in SSRT. The negative

846 contrast in Figure 4B indicates that the first site to exhibit increased TFUS-related

847 predictions is rIFG. This occurred both in the -40:20 and 20:100 time-windows. The

848 positive contrast found in early time windows indicates Stop-TFUS exerted effects on

849 stopping by also decreasing early activity in both bilateral parietal and right temporal

850 sites. We also found pre-SMA was only predictive of SSRT after rIFG, with the pre-SMA

851 modulation peaking at 100:180 ms. These results show that areas typically associated

852 with successful inhibition were predictive of TFUS-induced changes in behavior while

853 occurring before the SSRT itself.

859

TFUS effects in an inhibition network: Dynamic Causal Modeling (DCM)

The above TFUS results provide evidence that rIFG activity is causally related to

inhibition. Principally, differences in local activation can result from both local and inter-

areal connectivity (David et al., 2006). We used DCM to quantify network effects.

Bayesian model selection established a winning model as a hierarchical network in

865   which rDLPFC and rIFG sat at the top of the hierarchy and pre-SMA being below these

866   areas. The model also included nodes for right temporal (rTemporal), right inferior

867   occipital gyrus (rIOG), right parietal (rParietal), a hidden subcortical node (Deep) and

868   left motor cortex (M1). These results accord with networks proposed by previous studies

869   implicating both motor inhibition and attentional orienting (Weicki and Frank, 2013;

870   Munkata et al., 2011). The DCM (Fig. 5) was fit to individual subject's data to determine

871   how connectivity parameters differentiated (1) No-TFUS baseline SS and US inhibition

872   differences, and (2) between No-TFUS and Stop-TFUS SS trials and accompanying

873   changes in SSRT. The above approach revealed the models agreeably captured the

874   spatiotemporal properties of the ERP scalp data across both sets of model fits (Fig. 5).
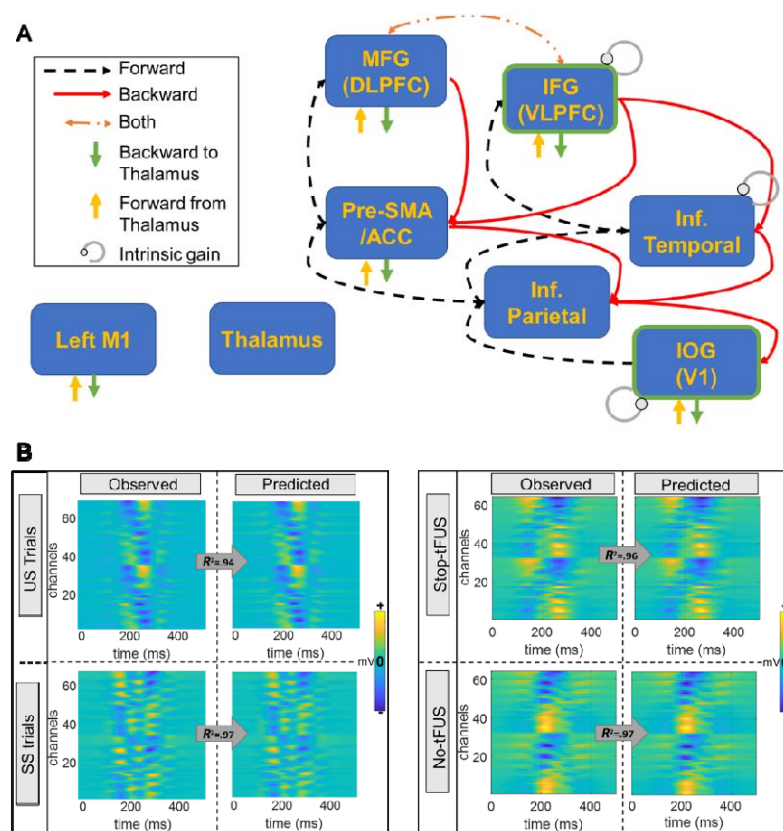

875

876   Figure 5. **A**. Connections used to implement the final dynamic causal model structure. Exogenous inputs
877   entered through rIFG and rIOG represented as a green box. All nodes except Left M1 and Thalamus

878   were all located in the right hemisphere. **B**. Left panel shows the mean observed and predicted scalp
879   ERP data derived from the dynamic causal model fit to the No-TFUS US and SS trials. Right panel shows
880   the mean observed and predicted scalp ERP data derived from the dynamic causal model fit to the No-
881   TFUS SS and Stop-TFUS SS trials. These results show that the final model provided a good fit to the
882   data. Data are plotted relative to stop signal onset (0 ms on x-axis).

883

884   The first set of analyses examined what connectivity parameters were altered

885   during No-TFUS successful inhibition. The first comparison examined whether

886   differential rIFG and pre-SMA interactions were related to baseline successful stopping,

887   as suggested by several functional and anatomical studies (Duann et al., 2009; Rae et

888   al., 2015; Swaan et al., 2012; Fig. 6A). Model comparisons revealed a winning family

889   included interactions between both areas, but with a moderate posterior probability

890   (0.78). BMA across families revealed both the connection from rIFG to pre-SMA (136%)

891   and pre-SMA to rIFG (193%) were altered during SS trials. Changes in this connection

892   suggest that SS trials were supported by prefrontal interactions. Considering previous

893   data indicating increases in pre-SMA projections (Forstmann et al., 2008) to striatum

894   render increased RTs, this result might reflect an effect of blocking the impetus pre-

895   SMA provides towards responding to the Go signal (Verbruggen and Logan, 2009).

896   The next comparison tested the hypothesis that both pre-SMA and rIFG

897   projections to deep areas are necessary for successful inhibition (Fig. 6B). Only a family

898   including changes from rIFG to deep was predictive of successful inhibition. BMA

899   indicated rIFG exhibited a mean reduction in the backwards connection of 65% during

900   successful stopping. This result agrees with previous fMRI studies (Aron et al., 2006;

901   Jahfari et al., 2011) indicating inhibitory processes are driven by cortical to basal ganglia

902   interactions.
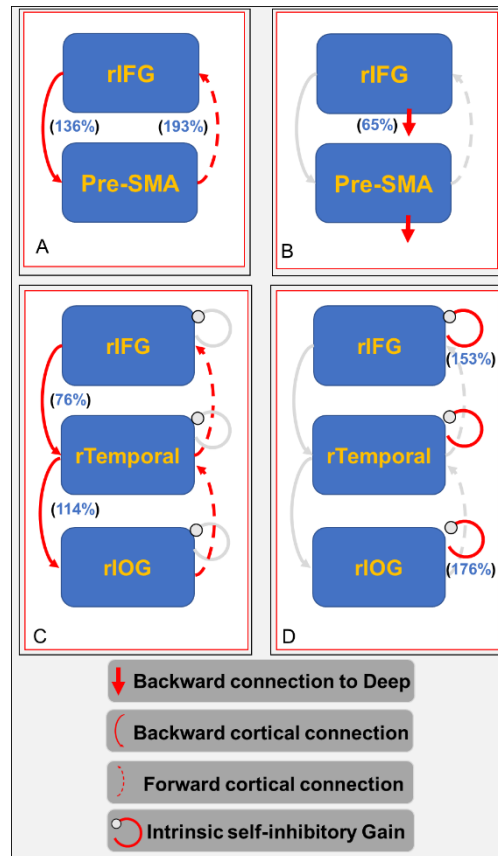

Figure 6. Family-based model comparison for different hypothesized interactions. Plots contain modulatory parameter of connections with strong positive evidence as being different between US and SS trials. Parameter estimates (>95% posterior probability) are in parentheses next to modulated connection in exponential percentage change. Anything above 100% reflects an increase in SS trials compared to US (opposite for below 100%). **A.** Test of rIFG and pre-Sma interactions. **B.** Tests of rIFG and pre-SMA backward projections to deep node. **C.** Tests for the ventral pathway connections. **D.** Comparison of intrinsic superficial pyramidal cell gains.

Another hypothesis that has been put forth regarding successful inhibition is that

it is mainly mediated by attentional orienting in ventral pathways (Hampshire and Sharp,

2015). DCM implementations of attentional process can be cast in terms of hierarchical

predictive coding models (Feldman and Friston, 2010). Previous work suggests

increased attention in sensory areas emerges as increased recurrent intrinsic gain

(increased disinhibition) of superficial pyramidal cells thought to report prediction errors

through forward connections (Auksztulewicz et al., 2015). In DCM, recurrent gains

919 would weight prediction error signals driven changes in top-down (backward)

920 connections (Bastos et al, 2012). We designed the next two comparisons to examine

921 whether SS trials exhibited these network changes. Extrinsic connection analysis in No-

922 TFUS SS indicated a winning family including only changes in top-down backward

923 connections predicted successful inhibition (Pp =1). BMA indicated, however, the

924 inhibitory connection from rIFG to rTemporal was reduced while backward connections

925 from rTemporal to rIOG increased in connectivity (Fig. 6C).

926   The final SS and US modulation comparison analyzed changes in recurrent

927 gains of rIFG, rTemporal and rIOG (Fig. 6D). The winning model (Pp = 0.99) included

928 an increase in gain for both rIOG (176%) and rIFG (153%). Importantly, the increased

929 rIOG gain is predicted by attentional orienting models of response inhibition (Hampshire

930 and Sharp, 2015) and accords with previous DCM studies that have manipulated

931 attentional cueing (Auksztulewicz et al., 2015). Mechanistically, the increased rIOG gain

932 in SS trials results in ascending signal that has a larger effect on decreasing rIFG top-

933 down expectation signals in backward connections.

934 **Stopping efficiency (SSRT) is driven by lower and prefrontal interactions**

935   Another primary goal of understanding inhibitory control is quantifying how the

936 efficiency of stopping, evaluated through the SSRT, is implemented via network

937 pathways. Previous work has employed between-subjects' correlations of SSRT and

938 connectivity parameters to isolate the pathways involved in this process (e.g., Jahfari et

939 al., 2011). Because previous studies using fMRI and a variety of connectivity methods

940 revealed pre-SMA and rIFG to basal ganglia connections are correlated in different

941 directions with SSRT (Jahfari et al., 2011), we adopted this approach when analyzing

942   the baseline No-TFUS SS versus US contrast. This correlational analysis indicated both

943   connections were correlated in opposite directions with SSRT. Figure 7 shows that

944   increasing connectivity from rIFG to deep targets predicted shorter SSRTs. The

945   opposite pattern was found for pre-SMA, wherein increasing pre-SMA backward activity

946   predicted longer SSRTs.

947
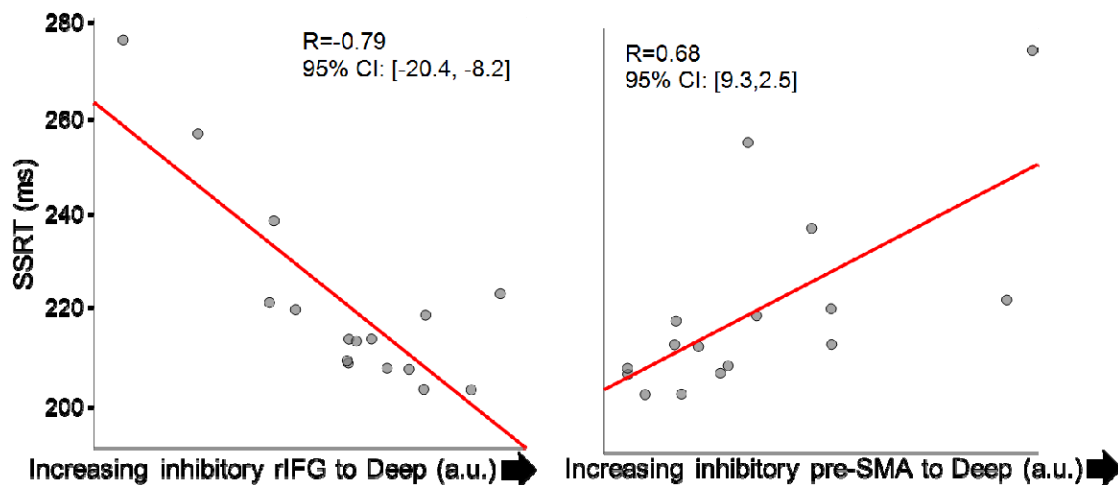

Figure 7. Left and right plots show linear regression fits predicting individual subjects' No-TFUS SSRT from the backward connection to the deep area projecting from rIFG and pre-SMA, respectively. Larger values on the x-axis denote decreasing backward inhibitory connectivity.

951

TFUS to rIFG causally dissociates inhibitory mechanisms

953   Building on TFUS's effect of increasing inhibition performance, a primary

954   question was whether the changes in connectivity strength between No-TFUS SS and

955   Stop-TFUS SS trials would reflect stepwise changes in the connections modulated in

956   the SS and US No-TFUS comparison. This comparison is in line with the idea of failed

957   stop trials resulting partially from less active inhibition mechanisms. By applying TFUS

958   to rIFG, we were able to causally dissociate rIFG's role in implementing inhibitory

959   mechanisms. Below, mean changes represent the average modulation of connectivity

960   going from No-TFUS SS to Stop-TFUS SS trials. SSRT-based effects represent how

961   changes in SSRT between TFUS conditions predict the change in connectivity between

962   TFUS conditions.

963   In first analyzing the family of models examining the rIFG and pre-SMA

964   interaction, there was no clear winning family of models for both the mean and SSRT

965   effect (Fig. 8A). For the mean, the model with projections from rIFG to pre-SMA (122%)

966   and pre-SMA to rIFG (75%) was highest in probability (Pp = 0.79). Of these

967   connections, SSRT change was only negatively related to the rIFG to pre-SMA pathway

968   (r^2 = 74%). indicating that an increase in inhibitory connectivity from rIFG to pre-SMA

969   during Stop-TFUS trials predicted a larger change in SSRT. Therefore, changes in

970   SSRT were not related to forward connections between these nodes, but instead were

971   modulated by a top-down inhibitory modulation from rIFG to pre-SMA.

972   When comparing models testing the role of rIFG or pre-SMA to deep backward

973   connections, family analysis revealed a strong effect of the mean change and SSRT

974   change for both backward connections (Pp > 0.95 both effects). BMA in the winning

975   family indicated both effects were above threshold for both connections. Both rIFG

976   (143%) and pre-SMA (139%) exhibited increased connectivity during TFUS. Concerning

977   changes in TFUS related changes in SSRT, the direction of effects was opposite for

978   rIFG (154%) and pre-SMA (67%): for rIFG, decreased inhibition yielded increased

979   SSRT change, and the opposite for pre-SMA. Together, these results point to

980   differential interactions of both pre-frontal areas with a deep node in responding to

981   TFUS. These results are further in line with the directionally opposite linear correlations

982   of the No-TFUS SSRT to each of these backward connections (Fig. 8B).

983   Finally, we examined ventral pathway parameters for TFUS modulation of top-

984   down, bottom-up, and intrinsic gain changes. Model averaging revealed the rIFG to

985   rTemporal top-down connections (66%) decreased with TFUS, suggesting a direct

986   effect from rIFG TFUS. This decrease in top-down rIFG connection agrees as well with

987   the results found during the SS versus US comparison, suggesting a causal and

988   overlapping pathway driving inhibition performance. All bottom-up connections

989   increased as well (Fig. 8C). With respect to SSRT change (Figure 8D), only the bottom-

990   up connections were related to changes in the SSRT. However, the forward connectivity

991   relations to SSRT were in opposite directions for modulations of the rIOG to rTemporal

992   (110%) and rTemporal to rIFG (78%). Finally, we found rTemporal recurrent gain

993   increased in mean (150%) and was positively related to changes in SSRT (163%). This

994   relation between the SSRT effect and rTemporal to rIFG forward connection was strong

995   enough such that a leave-one-out cross validation prediction of SSRT change using this

996   connection exhibited a large correlation with actual SSRT change (0.84, $p < 0.01$).

997   These results indicate neural implementation of stopping speed involves processing

998   efficacy of bottom-up, temporal cortex (prediction error) signals.

999
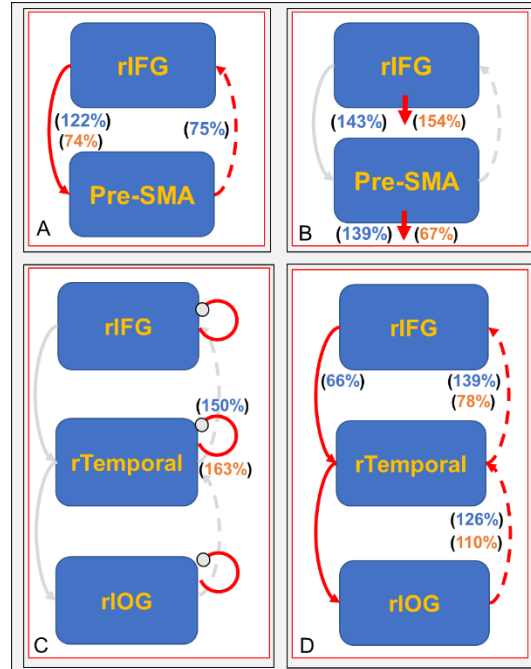

Figure 8. Results of the family-based model comparison for different hypotheses tested when comparing modulation from No-TFUS SS to Stop-TFUS SS trials. The family-based posterior probability (F-Pp) for the winning model is listed below each model. The outcomes of these plots can be interpreted of as revealing the modulatory parameters connections with very strong, positive evidence of US and SS trials being different. Parameters estimates with a greater than 95% posterior probability in these families are presented in parentheses next to the modulated connection. The parameters are presented in exponential form of percentage change. Values above 100% equates to a parameter increase in SS trials compared to US (and the opposite for values below 100%). Parameters in-active in each model are in a gray color. **A**. hypothesis test of rIFG and pre-Sma interactions. **B.** Hypothesis tests of rIFG and pre-SMA backward projections to deep node. **C.** comparison of intrinsic superficial pyramidal cell gains. **D.** tests for the ventral pathway connections.

1012

Discussion

1014   The present study examined whether pars opercularis sector of rIFG is explicitly

1015   involved in motor response inhibition. We used a stop-signal task, online TFUS, source-

1016   localized EEG, and dynamic causal modeling of ERPs to examine this hypothesis and

1017   examine underlying response inhibition network mechanisms. Behaviorally, TFUS

1018   applied to pars opercularis and coincident with the stop signal increased the likelihood

1019   of successful inhibition. Because TFUS enhancements of inhibition resulted from faster

1020   stopping processes (i.e., SSRT), without altering Go RTs, this supports pars opercularis'

1021   role as directly triggering action stopping. Examination of scalp ERP analysis indicated

1022   TFUS rendered a shift in the fronto-central P300 onset, which has been previously

1023   hypothesized as neural marker of stopping speed (Wessel and Aron, 2015).

1024   Imperatively, the shifted onsets were directly linked to and correlated with TFUS-

1025   induced changes in individuals SSRT. Spatial accuracy of TFUS was supported by

1026   whole-brain evoked activity indicating only pars opercularis exhibited a conjunction

1027   effect of TFUS with successful compared to failed inhibition (Figure 3). The hypothesis

1028   that pars opercularis activity is directly related to stopping efficacy was confirmed by

1029   TFUS-driven activity differences predicting between-subjects SSRT change (Figure 4B).

1030   Despite these results, recent work suggested TFUS effects result from auditory artifacts

1031   (Sato et al., 2018). Auditory effects, however, cannot explain our findings because

1032   control groups exhibited no behavioral effects, and no group exhibited evoked auditory

1033   cortex activity (Figure S7). We interpret the above results as indicating TFUS selectively

1034   modulated pars opercularis activity, and pars opercularis explicitly implements response

1035   inhibition.

1036   Generally, response inhibition involves several processes embedded in

1037   connections across a neural network, ranging from sensory cue detection, attention,

1038   performance monitoring, and presumably explicit motor inhibition (Munkata et al., 2011;

1039   Weicki and Frank, 2013; Wessel and Aron, 2017). Many have proposed that motor

1040   inhibition is implemented directly in rIFG connectivity to basal ganglia (STN and

1041   striatum), either in parallel or routed through pre-SMA (Aron et al., 2014), or both. In

1042   contrast, others have proposed motor inhibition is better understood as an emergent

1043 outcome of attentional orienting and biased competition between neural processing of

1044 response and inhibition cues (Hampshire and Sharp, 2015). Extant evidence indicates,

1045 however, that motor inhibition and attentional processing are likely all involved in

1046 different processing stages of inhibitory control tasks (Wessel and Aron, 2017).

1047   Given the evidence for response inhibition as a multi-process phenomenon, a

1048 key question is what network connections and biophysical mechanisms support action

1049 stopping. A core component of models positing a direct rIFG motor inhibitory process is

1050 that its connectivity with subcortical nodes should change with stopping success or

1051 efficacy. The present study's DCM analysis of No-TFUS successful and failed inhibition

1052 is consistent with the hypothesis that rIFG and pre-SMA subcortical connections are

1053 relevant for motor inhibition. DCM results of No-TFUS successful stopping also revealed

1054 an anti-correlation of SSRT to pre-SMA and rIFG deep connection strength (Figure 7).

1055 Our findings agree with another fMRI connectivity study (Jahfari et al., 2011) that found

1056 successful stopping accompanied increasing pre-SMA to striatum connectivity and

1057 predicted longer SSRTs, with the opposite correlation for rIFG to striatum. Pivotal

1058 support for rIFG's role is the result that TFUS effects on SSRT were directly related to

1059 changes in rIFG and pre-SMA to deep connectivity with a similar anti-correlation pattern

1060 as the baseline. We take these results to indicate pars opercularis subcortical

1061 connectivity is directly involved in driving motor inhibition through feedback pathways.

1062 This indicate a potential mechanistic effect of TFUS, wherein inhibition improved by

1063 altering the connectivity of layer V rIFG pyramidal neurons by increasing the excitability

1064 of these cells. Notably, this conjecture of an excitatory TFUS effect on pyramidal

1065 neurons and our TFUS parameterization are in accordance with the neuronal

1066   intramembrane cavitation excitation (NICE) model that has been used recently to

1067   explain the acoustical stimulation effects on the biophysics of neuronal firing (see

1068   Plaksin et al., 2016).

1069   An unresolved issue regarding the inhibition network is how rIFG and pre-SMA

1070   interactions areas relate to inhibition in general (Duann et al., 2009; Swaan et al., 2012).

1071   Our DCM optimization indicated rIFG projected to pre-SMA through backwards

1072   inhibitory connections and pre-SMA to rIFG via excitatory forward connections. This

1073   bidirectional connectivity agrees with previous fMRI stop-signal and DTI studies (Duann

1074   et al., 2009; Rae et al., 2015). Functionally, No-TFUS DCM results revealed successful

1075   stopping was accompanied by increases in both connections. However, when

1076   comparing baseline and TFUS DCMs, our results indicate that only the rIFG to pre-SMA

1077   connections in this subset of connections were effectively related to inhibition in terms of

1078   the mean gain change in backwards connectivity and its covariation with TFUS induced

1079   changes in SSRT (Figure 6A-B). This result is directly relevant to several studies that

1080   have either concluded pre-SMA drives rIFG (Swann et al., 2011) during inhibition or the

1081   opposite (Duann et al., 2009). Combining DCM and TFUS indicated the inhibitory effect

1082   of rIFG onto pre-SMA is causally responsible for driving inhibition at a cortical level.

1083   This raises the question of why the pre-SMA to rIFG connection was only relevant

1084   during baseline successful inhibition. An alternative interpretation is found in

1085   neuroimaging (Crone et al., 2006), ECoG (Swaan et al., 2012), and TMS studies of

1086   proactive inhibition and response switching (Rushworth et al., 2002). These studies

1087   have indicated pre-SMA encodes a set of potential actions. During response inhibition,

1088   this predicts successful stopping involves pre-SMA signaling the action(stopping)-rule to

1089   rIFG. Therefore, the action rule and connectivity conveying it should not differ for

1090   successful No-TFUS and Stop-TFUS trials because it should have been similarly

1091   communicated under both conditions.

1092   The above results provide causal evidence that pars opercularis and its

1093   connectivity are directly involved in motor inhibition. Nonetheless, neuroimaging studies

1094   have shown rIFG-related activation predicts attentional orienting and stimulus

1095   expectancy processes during response inhibition (Erika-Florence et al., 2014;

1096   Hampshire and Sharp, 2015; Xu et al., 2017). Although attention was not manipulated in

1097   our study, we derived predicted network mechanisms from predictive coding models of

1098   attention (Feldman and Friston, 2010) and DCM-EEG studies directly manipulating

1099   attention and stimulus expectancy (Auksztulewicz et al., 2015). Importantly, the

1100   microcircuits implemented in the DCM presently used are directly related to predictive

1101   coding models and have explicit mechanisms supported by previous DCM studies. For

1102   example, these studies have shown increased attention is linked to increased recurrent

1103   gain on ascending (forward) sensory (prediction error) signals, while violations of

1104   stimulus expectations were linked to decreased top-down and increased in bottom-up

1105   connectivity, respectively (Auksztulewicz et al., 2015; Fardo et al., 2017). Along these

1106   lines, our DCM during baseline stopping featured increased rIOG recurrent gain as

1107   expected if attention increased the precision afforded to the sensory processing of stop

1108   cues (Moran et al., 2013; Figure 7C). Concerning top-down changes, rIFG to rTemporal

1109   decreased and rTemporal to rIOG increased (Figure 7D). Successful stopping at

1110   baseline therefore may rely on an increased rIOG gain weighted sensory signals that

1111   drive top-down changes in rIFG. However, increased connectivity from rTemporal to

1112   rIOG seems at odds with this interpretation because it implies a larger reliance on top-

1113   down information during successful stopping. This is explained by the finding that

1114   optimized inputs to rIOG were negative and therefore inhibitory (rather than excitatory)

1115   across subjects. Therefore, increasing rTemporal backward connectivity rendered an

1116   enhanced negative rIOG signals.

1117   Although the preceding results seem to accord with attention-based formulations

1118   of inhibition, examination of TFUS effects on connectivity indicate inhibition success

1119   was generally unrelated to these mechanisms. The only overlap between baseline and

1120   TFUS conditions was a decrease in top-down rIFG to rTemporal backwards

1121   connectivity. Still, this effect was not directly predictive of a change in SSRT. TFUS

1122   effects also involved an increase in bottom-up connectivity that was predictive of SSRT

1123   change (Figure 8D) in agreement with expectation violation effects found in other EEG-

1124   DCM studies (Auksztulewicz et al., 2015). The most interesting effect was recurrent

1125   gains only increased in rTemporal, indicating SSRT changes were not due to increased

1126   sensory weighting. We propose that cortically-related SSRT changes were driven by

1127   TFUS altering the effects the rIFG to rTemporal connection had on the rTemporal gain.

1128   A partial correlation supported this hypothesis by showing covariation of rTemporal gain

1129   and SSRT change was rendered null when accounting for the correlation of rIFG to

1130   rTemporal and rTemporal gain. A potential explanation for this result is that rIFG

1131   engages in a proactive inhibitory function whereby it biases bottom-up processing of the

1132   temporal cortex, which itself may encode the expected probability of stop signal

1133   occurring. This interpretation is consistent with fMRI stop-signal studies demonstrating

1134   temporal cortex encodes a prediction error of stop-signal probability (Hu et al., 2015; Ide

1135   et al., 2013).

1136   In summary, TFUS can induced enhanced response inhibition performance,

1137   allowing the underlying mechanisms to be linked to direct and source-resolved

1138   electrophysiological neural processes in humans. By pairing TFUS with DCM, we found

1139   a network model of response inhibition suggesting pars opercularis explicitly invokes

1140   motor inhibition through deep pyramidal connections directly synapsing onto subcortical

1141   nodes, as well as pre-SMA and temporal cortex. These results also significantly extend

1142   the possible applications by showing TFUS combined with network modeling has the

1143   potential to alter and infer the effective connection between biophysical network

1144   mechanisms and behavior.

1410   **S1. Dynamic causal modeling structure optimization**

1411   Below we show the structures used for building and optimizing the dynamic causal

1412   model based on the no-TFUS successful stopping event related potentials. The full steps of the

1413   process are described in the Methods section. Figure S1 shows the tested structures and

1414   possible connections. Figure S2 shows outputs for comparing these models using Bayesian

1415   model comparisons, as well as model comparisons for which nodes receiving thalamic input,

1416   and tests for the type of connection projecting from cortical to deep areas (forward, backward, or

1417   both).
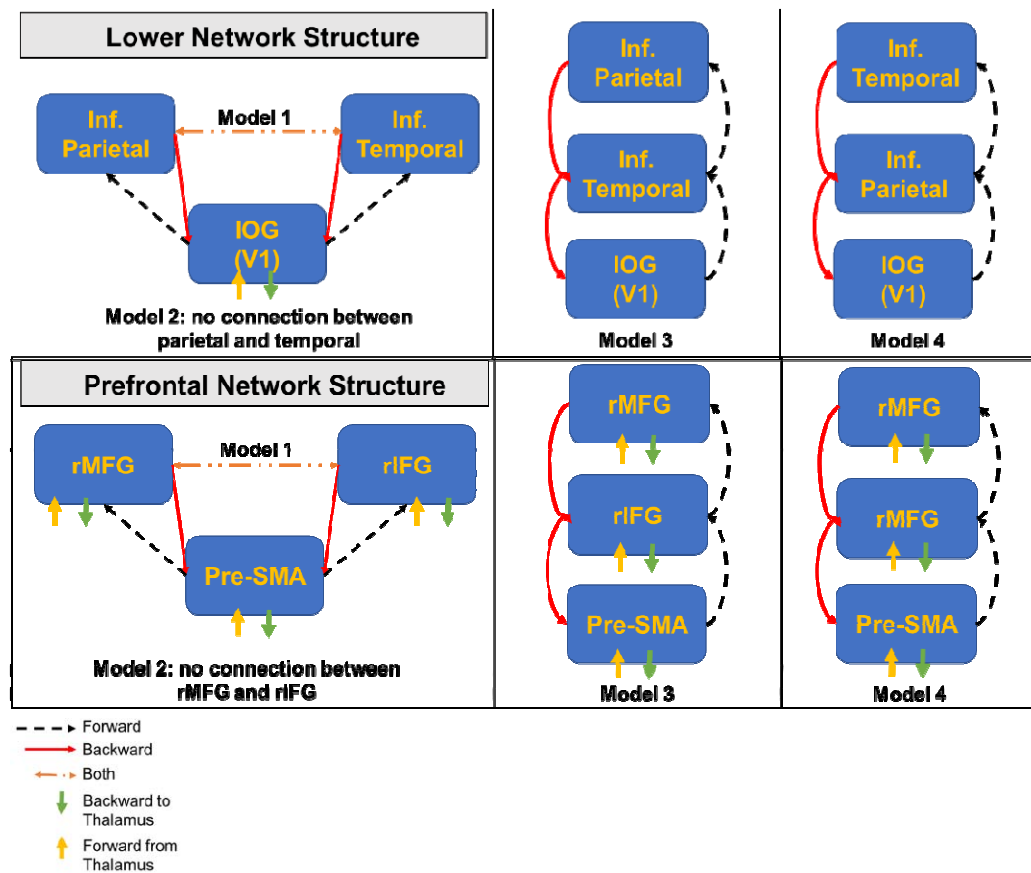

1418

1419   Figure S1. Differences in dynamic causal model spaces that were compared for the lower network
1420   structure and prefrontal network structure (top and bottom panel, respectively). The legend on the bottom
1421   shows how different connections are coded in these putative model spaces.

Model structure optimization on mean no-tFUS SS trials
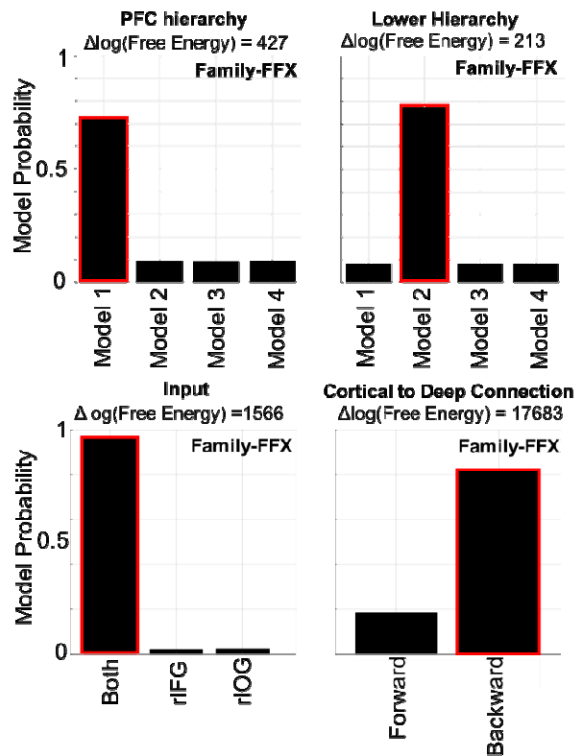

1422

Figure S2. Model probabilities for the different model tests. Each of these tests was examined on the mean ERP data for No-TFUS SS trials using family-wise fixed effect Bayesian model selection. Above each plot shows the model component being optimized. For example, the first bar plot shows the different prefrontal hierarchy arrangements. Above each plot is the difference in log-free energy between the best family and the 2nd best. The log difference of free energies approximates a log-Bayes factor (Penny, 2012). It is considered positive evidence in favor of a model if this value is > 5. Evidence in favor of the winning models (bars enclosed in red) was very strong. The plots on the right show the different structural arrangements used to examine the prefrontal and lower-level hierarchical structure.

S2. Go Reaction Times

We addressed whether TFUS (real or sham) exerted any effects on simply responding to the Go signal. We analyzed this by extracting the ex-gaussian-based mean RT using a maximum likelihood approach (Lacoutoure and Cousineau, 2008). The means were calculated separately for all subjects, and then analyzed using a 3 × 2 mixed-design ANOVA with factors of the 3 groups, and TFUS state: No-TFUS and Go-TFUS trials. This analysis allowed us to assess if "going", independent of "stopping", was altered by potential TFUS auditory artifacts,

1440 stimulation to unrelated areas (S1 group), or whether TFUS to rIFG also influenced Go RT

1441 processes independent of a stopping context signal. Table 1 shows the per group mean

1442 difference of the RT between No-TFUS and Go-TFUS per group. Across groups, there was a

1443 consistent negative difference indicating that RTs during TFUS may have been slightly shorter.

1444 These differences in means seemed marginally larger for the rIFG group. However, the ANOVA

1445 did not reveal any significant effect of TFUS, group, or their interaction (all $p > 0.05$). These

1446 results suggest that neither TFUS (rIFG and S1 groups) nor auditory factors alone (sham rIFG

1447 group) altered Go RTs independent of a stop signal.

1448 **S3. Signal-respond RTs and context independence**

1449 Calculating a measure of stopping latency (SSRT) based on the independent race-

1450 model (Logan and Cowan, 1984; Bissett and Logan, 2014) assumes that signal-respond RTs

1451 are Go processes resulting from a censoring of the Go RT distribution. Testing this assumption

1452 predicts that (a) mean signal-respond RT should be faster than mean Go RT, and (b) during

1453 fixed-SSD paradigms like the one employed here, signal-respond RT should increase with

1454 longer SSDs because there are more failed inhibitory responses. Before testing (a) and (b), we

1455 wanted to discern whether our TFUS manipulation exerted any effects on the signal-respond

1456 RTs. Based on the context-independence assumption of the race model that signal-respond

1457 RTs are Go processes escaping inhibition, and (2) if the TFUS-driven changes in inhibition

1458 (P(respond|signal) (Fig. 3) are due to changes in inhibition, we should expect no differences in

1459 signal-respond RTs between conditions or groups. We used a mixed-design ANOVA to examine

1460 the subject level signal-respond RT means with Group (3 levels) and TFUS (3 levels: no-TFUS,

1461 Go-TFUS, Stop-TFUS). We found no significant interactions or effects. Importantly, follow-up t-

1462 tests revealed no differences across TFUS conditions within the rIFG group (mean signal-

1463 respond RT: no-TFUS: 375 ±18 ms; Go-TFUS: 368 ±13 ms; Stop TFUS: 353 ±13 ms). This

1464   supports the conclusion that TFUS did not alter the mean of Go processes that escaped

1465   inhibition.

1466   Given the lack of difference in mean signal-respond RTs (across all SSDs) across TFUS

1467   conditions, we collapsed these RT means across TFUS conditions and compared them to each

1468   subject's mean Go RT with a mixed-design ANOVA. There was no interaction or Group

1469   differences ($p > 0.05$). As expected, the mean signal-respond RT (all groups: 365 ±15) was

1470   significantly shorter ($F(1,50) = 89.77$, $p < 0.0001$) than the mean Go RT (all groups: 436 ±22).

1471   Next, we examined whether the signal-respond RT increased with increasing SSD by

1472   regressing all subjects' signal-respond RTs (collapsed across TFUS conditions) onto their SSDs

1473   to obtain a single-slope parameter. This revealed a significant regression slope of 0.44 ($p <$

1474   0.001), indicating signal-respond RTs did increase with increasing SSD.

1475   Having confirmed that TFUS did not alter signal-respond RTs or the Go RTs, we sought

1476   to test the context-independence assumption of the race model. This has been done in several

1477   ways (see Bissett, 2014 for a non-parametric approach). The standard approach for examining

1478   this assumption is comparing predicted signal-respond RTs from fitting the independent race

1479   model to the observed signal-respond RTs (Verbruggen and Logan, 2009). The independence

1480   assumption is typically assessed by showing that observed signal-respond RTs and those

1481   predicted by the independent race model are not different. Because we used a parametric (ex-

1482   gaussian) based approach to estimate the SSRT (Matzke et al, 2013), we verified these derived

1483   fits by using a posterior predictive model comparison to the observed data. The models were

1484   used to simulate 500 predictive distributions of signal-respond RTs to estimate the absolute

1485   goodness of fit (Gelman & Hill, 2007) to each individual subject's signal-respond RT. This

1486   approach generates *p*-values that test for the difference in the predicted and observed signal-

1487   respond RTs at each SSD level. The typical metric for assuming goodness of fit is that the *p*-

1488   value is close to 0.5, while being below and above 0.05 and 0.95, respectively, is considered a

1489   poorly predictive model. As pointed out by Matzke et al. (2013), these estimates are most stable

1490   for SSDs in which several signal-respond RTs are observed. Therefore, we analyzed each

1491   subject's p-values averaged across the two highest SSDs.

1492   The mixed-design ANOVA across groups and TFUS conditions did not reveal any

1493   effects or interaction on the *p*-values. This result also agrees with the analysis showing no

1494   differences in signal-respond RTs between TFUS conditions, indicating the Bayesian procedure

1495   for estimating SSRT provided accurate predictions of signal-respond RTs. For all participants,

1496   the *p*-values were in the range of 0.1 to 0.9 with a mean of 0.48 and standard deviation of 0.2.

1497

1498   **S4. SSRT Variability was not altered by TFUS.**

1499   One possible driver of increased response inhibition performance in the rIFG TFUS

1500   group is that it may have reduced within-subject SSRT variability. Therefore, as TFUS did not

1501   alter mean or variance of Go RTs, if it reduced SSRT variability, this would increase the

1502   likelihood of successful inhibition. Using the same statistical approach for the mean SSRT in the

1503   main text, we found no significant effects of SSRT variability between any of the conditions (all *p*

1504   > 0.05).

1505

1506   **S5. SS (No-TFUS) – SS (Stop-TFUS) whole-brain regression table**

1507   Table S1 lists the peak coordinates of clusters of the difference in evoked activity of No-

1508   TFUS and Stop-TFUS SS with the between-subjects changes in SSRT. These coordinates were

1509   used to identify which areas exhibited differential activation with respect to the speed of

1510   stopping across subjects. Coordinates for relevant regions of interest were used as prior

1511   locations in subsequent dynamic causal modeling in the main text.

1512

Regression of ΔSSRT and SS (No-TFUS) – SS (Stop-TFUS)

1513   Table S1. Significant regions of regression for the change in TFUS induced SSRT.

1514

1515   **S6. Whole-brain SPM analysis**

1516   We performed a whole-brain SPM analysis for (1) positive t-contrast for SS (No-TFUS) –

1517   SS (Stop-TFUS) trials to examine where activity was larger for TFUS compared to No-TFUS

1518   trials, (2) SS-US main effects, and (3) TFUS main effect. In all of the analysis below, we used a

1519   cluster-forming voxel threshold of p< 0.005

1520   *SS-SS t-contrast.* In the stop-signal locked window (-40:20 ms), we found differences in

1521   left supramarginal gyrus. In the N100 window (20:100 ms), the contrast was significant, as

1522   anticipated, in rIFG. This result supports our scalp ERP measures and previous results

1523   indicating that an N100 occurs in the rIFG that is predictive of stop success. In the N200 window

1524   (100:180 ms), we found increased source activity in TFUS trials in bilateral clusters with

1525   locations indicative of pre-SMA (Mayka et al., 2006). Consideration of the fourth time window

1526   (180:260 ms), which overlapped with the SSRT, revealed that only the right inferior occipital

1527   area produced a larger response in TFUS trials. In the last window (260:340 ms), we found

1528   clusters of activity larger in TFUS trials for left superior occipital, right cuneus, and anterior

1529   cingulate. Because this window always occurred after the SSRT for both No-TFUS and TFUS

1530   conditions, it is likely these changes in activity represent a component of performance

1531   monitoring rather than inhibition *per se.* Examination of the contrast for larger No-TFUS SS trial

1532   activity revealed this contrast was only significant in the latest time-window (260:340 ms). This

1533   contrast indicated source ERP activity was larger in No-TFUS trials in bilateral postcentral gyrus

1534   clusters. An important result from these contrasts is the primary areas in which activity was

1535   larger during TFUS trials. We found that both rIFG and pre-SMA activity coincided with

1536   increased TFUS-related stopping. Interestingly, this analysis confirmed that rIFG differences

1537   occurred before those in pre-SMA. However, a temporal precedent of change in ERP does not

1538   necessitate that stopping-related changes occurred in rIFG before pre-SMA. The source cluster

1539   MNI locations and cluster sizes are presented in Table S2.

1540

1541

SS (No-TFUS) – SS (Stop-locked TFUS)

P. Uncorrected Voxel < 0.005 and P. Cluster Uncorrected < 0.05					

1542   Table S2. MNI locations for SS-SS contrasts

1543   *SS-US and TFUS F-contrast.* Here we show brain areas that exhibited differential

1544   evoked activation according to (1) successful compared to unsuccessful stopping (SS − US F-

1545   contrast), and (2) which areas were modulated by TFUS (TFUS F-contrast). We computed

1546   these whole-brain SPM contrasts using a flexible factorial model to implement a repeated-

1547   measures ANOVA. We examined these contrasts over three time windows that covered the

1548   time from stop-signal onset till after the range of subject SSRTs. The main result from all of

1549   these analyses is that the only brain area exhibiting overlap between a significant SS-US and

1550   TFUS contrast was a right inferior frontal gyrus cluster centered on pars opercularis, during the

1551   20:100 ms time window. This result supports the accuracy of our TFUS manipulation and its

1552   effects on inhibition performance. These data are shown in Figures S3-5.

Interaction t-contrasts. The most common contrast in analyzing stop-signal neural data involves comparing successful to unsuccessful stop activation (SS – US) as we did for the above whole-brain analysis. The rationale is based on the assumption that areas directly related to stopping/inhibition are more 'potently' active in successful trials, and that failed stop trials (US) also reflect go activity according to the independent race model of Logan and Cowan (1984). This choice of contrast also stems from the fact that typical stop-signal tasks do not offer a second set of SS trials for comparison (which our experiment does). Therefore, this raises the following question: Did TFUS yield changes in stopping by merely altering what would have

1577   been US Stop-TFUS trials? If TFUS merely raised the overall level of activity across all stop

1578   trials, (i.e., SS and US), then we should expect no interactions. We examined the whole-brain

1579   SPM interaction across the 4 time windows used in the previous analysis. In each window, we

1580   examined the t-contrast interaction that compared for a bigger SS-US difference in either Stop-

1581   TFUS or No-TFUS trials. We only found these effects for the 100:180 ms and 180:260 ms

1582   window. The interaction t-contrast SPMs and corresponding tables are shown in Figures S6-7.

1592 Figure S7. SPM interaction t-contrasts of source evoked power during the 180:260 ms post stop
1593 signal window. The t-contrast tested for areas in which the SS-US contrast was higher during
1594 stop-TFUS compared to non-TFUS. The cluster corrected statistics are shown are shown below
1595 the plot.

1596

1597 We note that we only found significant contrasts in the latter two time windows, i.e., 100-

1598 180 and 180-260 ms from the Go signal. In both contrasts, the SS-US difference was larger in

1599 the Stop-TFUS conditions. Generally, these results agree with that of the main text examining

1600 just the SS-SS contrast and other studies (Aron and Poldrack, 2006; Boehler et al., 2010).

1601 However, as Boehler et al. (2010) point out, this contrast is conservative which lends itself to

1602 identifying areas primarily involved in successful stopping. It is also unlikely that this

1603 conservative contrast can identify areas involved in the broader stopping network. It is therefore

1604 not surprising that we did not find difference in parietal cortices, for example. Importantly,

1605 though, these results demonstrating mainly activation differences in inferior frontal and occipital

1606   cortices is almost identical to that found in Boehler et al. (2010). This indicates that our results

1607   generally agree with previous studies using the SS − US contrast.

1608

1609   **S7. ROI Interaction analysis**

1610   In the main text we presented a time-based source analysis of the main ROIs of interest,

1611   including Right IFG, Right pre-SMA, Right DLPFC, Left M1, and Right Inferior Temporal

1612   cortices. In the main text's analysis, we compared SS trials across TFUS conditions. To address

1613   the change in time-course activation at the ROI level, we computed the interaction of SS-US

1614   (no-TFUS) and SS-US (Stop-TFUS) trials using the same MNI locations as used for analyses

1615   reported in the main text (Fig. S6).
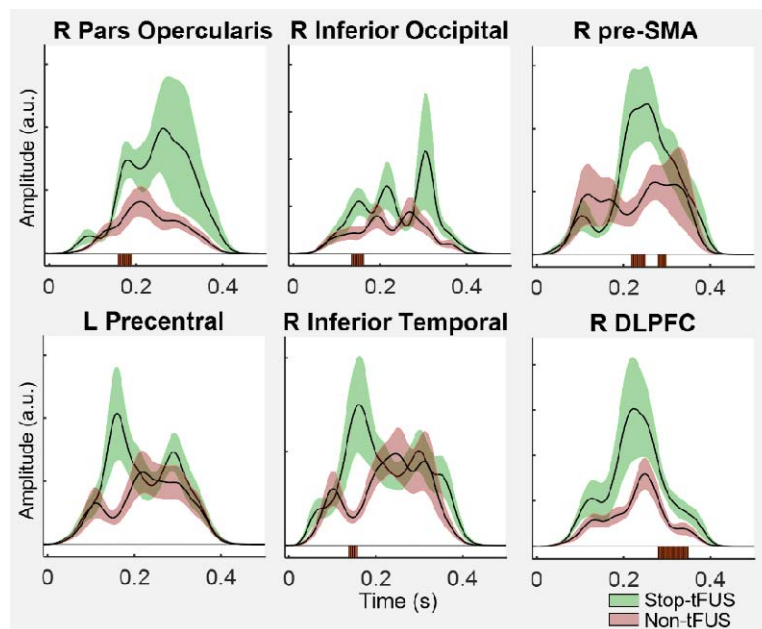

1616

1617   Figure S8. Source-base evoked power time-series for different regions-of-interest listed in the
1618   figure. Each ROI was extracted with a radius of 6 mm.

1619   Only three of these ROIs are different before the minimum SSRT across TFUS conditions (185

1620   ms). These include pars opercularis, Right Inferior Occipital, and Right inferior temporal ROIs.

1621 This result is mostly in line fMRI (Boehler et al., 2010; Li et al., 2006) and EEG/MEG (Boehler et

1622 al., 2009; Wessel and Aron, 2015) studies, although previous work has also identified Right

1623 temporal cortex (Rae et al., 2015; Xu et al., 2017). Nevertheless, previous findings of differential

1624 temporal cortex activity have been based on comparing SS to Go trials rather than the SS – US

1625 (and interaction) comparison we used here. Given the DCM and SSRT regression results

1626 indicating changes in temporal cortex activity – as well as the temporal cortex's role in visual

1627 signal in both the top-down and bottom-up processing directions – these results suggest the

1628 success of stopping may rely on information transfer of node between sensory and prefrontal

1629 ventral areas, e.g., rIFG. Finally, an interesting result is the lack of difference in r pre-SMA

1630 before SSRT. Notably, there was differential activation but only after SSRT. This result speaks

1631 to the broader debate of whether pre-SMA or rIFG lead to stopping in a serial process fashion

1632 (Aron et al., 2016; Obeso et al., 2013). For example, some studies have suggested that

1633 information for stopping passes through pre-SMA onto rIFG and vice versa in other accounts.

1634 These serial accounts, though, forego three factors. First, visual information regarding stop

1635 contexts are passed up both the ventral and dorsal pathways which inherently project

1636 separately to rIFG and r pre-SMA, respectively. Second, the prefrontal cortex is likely arranged

1637 hierarchically with both areas connected with basal ganglia structures, such as the STN and

1638 striatum. The third comparison is based on considering the current EEG-DCM (main test)

1639 results to those from other fMRI-DCM and other connectivity results (Jahfari et al., 2017) on

1640 inhibition. Specifically, the previous bilinear DCM models used in fMRI accounts of response

1641 inhibition are unlikely to capture the fast-timescale processes that underlies stopping processes.

1642 Along this same line, though, when considering connectivity as a property of inhibition

1643 processes, caution should also be used in interpreting temporal precedence of control between

1644 brain areas based solely on activation. Thus, the above results indicate that the set of expected

1645 ROIs were differentially modulated by TFUS during SS stopping.

1646 **S8. Assessment of possible auditory effects of TFUS**

1647   Recent work examining the effects of TFUS on cortical activity has employed animal

1648 models to consider the possibility that TFUS may alter activity in auditory pathways. Using a

1649 single-element transducer and optical imaging on a mouse model, Guo et al. (2018) showed

1650 that, regardless of the transducer placement and target, TFUS caused activation of the auditory

1651 pathway. They suggested that this activity may spread cortically and induce artifactual effects of

1652 TFUS in cortical areas not directly targeted by TFUS. It remains unknown how auditory pathway

1653 activation via TFUS would yield our behavioral and neural effects. Nevertheless, it is critically

1654 important to quantify the extent to which auditory pathway activation might have affected our

1655 results. To address this question, we analyzed source-localized evoked results across the rIFG

1656 group, as well as S1 and sham rIFG control groups. Because our goal was to determine

1657 whether TFUS altered the evoked activity with respect to No-TFUS, we compared the time

1658 courses of source power for stop-locked data by using a source-based ROI of right auditory

1659 cortex. We used the source location of X: 46, Y: -14, Z: 8 for right auditory cortex, which was

1660 obtained from Rademacher et al. (2001). These locations were used to extract the eigenvariate

1661 time-course after source localization in a sphere with radius of 8 mm to be conservative. These

1662 source-time courses were converted to a pseudo activation using the (exp(SOURCE)+exp(-

1663 SOURCE))/2 transform. We used this procedure to ensure we could properly detect differences

1664 regardless of the ERP activity sign (Fig. S9).

1665   If the behavioral results in the rIFG group were merely the result of changes in auditory

1666 pathway activity, we should at least see a difference when contrasting the SS-US trials for No-

1667 TFUS and Stop-TFUS conditions in the rIFG group, or at least across groups. Paired samples t-

1668 tests did not reveal any significant differences (after false discovery rate correction of $p < 0.05$)

1669 when comparing the time courses of the No-TFUS and Stop-TFUS conditions (Fig. S9).

1670 Therefore, given the spatiotemporal fidelity of EEG, we conclude that our results were not

1671 contaminated by TFUS artifacts activating the auditory pathway.

1684
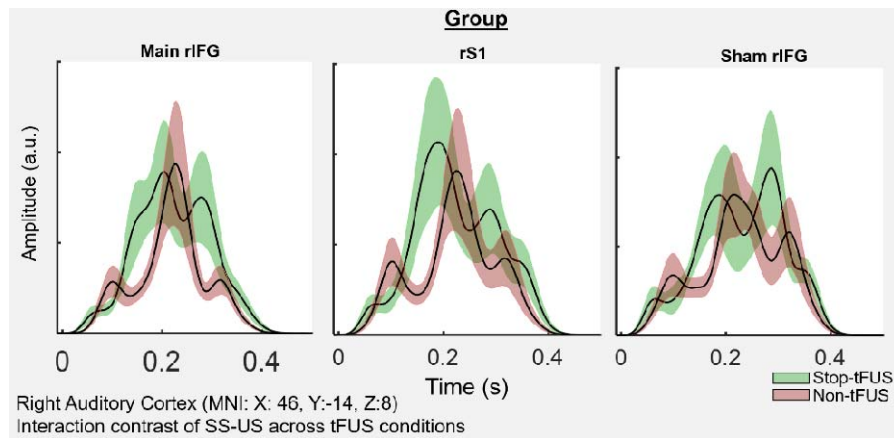

1685 Figure S9. Group source-evoked power time series from right auditory cortex.

1686 Overall, these results suggest that, although TFUS may exert an auditory pathway

1687 effects measurable in mouse single neurons and LFPs, (1) this activity may not be measurable

1688 at the macroscopic level, and (2) support the notion that changes in auditory cortical activity

1689 cannot account for our TFUS-related neural and behavioral effects. Additionally, we note that

1690 Guo et al. (2018) found that the auditory pathway activation was accompanied by startle-like

1691 reflexes. Our behavioral results (Fig. 2) are not compatible with a startle release reflex. If that

1692 were the case, TFUS auditory-related startle activity would likely predict shorter RTs during Go

1693 trials and failed inhibition Stop trials. The effects of TFUS on our behavioral responses are not

1694 compatible with the involvement of startle reflexes, as we found no TFUS effects on the Go

1695 RTs. Therefore, we conclude that the effects of TFUS on stopping behavior, nor processing by

1696 the cortical and subcortical nodes of the inhibition network, were not induced by artifactual

1697 stimulation of the auditory pathway.

1698

1699   **S9. DCM family model hypothesis spaces and results**

1700   Below we show the resultant family model posterior probabilities for the family comparisons over

1701   the 4 factors (3 levels each) for both parametric empirical Bayesian (PEB) GLMs (Figure S10-

1702   11). PEB GLM model 1 examined the changes in mean connectivity from No-TFUS US to SS

1703   trials. Changes in mean connectivity represent the gain on connectivity to represent the No-

1704   TFUS SS trials. PEB GLM model 2 examined the effects of TFUS-induced changes in mean

1705   connectivity and changes in connectivity that accompanied change in SSRT across subjects.

1706   Figures S8 and S9 show the changes in connections and family model probabilities for PEB

1707   model 1. Figure S12 shows the results of tests of the exact same factor space displayed as bar

1708   plots to represent the family probability of each model separately for the TFUS-induced mean

1709   and SSRT change in successful inhibition connectivity.
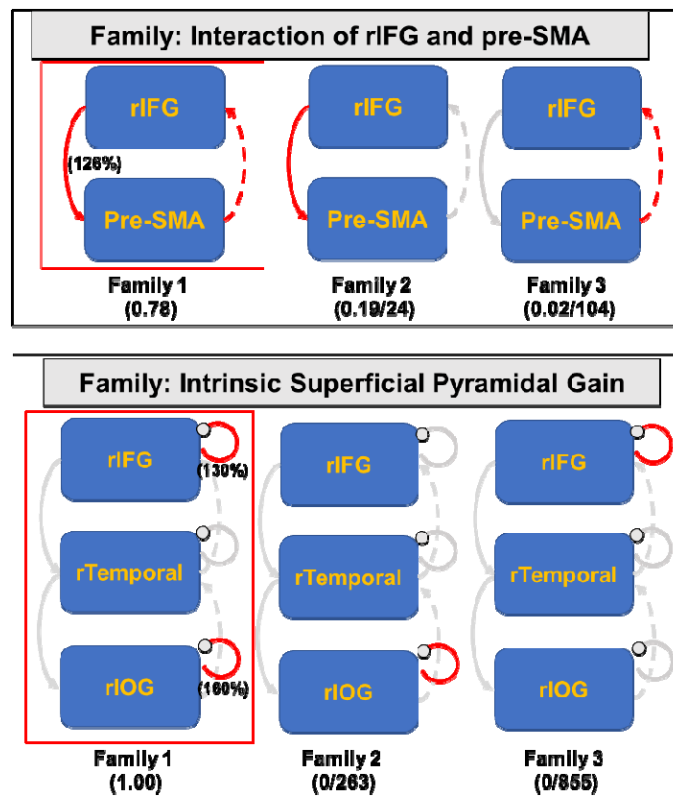

1710

1711   Figure S10. Hypothesis space and results of the Family based PEB Bayesian model
1712   comparison for different hypotheses. Family-based posterior probability (F-Pp) and the log-

1713   bayes factor with respect to the winning model are listed below each model and were computed
1714   as the difference in free energy between families (F-Pp/Log-Bayes). The winning model family is
1715   enclosed in a red box. The outcomes of these plots can be interpreted of as revealing the
1716   modulatory parameters connections with very strong, positive evidence being different between
1717   US and SS trials. Parameters estimates with a greater than 95% posterior probability in these
1718   families are presented in parentheses next to the modulated connection. The parameters are
1719   presented in exponential form of percentage gain. Values above 100% equates to a parameter
1720   increase in SS trials compared to US (and the opposite for values below 100%). Parameters in-
1721   active in each model are in a gray color. The top Panel shows the hypothesis test of rIFG and
1722   pre-SMA interactions. The bottom panel shows the hypothesis test of intrinsic gains modulation.

1723
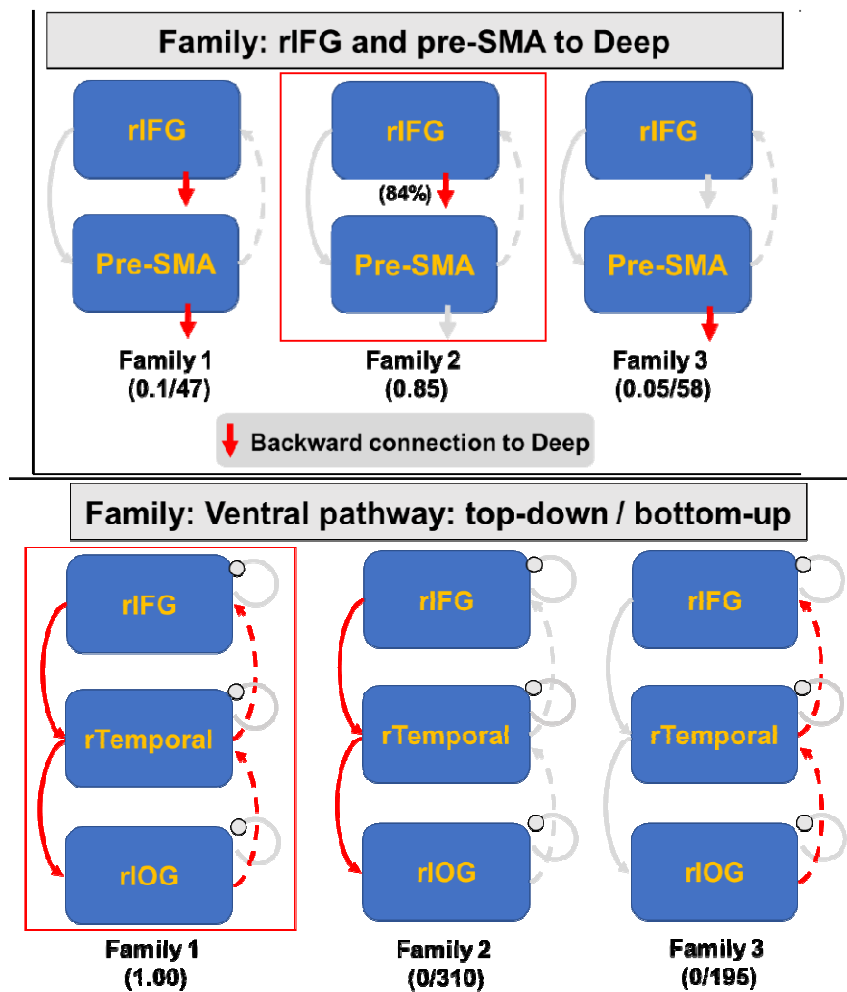

1724

1725   Figure S11. Hypothesis space and results of the Family based PEB Bayesian model
1726   comparison for 3 different families comparing hypothetical different interactions between rIFG
1727   and the deep node, pre-SMA and the deep node, or both interacting with the deep pathway. The
1728   plot is in the same format as Figure S8. Both of these nodes had backward, inhibitory
1729   connections with the deep pathway. The top panel compares families comparing the rIFG and
1730   pre-SMA to deep backwards connection. The bottom panel compares families testing for
1731   differences in top-down v bottom-up connections along the ventral pathway.
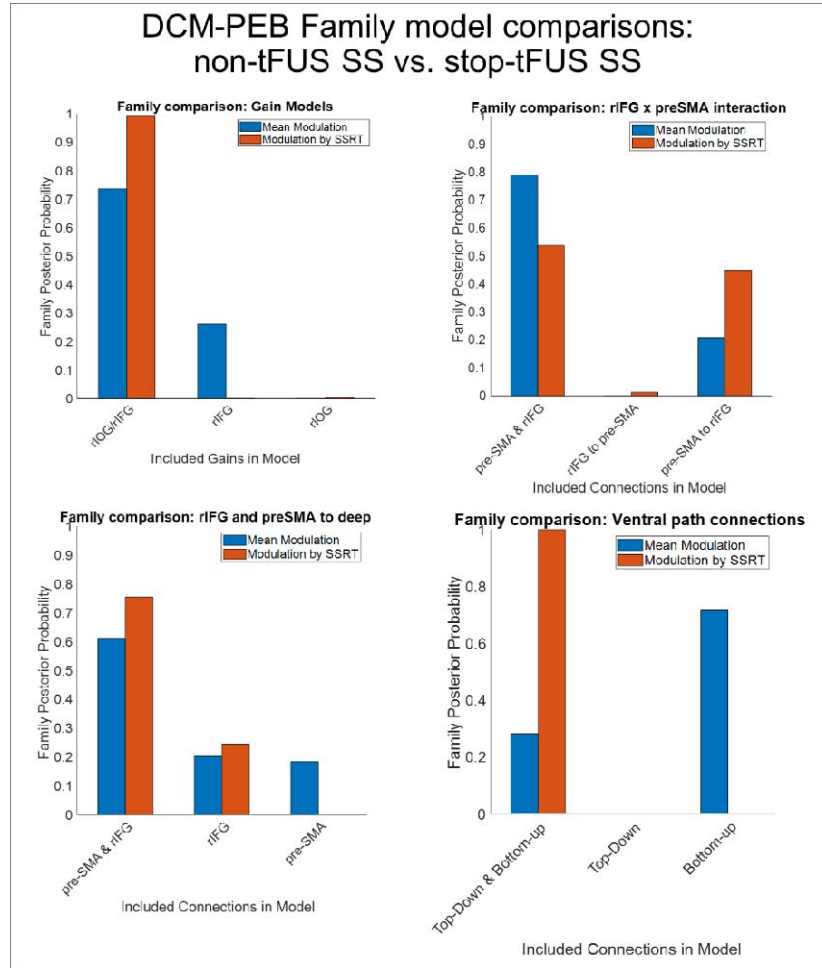

1732

1733

Figure S12. Resultant family posterior probabilities for the comparisons of each factor. Each bar plot shows the marginal probability of each family marginalized separately for changes in the mean connectivity (blue bars) and connectivity changes predicted by TFUS induced changes in SSRT (orange bars). The Bayesian model averaged parameters are presented in the main text.
