Abstract (150 WORDS)

Astroglial cells are emerging as key players in the development and homeostatic maintenance of neurons and neuronal networks. Astroglial cell functions are critical to neuronal migration and maturation, myelination, and synapse dynamics, however little is known about astroglial phenotypic changes over development. Furthermore, astroglial cells express steroid hormone receptors and show rapid responses to hormonal manipulations, however, despite important sex differences in telencephalic regions such as the cortex and hippocampus few studies have examined sex differences in astroglial cells in development and outside of the hypothalamus and amygdala. To phenotype cortical astroglial cells across postnatal development while considering potential sex differences, we used translating ribosome affinity purification together with RNAsequencing (TRAPseq) and immunohistochemistry to phenotype the entire astroglial translatome in males and females at key developmental time points: P1, P4, P7, P14, P35 and in adulthood. We found that although astroglia show few sex differences in adulthood, they show significant sex differences in developmental gene expression patterns between p7 and P35, that suggest sex differences in developmental functions. We also found two distinctive, non-overlapping, astroglial phenotypes between early (P1-P7) and late development (P14-Adult). Together these data clearly delineate and phenotype astroglia across development and identify sex differences in astroglial developmental programs that could have an important impact on the construction and maintenance of neuronal networks and related behavioural phenotypes.

We thank Dr. Julianna Tomlinson, Dr. Michael Schlossmacher and his laboratory members at the University of Ottawa for providing us with infrastructural support and more. Finally, we would like to thank Dr. Alfonso Abizaid for his invaluable input into the planning and preparation of this research project.

Introduction

The cerebral cortex is a complex network of layered neuronal cells that uses a balance of excitatory and inhibitory signals to communicate both within the cerebral cortex itself and to lower brain regions[1]. It is the most recently evolved component of the mammalian central nervous system and is uniquely involved in higher order cognitive functions[2] that are central to intelligence and emotional processing. The complex layered structure of the cerebral cortex emerges during embryonic development in an "inside-out" pattern consisting of radial glial cell (RGC)-assisted neuroblast migration to lower layers (i.e. VI) before the upper layers are formed [3,4]. The appropriate migration of developing neuroblasts is an integral part of the maturation of the cerebral cortex. Early insults or perturbations during this critical period of development may disrupt the gross organization of excitatory and inhibitory networks leading to neurodevelopmental disorders including autism spectrum disorders (ASD) or schizophrenia, and mood disorders such as bipolar disorder[5,6]. Importantly, even subtle modifications in the number or functionality of cortical synapses may lead to serious behavioural consequences and have been related to a number of psychiatric diseases[7].

The prevalence of many, if not all, neurodevelopmental disorders and mood disorders related to cortical function are sexually dimorphic in human populations[8] .Thus understanding sex differences in the organization and function of the cerebral cortex is critical to understanding the neurodevelopmental underpinnings of psychiatric disease. There is a great deal of literature that suggests that gonadal hormones can directly modulate disease states associated with schizophrenia, anxiety and mood disorders[9,10]. Similarly, in rodent models, basal changes in behaviours such as in the forced swim task have been demonstrated across the estrous cycle[11]. Together, these data support an important role for ovarian hormones and in particular, estrogen, in mediating those behaviours related to higher order cognitive functioning in situ. Effects on behaviour and physiology that depend on current levels of hormones such as those described above are referred to as activational. The sex steroid milieu of embryonic and neonatal life, however, can also have organizational effects. These are changes induced in this early stage of development that persist even when the hormonal state producing them has dissipated. Testosterone secreted from the testes of XY-male embryos acting either

directly or via aromatisation to estradiol is the primary organizing influence in the sexual differentiation of the brain[12,13]; The role of estradiol in mediating organizational sex differences through neuronal estrogen receptor (ERs) signaling has been extensively studied in the hypothalamus and amygdala. For example, in the MPOA, estrogen receptor signalling induces prostaglandin-mediated synapse formation through microglial and astroglial-mediated functions[13]. Neuroanatomical and functional sex differences are also well defined in various neuronal populations of the hypothalamus[14], amygdala[15], and hippocampus[16]. The cerebral cortex, however, has received less attention than other telencephalic regions[17].

While it is possible that sex differences in cortical network functioning may be completely mediated by direct hormonal modulation, sex differences in prevalence of anxiety disorders[9] and ASD[18] are apparent prior to puberty, and pro-dromal behaviours associated with psychosis also show sex differences early in development[19], suggesting that organizational sex differences (presumably in cortical networks) may be involved in differences in risk or vulnerability for psychiatric disease.

Astroglial cells have recently emerged as key mediators in brain development and the etiology of neurodevelopmental and mood disorders has been related to astroglial-mediated functions such as neuroblast migration and synapse formation, maturation, and elimination[20,21]. Astroglial cells are a heterogenous cell population comprised of three main subtypes. The first subtype of astroglial cells to emerge in development are RGCs[22]. In addition to providing scaffolding for migrating neuroblasts, astroglial cells exhibit stem-like potential in early development and following injury that allows them to give rise to other neuronal cells before maturing and populating the cortex as fibrous or protoplasmic astroglial cells[23,24]. As astroglia mature, their stem cell potential diminishes, as marked by an increase in glutamate synthetase and decreased expression of Sox2 and vimentin[25]. The two main mature subtypes are characterized as protoplasmic; canonical astroglia with large domains of many fine processes, and fibrous; astroglial cells with many long fibrous extensions[26]. These mature astroglial cell populations are responsible for the construction and maintenance of both excitatory[27] and inhibitory[28] synapses in the developing neocortex, modulating neuron signaling and maturation[29], and the elimination of synapses during cortical maturation[21]. Work from

the Barres laboratory characterised astroglial cells in brain development using next generation sequencing techniques, however these studies did not examine the contributions of biological sex, or early developmental periods[30]. Astroglial cells express ERα[31], ERβ[32], and G-protein coupled ERs[33], and although the full extent of ER functionality in astroglial cells is not understood[34], astroglia show rapid responses to hormones across various states and manipulations[35].

Because astroglial cells contribute to cortical development through neuroblast migration, neuronal network integration, and synapse formation, maturation and elimination, and because astroglia show rapid responses to hormones, we hypothesized that cortical astroglial cells may 1) show phenotypic sex differences both overall and across development and 2) execute developmental functions in a sexually dimorphic way. To address this, we employed a transgenic mouse model expressing enhanced green fluorescent protein (eGFP) fused to the L10 ribosome under the pan-astroglial cell promoter AldH-L1 and used immunohistochemistry and TRAPseq to phenotype the astroglial translatome and protein expression. We examined time points pertaining to critical periods of postnatal neocortical development.

Results

To measure total numbers of neocortical astroglial cells (astroglial cell number) across development, we used unbiased stereology to quantify eGFP+ cells (eGFP was expressed under the control of the pan-astroglial promoter, (AldH-L1). No sex differences in total astroglial number were observed ($F=0.186$; $p=0.966$) (Figure 1A), however there was a main effect of age on this measure ($F=55.544$, $p<0.001$), whereby the number of astroglial cells did not show further increase in males or females after P14 (Figure 1A). Neocortical volume did not exhibit sexual dimorphism ($F=0.302$, $p=0.909$) (Figure 1B). Not surprisingly, we observed a significant increase of brain volume with age ($F=135.181$, $p<0.001$) (Figure 1B).

Astroglial cell phenotype was assessed by looking at protein expression of common astroglial markers and characterising morphology. Astroglial cells show morphological heterogeneity that is often associated with functionality (Sofroniew & Vinters, 2010). In order to assess changes in morphology across age and/or sex, eGFP+ cells were characterized as radial or non-radial based on the presence of a leading, radial process in the neocortex. No significant sex effects were found ($F=0.249$, $p=0.938$), however there was a significant effect of age ($F=89.291$, $p<0.001$) (Figure 1C). Nearly all (~95% in both males and females) astroglial cells in the neocortex at P1 exhibited radial morphology (Figure 1C). At P4, there was a marked decrease in the proportion of radial astroglial cells and most cells shifted to a non-radial morphology with no marked sex differences. By P7, only 5% of astroglial cells in males and 4% of astroglial cells in females exhibited a radial morphology and, as expected, from P14 onwards there were virtually no radial astroglial cells remaining in the neocortex (<1%) (Figure 1C). We quantified expression of the astroglia-specific cytoskeletal filament protein glial acidic fibrillary protein, (GFAP). GFAP expression was not sexually dimorphic across development ($F=0.204$, $p=0.959$) however, there was a main effect of age ($F=30.328$, $p<0.001$) (Figure 1D). The number of GFAP+ cells reached peak levels at P14 and remained stable at later timepoints (Figure 1D). Prior to P14, no more than 15% of eGFP+ cells co-expressed GFAP, from P14-onwards approximately 25% of eGFP+ cells expressed GFAP, consistent with previous work that has demonstrated

that a large proportion of cortical astroglia do not express GFAP under basal conditions (Simard et al., 2018).

Next, we quantified the number of cells that expressed vimentin, an intermediate filament protein associated with a stem-like radial sub-type of astroglial cells. A significant interaction of sex by age was found ($F=3.871$, $p=0.006$) (Figure 1E), such that females showed significantly more vimentin+ cells compared with males at P7 ($t=3.41$, $p=0.011$) and males showed significantly more vimentin+ cells in adulthood ($t=3.895$, $p=0.005$) (Figure 1E,G). Because vimentin expression is associated with astroglial cell neurogenic and stem cell potential and because we observed sex differences in vimentin expression, we quantified the proportion of actively dividing eGFP+ cells across the postnatal period. Using a marker of active s-phase cell division, Ki67, we quantified the percent of Ki67+eGFP+ cells. Ki67 was present in less than 2% of the astroglial cell population throughout the postnatal period in both males and females (Figure 1F). There were no significant sex differences across development ($F=1.608$, $p=0.179$) however there was a main effect of age ($F=26.799$, $p<0.001$).

To generate a complete phenotype of astroglial cells across development by sex, we used TRAPseq to assess the astroglial translatome at each time point. In order to further characterise astroglial-specific markers by sex and age, we plotted expression data for each of the top 20 genes expressed only in astroglia as described in[30] (Figure 2). Interestingly, most astroglia-specific genes are expressed at slow-rising or stable levels across development, however *CYP4F14*, a Vitamin E hydoroxylase and *SLC39A12*, a zinc transporter involved in the pathophysiology of schizophrenia[36] both have low expression levels early on and rise to adult levels at P14. We did not find any sex differences in astroglia specific genes.

Figure 3A shows the hierarchical organization of the astroglial translatomes by sample. Overall, the clustering shows a pattern of organization that is primarily affected by age, with P1, P4 and P7 (early) showing similar expression patterns and P14, P35 and adult mice (late) showing similar expression patterns that differ from the early timepoints. We manually sorted samples by sex and age and although some organization by sex is noted in Figure 3B, this is not as clearly demarcated as that observed by age. Indeed, when we collapsed gene expression levels across all time

points, 43 genes were differentially expressed between female and males (Supplementary Data File 1) in total, suggesting little to no sex differences in cortical astroglia overall. Moreover, many of these sex differences in gene expression are for genes located on the sex chromosomes. These findings suggest that overall, the basal translatome of cortical astroglia is not sexually dimorphic and that there are two major cortical astroglial phenotypes across age: an early (P1-P7) and late (P14-adult) phenotype.

To further characterize the *"early"* and *"late"* phenotype observed in the astroglial cell translatome, we examined the number and proportion of up- and downregulated genes in the early versus late developmental phenotypes, both by sex and collapsed across sex (Figure 4A). The early versus late phenotype in males showed 5528 DEGs whereas the female early versus late phenotype had 8593 DEGs (full list of DEGs in Supplementary Data File 2). Interestingly, the proportion of up- or downregulated genes was fairly equal, with males and females showing 56% and 55% of DEGs in the early versus late phenotype being upregulated, respectively. When we collapsed the DEGs across sex to generate a general astroglial cell early vs late phenotype, the number of DEGs reaches 9219, distribution of up- (58%) and downregulation (42%) (Figure 4A). This suggests that the difference in the early and late developmental phenotype is not merely reflective of turning off developmental genes but rather is a combination of downregulating genes associated with early development and turning on genes associated with later development and early adulthood.

Some key DEGs stand out as they have not previously been functionally described in astroglial cells. In particular, *Trim67*, an important and evolutionarily preserved guidance cue for neurite outgrowth[37], is high in early development and, as expected, decreases with age. This gene is also upregulated at P7 in females compared to males (Supplementary Data File 1 & 2). Additionally, *Ntng1*, codes for Netrin G1, another guidance cue that is paramount to developing neuroblasts, is higher during the "early" developmental phenotype in astroglial cells. Interestingly, differential *Ntng1* expression appears when examining both the overall and the female-specific early versus late astroglial cell phenotype, however it does not seem to be differentially regulated in the male-specific early versus late astroglial cell phenotype. *Ntng1* has

been implicated in the etiology of familial schizophrenia[38] and *Ntng1* mRNA is in lower cortical samples from individuals with schizophrenia and autism[39].

Next, we compared the proportion of overlap between the female-specific and male-specific DEGs in the early versus late phenotype, and a clear sex difference emerges in the developmental expression pattern of astroglia. Of the 9219 DEGs, approximately 55% overlap between males and females, however a staggering 39.4% of total DEGs are specific to females and 10% are specific to males (Figure 4B). This suggests that there are distinct developmental phenotypes in cortical astroglial cells that emerge between the sexes. When we further characterize the sex-specific canonical pathways (CPs) by gene set over-representation, a large proportion of the top 10 female-specific CPs are related to cell cycle/mitosis, marked by CPs related to M-Phase of cell division, “Mitotic, Cell Cycle,” mRNA processing, and Wnt signalling (Figure 4D). In comparison, male-specific CPs are related to ion homeostasis, small molecule transportation, and adenosine triphosphate regulation (Figure 4C). In particular, we see “prostaglandin synthesis and regulation” in male, but not female CPs. Prostaglandins are essential mediators in sexual differentiation of the hypothalamus and amygdala[13]. The emergence of the prostaglandin CP in the cortex suggests that prostaglandins may also be regulators of neocortical sexual differentiation.

To broaden the understanding of sex differences in astroglial cell gene expression across development, we identified DEGs of females versus males at each time point (Figure 5A). At P1, there are only 14 DEGs however at P7, P14, and P35 there are 193, 134 and 176 DEGs, respectively (Figure 5A; full list of DEGs in Supplementary Data File 1). In Figure 5B we show the number of DEGs between developmental time points in males and females, the peak in DEGs in males occurs between P4-P7, with 507 DEGs whereas the peak number of DEGs in females is between P7 and P14 and is substantially larger, with 3113 genes differentially expressed at this timepoint. These sex differences between P4-P14 are particularly striking given that these are the developmental timepoints where sex hormones are largely dormant (Figure 5D; full list of DEGs in Supplementary Data File 3), suggesting that these sex differences in gene expression were induced by earlier exposure to hormones or by sex-linked chromosomes. Remarkably at P7, P14, and P35, 85%, 66%,

and 98% of DEGs are downregulated in females. Within these downregulated genes are typical markers of cell activity, *Fos* and *Arc*, suggesting decreased basal activity in female astroglial cells at these timepoints (Supplementary Data File 1).

Work from the McCarthy laboratory has previously demonstrated that prostaglandins, and in particular, glial release of cyclooxengase 2 (COX-2) is a key regulator of estrogen-mediated architectural sex differences in the hypothalamus and the amygdala[40,41]. The gene for COX2, *Ptgs2*, is a sex-specific DEG in our data set in the overall females versus males, in the early female versus male phenotype, and at P1 female versus male (Supplementary Data File 1 & 2). COX2-mediated masculinization of the hypothalamus occurs in response to estradiol, which is aromatised from the surge in testosterone in males that occurs perinatally in rodents (Figure 5D). This perinatal surge in testosterone has been linked to sexual differentiation of the hypothalamus, amygdala, and mediates sexually dimorphic juvenile and adult behaviours[42-44]. To validate our findings and to test if COX2 protein levels are similarly regulated by estrogen in the cortex, we subjected P0 females to estradiol benzoate injections and sacrificed them 36 hours later. Females at P1 show fewer COX2+ cells in the frontal cortex compared to males and females exposed to estrogen ($F=3.509$, $p=0.034$) (Figure 5C). This suggests that estrogen exposure at P0 is sufficient to masculinize COX2 expression the cortex.

Next, we integrated the different altered gene sets in a coherent, systems-level context, using co-expression network analysis (see Online Methods). We inferred, (separately) a co-expression network in females and males throughout development, and identified 12 and 14 co-expression modules, respectively. We then characterized the modules in terms of overlap with the DEGs in the late vs early phenotype, correlation with developmental time point, and enrichment in GO terms and canonical pathways.

In females, the blue, brown, magenta and pink modules are enriched in genes upregulated in late vs early in females, and the black, turquoise and yellow modules are enriched in genes downregulated in late vs early in females (see WGCNA Summary data). Interestingly, the blue and brown (upregulated), and the black (downregulated) modules are enriched in astrocyte genes. The turquoise module (downregulated) is

enriched in cell cycle terms, and the yellow module (downregulated) is enriched in genes involved in ligand-receptor interaction, probably in relationship to cell cycle.

In the males' network, the black, blue, brown, magenta, pink and tan modules are enriched in genes upregulated in late vs early in males, and the green, red and turquoise modules are enriched in genes downregulated in late vs early in males (see Table WGCNA). Similar to what was observed in the female network, some of the modules enriched in upregulated genes in the late vs early phenotype in males (black, blue and brown), are enriched in astrocyte genes. It is likely that, in both networks, the astrocyte signature for the modules enriched in upregulated genes reflects a shift in astroglial phenotype during development. Finally, the green and turquoise modules (downregulated) are enriched in cell cycle terms. The cell cycle signature for some of the downregulated modules likely reflects a reduction of proliferative potential of the cells over time, as would be expected over development.

Next, we tested each network, female and male, for enrichment in DEGs related to the opposite sex, to identify differentially enriched modules that might point to sex-specific modules, and, potentially to sex-specific regulation processes. In the female network, we found that one module, black, is enriched in downregulated DEGs in late vs early phenotype in female, but not in male DEGs. Further annotation of the black module highlights enrichment in genes defined as response to androgen (MSigDB:Hallmark) and genes downregulated in response to estradiol treatment in mouse (EnrichR: GSE52649).

The relationships are more complex in the male network however, we find differential enrichment with both upregulated and downregulated DEGs. The tan module overlaps with upregulated DEGs in males, but not in females, which instead overlap with the yellow module. Further annotation of the tan modules shows enrichment in genes upregulated after treatment with testosterone in human skeletal muscle cells (EnrichR:GDS2920). In addition, the red module overlaps with downregulated DEGs in males, but not in females, which instead overlap with the purple module. Further annotation of the red modules shows enrichment in cell cycle genes and defining early response to estrogen (MSigDB:Hallmark); also with genes downregulated after

treatment with triiodothyronine (thyroid hormone) in human HepG2 cells (EnrichR:GDS3945).

We next contrasted the modular organization of the two networks to assess the degree of correspondence, or the lack thereof, between the networks to uncover potential differential regulation between males and females. Overall, we found good overlap between the two network modules, with each module in one network overlapping significantly with one or more modules of the other network, with the exception of the salmon in the male network and the greenyellow in the female network (see Figure 6). It should also be noted that overall module overlap does not imply similarity in structure, as the internal correlation structure may be different and because a module in one network may overlap with multiple module in the other network, thus hinting at differential regulation between the networks.

Discussion

In the current study, we generated a translatome database of cortical astroglial cells across development in both male and female mice. We show two clear astroglial phenotypes across development, an early (before P14) and late (after P14) phenotype. These early and late gene expression profiles reflect astroglia associated with early developmental functions related to gliogenesis and synaptogenesis and astroglia associated with functions involved in maturation, synapse elimination and maintaining a stable, homeostatic environment in adulthood (Figure 5D).

Surprisingly, cortical astroglial cells showed very little sexual dimorphism in either morphology or gene expression particularly in adulthood where very few DEGs were not sex-chromosome associated genes. Importantly, to assess basal differences between males and females in a conservative way, we chose to examine females during the metestrus phase, when ovarian hormones are at their lowest and therefore more similar to levels observed in males. As such, it is likely that greater sex differences in the astroglial translatome would be observed during other estrous cycle phases, such as in proestrus, when estrogen peaks. Indeed, we have previously demonstrated changes in cortical astroglial expression of GFAP and fibroblast growth factor 2 (FGF2), an astroglial mitogen and growth factor across the estrous cycle[45]. Together these results would suggest that astroglial cells show phenotypic changes in response to ovarian hormones, but they do not show basal sexual dimorphism.

Interestingly, the sex differences in DEGs observed at P7, 14, and 35 were not related to sex-specific canonical pathways or functions per se, but rather, they were related to general developmental phenomena such as cell cycle, and neuronal, dendritic and synaptic development, suggesting that astroglia modulate neuronal networks in a sexually dimorphic way. This could, in turn, potentially lead to the formation of sexually dimorphic neuronal networks, and presumably, sexually dimorphic behavioural expression later in life. Given the critical role of the neocortex in psychiatric disease and complex human behaviours[46], one might imagine that changes in neuronal network development may be induced by estrogen-modulated changes in astroglia. In addition, these may be particularly susceptible to developmental perturbations that modulate hormone expression levels including exposure to stress hormones and environmental

endocrine disruptors. Moreover, because hormone levels vary between individuals under normal conditions, this allows for a potential range of sexual differentiation of cortical networks, which would mirror behavioural sex differences observed across species, that are typically expressed on a continuum.

In contrast to the sex differences in gene expression seen on P4-P35, we see few DEGs between astroglia in male and female mice at P1 and in adulthood. This, in addition to the sex differences in CP of early versus late astroglial phenotype, suggests that cortical astroglial cells employ different developmental strategies to reach a similar phenotype. The idea that distinct mechanisms might lead to similar functional results is similar to that put forward by Woolley[47], which was based on findings of estradiol potentiating glutamatergic synapses, albeit on a much more general level. Earlier DeVries[48] postulated that sex differences in gene expression patterns over development may actually prevent sex differences in specific regions or ensure that neuronal systems develop and are functional in the presence of cues such as sex hormones that are crucial for stimulating sex differences in target regions. It is possible that the sex differences in gene expression profiles between astroglia ensure that these systems develop “equally” in both sexes to achieve similar functionality in adulthood in the presence of sex chromosomes and hormones that are necessary to differentiate regions critical to sexually dimorphic behaviours, such as the hypothalamus.

The question remains as to what induces sex differences in cortical astroglia gene expression patterns over development. Three potential scenarios emerge: 1) sex chromosome-linked genes directly induce changes in gene expression patterns in astroglia, 2) the perinatal testosterone surge initiates cascades of gene expression patterns in astroglia that modulate cell maturation and network development, and 3) given that astroglial cells have similar start and end points, and that sexual differentiation of the hypothalamus includes dramatic changes in neuronal number, arbours, and synapses, and that these project to other brain regions (including the neocortex), sex differences in astroglia gene expression could represent an active process to compensate for the influence of sex differences in developing inputs. Importantly, these scenarios need not be mutually exclusive and may be active in parallel systems.

Kdm5d appears as one of the few DEGs between females and males at P1 in our dataset, female expression levels are lower than males. *Kdm5d* is a Y-linked gene that encodes for demethylation enzymes and is required and sufficient to induce sexual differentiation of gene expression[49]. Indeed, changes in gene methylation may have profound effects that persist throughout time and cascades of gene expression may or may not be initiated, altering the responsiveness of the cell, and thus the network as a whole. Moreover, even in the absence of the testes determining *Sry* gene, the Y-chromosome has been shown to exert differential effects on developing peripheral and nervous tissue (reviewed in[50]), lending support to the idea that sex chromosome linked genes induce later sex differences in astroglia across development.

Similarly, there is evidence that the perinatal testosterone surge, and consequentially, estrogen is involved in the induction of developmental sex differences in astroglia (scenario 2). Our weighted network analysis shows enrichment of genes in several modules associated with responses to sex hormones and we show sex differences in the prostaglandin system (including Cox2) and that neonatal estrogen administration induces changes in cortical COX2 expression. Similar changes in astroglia have been demonstrated in the hypothalamus and are sufficient to produce observable sex differences in neuronal networks and associated behaviour[13]. Thus, the endogenous expression of estrogen early in development may facilitate a cascade of cellular maturation that in-turn will alter subsequent genetic programs. As such, the neuronal network will facilitate different programs as a result of the staggered pattern of maturation and communication.

Finally, scenario 3 suggests that sex differences in the hypothalamus are necessary for a functional behavioural outcome that is overt and essential for sexual reproduction, first suggested by de Vries[48]. However, there are few overt measures that can be linked to cortical functioning that exhibit similar sexual dimorphisms, although sex differences in risk and resilience for psychiatric disease associated with cortical functioning are well-supported. For example, schizophrenia and ASD are more prominent in the male population[8] and both show changes in developmental pathophysiology that occur both during the prenatal and postnatal periods[51,52]. There may be a relationship between astroglial neurogenic potential and the terminal phases

of neuronal migration and construction and maturation of functional cortical networks that buffers females against developmental anomalies which, if left unchecked, may lead to schizophrenia or ASD morbidity.

In-line with this hypothesis, there are a number of models where estrogen treatment improves recovery or where females are protected in developmental injury models. Chronic postnatal hypoxia in rodents is used as a model of premature birth and induces loss of brain volume, particularly in the cortex and hippocampus, and leads to motor and cognitive impairments later in life[53,54]. The loss of cortical volume in the hypoxic model is less pronounced in females[53] and interestingly, estradiol treatment at the time of the injury improves white matter damage recovery[55]. It is also known that chronic postnatal hypoxia increases astroglial stem cell capacity[23,56]. This process may be enhanced in females allowing augmented recovery from the aversive effects of hypoxia, but may also speak to the nature of enhanced early postnatal plasticity in females compared to males. It is possible that females experience an enhanced or shifted neurogenic period early postnatally when we have observed an increase in vimentin+ astroglia that may translate to increased neurogenic potential of astroglial cells in the cortex. Similarly, while overt network or cellular sex differences may not modulate sex differences in risk for psychiatric disease, sex differences in developmental programs may leave one sex more vulnerable to perturbations during that time. Future studies will be needed to determine the functional significance of sex differences in developmental programs. Nevertheless, our data show a clear developmental pattern in cortical astroglia that differs between males and females, while no apparent basal sex differences in astroglia exist.

Online Methods

Animals

54 male and female C57/Bl6-AldHl1-L10-GFP transgenic mice generated from our breeding colony maintained at the Carleton University animal facility within the University of Ottawa. Mice were genotyped as in (Simard et al., 2018) and sex was determined by the presence or absence of tissues in the urogenital tract and confirmed by genotyping for the *Zfy* gene. All animals were group-housed until sacrifice in standard (27cm x 21cm x 14cm), fully transparent polypropylene cages with chew block, bedding, house and *ad libitum* access to standard lab chow (2014 Teklad Global 14% protein®) and water. Animals were raised in the standard environment with no outside manipulation except for standard care and to monitor estrous cycle stage (when applicable). The mice were maintained on a 12-hour light/dark cycle in a temperature controlled (21 degrees) facility. All animal use procedures have been approved by the Carleton University Committee for Animal Care, according to the guidelines set by the Canadian Council for the Use and Care of Animals in Research. Mice were overdosed and perfused for immunohistochemistry or rapidly decapitated for TRAPseq processing each on postnatal day 1* (P1) (36 hours postnatal), P4, P7, P14, P35 and adulthood (defined as 7-9 weeks of age) at the same time of day. Developmental time points and subject numbers are summarized in Supplementary Figure 1.

Organizational hormones study- 5 pregnant dams were ordered from Charles River and arrived at the Carleton University animal facility at the University of Ottawa at gestational day 15/16 and given 3 days to acclimatize to the environment. Dams were monitored intermittently overnight starting on gestational day 19 using red light. 31 male and female pups were randomly assigned to control or treatment groups approximately 1 hour following birth and sacrificed 35 hours later. The majority of groups in all experiments were formed with subjects from 3-5 separate litters to control for litter effects.

Estrous Cycle Monitoring

All adult group female animals were monitored daily after P35 to identify stage of estrous cycle using a saline lubricated swab inserted into the opening of the vagina to collect cells from the vaginal wall. Samples were smeared on a glass microscope slide

and examined under a 10x objective using a light microscope (VistaVision^{TM}). To understand basal organizational sex differences in astroglia, we used female mice in the phase of the estrous cycle with the lowest circulating ovarian hormones that has the least effect on cortical astroglial morphology and protein expression: metestrus[57]. After the stage of estrous cycle (Metestrus, Diestrus, Proestrus and Estrus) had been established for at least two full cycles, females were sacrificed during the light cycle of the metestrus stage.

Organizational hormones-injections

Estradiol benzoate (Chem Cruze, sc-205314) was dissolved in peanut oil (0.8g/mL) as per Hisasue et al., 2010 to allow for an injection of 20µg in a 25µL injection volume. Letrozole (Sigma-Aldrich, LG545-10MG) was dissolved in 0.3% hydroxypropyl cellulose PBS (Aldrich, 435007-5G) as per[58], to allow for an injection of 250mg/kg in a 25µL injection volume, sufficient to block all testosterone conversion based on average pup weight of 5g. Estradiol benzoate and letrozole solutions were prepared using glass materials and stored in a glass amber bottle to prevent absorption and disruption from plastics or ultraviolet exposure.

Animal Sacrifice

Rapid Decapitation for immunohistochemistry and qPCR- Animals in the P1 immunohistochemical group were rapidly decapitated and brains immediately placed in a 4% paraformaldehyde (Fisher Scientific) (PFA) solution at 4 ºC for 24h after which the brains were switched to 30% sucrose at 4 ºC for 24h. Following this period, brains were flash frozen until slicing. For the organizational hormone experiment, pups underwent rapid decapitation 36h following treatment. Brains were harvested and split along the central fissure. One hemisphere was flash frozen at -80°C for analysis in qPCR and the other hemisphere was fixed as above.

Cardiac Perfusion for Immunohistochemical Analysis- All mice were sacrificed for tissue collection at the same time of day during the light cycle. All mice in the immunohistochemical group underwent cardiac perfusion aside from those in group P1 (see above). Animals in P4, P7, P14, P35 and adult groups were given an overdose of 44mg/kg sodium pentobarbital (CDMV Canada), followed by intra-cardiac perfusion upon all spinal reflex cessation. Animals from the P4 and P7 groups underwent manual cardiac perfusion with 1mL of saline solution before receiving 1mL of 4% PFA via syringe. Mice in the P14, P35, and adult groups blood were flushed using 10mL of saline through the left atrium followed by 20mL of 4% PFA to fix the tissue. Brains were extracted and placed into vials containing 4% PFA and stored at 4 ºC. Following a 24h period, brains were transferred to a 30% sucrose in PBS (Fisher Scientific) solution and placed at 4 ºC.

Tissue sectioning

Following sucrose treatment, all brains were then flash frozen at -80 ºC until sectioning on a Leica (Leica™ CM1900) cryostat (30µm thick). 15 sets of sagittal sister sections were adhered to electrostatic slides (Fisher Scientific™) in rotating order, each slide therefore contained a full representation of the brain for stereological analysis as per previous studies[56,59].

Immunohistochemistry

All immunohistochemical processes took place at room temperature (~21 ºC) as per our previous studies[23,56,60]. One representative slide was taken from every subject and all subjects were processed simultaneously. Brain tissue from all groups were

prepared for immunohistochemistry using a 10% horse serum (Gibco™) PBS-T (0.3% TritonX (Fisher Scientific)) pre-block solution for 1 hour before being incubated with the respective primary antibody solution (see Supplementary Figure 1). Primary antibodies were diluted in 10% horse serum PBS-T (0.3% TritonX). Following approximately twenty-four hours of primary antibody incubation, slices were washed in a 1x PBS solution 3 times to remove unbound antibodies before being incubated with the species-appropriate fluorescein conjugated secondary antibody for visualization. Secondary antibodies were diluted in 10% horse serum PBS-T (0.3% TritonX) and incubated for 2 hours before slides were submerged in a 1x PBS wash 3 times to remove unbound antibodies. Slides were then coated with a nuclear stain, DAPI with hard setting mounting medium (VectorLabs), to fix glass cover slips and allowed to set before analysis. See Supplementary Figure 1 for antibodies and dilutions used.

Stereological Analysis

Unbiased estimates of cell numbers were obtained through use of Zeiss AxioImager M2 with ApoTome motorized fluorescent microscope (Carl Zeiss, Thornwood, NY, USA) in conjunction with a motorized stage and a computer running on Windows 7 using the program StereoInvestigator™ (MicroBrightfield, Colchester, VT, USA). Serial sagittal sections of the right hemisphere obtained through cryosectioning at 30µm on 15 sister sections were used for stereological analysis. Contours encompassing the whole right hemisphere neocortex on each section were drawn as boundaries in StereoInvestigator™. Cells were counted for expression of individual and/or co-expressed proteins using the optical fractionator probe at 40x. Sampling grids were optimized for cortical contours to include at minimum 3 sampling sites per contour to allow for a systematic and unbiased method to estimate cell density and cell quantification for right hemisphere of the cortex regardless of cell shape, size, orientation, spatial distribution, or post-mortem brain shrinkage[61]. Sampling boxes are randomly placed by StereoInvestigator™ within the sampling frame measuring 150µm x 150µm x 30µm with 3 of 6 exclusion borders. Total number of cells per count are reported via StereoInvestigator™ output. For analysis of astroglial morphology, StereoInvestigator™ (MBF, Vermont ™) software on a Zeiss Observer with Apotome (Zeiss™) was employed. We identified and distinguished between radial and non-radial

astroglial cells, counting these using unbiased sampling via the StereoInvestigator (MBF, Vermont ™) at 40x. Representative confocal mosaic images used for photomicrographs were taken using ZEN software (Zeiss™) with the Airyscan 800 microscope (Zeiss™).

TRAPseq

Translating ribosome affinity purification (TRAP)-sequencing was performed as per[62]. Briefly, eGFP-positive animals were rapidly decapitated and the brains removed and placed into a 1000x activated cyclohexamide (CHX) (100µg/ml, Sigma, dissolved in methanol, American Bioanalytical) dissection buffer at which point the cortex, removing any remaining white matter was dissected and flash-frozen in CHX dissection buffer at -80°C. When appropriate, brains were thawed on ice in homogenization buffer containing protease inhibitors, 1000x activated CHX, and RNAse inhibitors. Tissue samples were mechanically homogenized and then incubated on a rotisserie with anti-GFP (HtzGFP_04 (clone19F7) and HtzGFP_02 (clone 19C8): Memorial Sloan-Kettering Monoclonal Antibody Facility) coated biotinylated magnetic beads (Streptavidin MyOne T1 Dynabeads; Invitrogen # 65601) coated with Protein L (Fisher # PI-29997) at 4 ºC overnight. Following incubation with magnetic beads, the samples were collected on a magnet (DynaMag-2; Invitrogen #123-21D) and the unbound fragment was collected and frozen at -80 ºC. Bound mRNA fragments washed in polysome buffer underwent RNA extraction with DNAse treatment using Absolutely RNA Nanoprep Kit (Stratagene #400753).

RNA samples were sent to the Yale K.E.C.K facility for sample QC as per Simard et al. 2018: RNA quality was determined using a nanodrop and RNA integrity was determined by running an Agilent Bioanalyzer gel (RINs >8). mRNA was purified from approximately 500ng of total RNA with oligo-dT beads and sheared by incubation at 94C. Following first-strand synthesis with random primers, second strand synthesis was performed with dUTP for generating strand-specific sequencing libraries. The cDNA library was then end-repaired and A-tailed, adapters were ligated and second-strand digestion was performed by Uricil-DNA-Glycosylase. Indexed libraries that met appropriate cut-offs for both were quantified by qRT-PCR using a commercially available kit: Kapa Library Quant Kit (Illumina) (KAPA Biosystems # KK4854-

07960298001) and insert size distribution was determined with the LabChip GX or Agilent Bioanalyzer. Only samples with a yield of ≥0.5 ng/ul were used for sequencing.

Sample concentrations were normalized to 10 nM and loaded onto Illumina Rapid or High-output flow cells at a concentration that yields 130-250 million passing filter clusters per lane. Samples were sequenced using 75bp paired-end sequencing on an Illumina HiSeq 2500 according to Illumina protocols. The 6bp index was read during an additional sequencing read that automatically follows the completion of read 1. Data generated during sequencing runs were simultaneously transferred to the YCGA high-performance computing cluster. A positive control (prepared bacteriophage Phi X library) provided by Illumina is spiked into every lane at a concentration of 0.3% to monitor sequencing quality in real time.

Quantitative Real-Time PCR

To validate the enrichment of astroglial cell genes in our bound, immunoprecipitated fragment, GFAP expression levels were compared between input and TRAP-immunoprecipitated fragments. 20ng of RNA (concentration determined using NanoDrop (Thermofisher Scientific)) was used to produce cDNA using SuperScript IV First Strand Sythesis System (ThermoFisher Scientific). Best-coverage TAQMAN assays (Life Technologies) were run as per manufacturer's instructions and analyzed using the Applied Biosystems 7500 Real-Time PCR system and software.

Statistical Analysis

All immunohistochemical and qPCR data were analyzed for using a 2 (male vs. female) x 6 (P1 vs. P4 vs. P7 vs. P14 vs. P35 vs. Adult) between-subject factorial analyses of variance (ANOVA) design using IBM SPSS Statistics (Version 20.0). Because the treatment differed in males and females, for the organizational hormones study we employed a one-way ANOVA to determine overall significance. Post-hoc analysis using Bonferroni correction of pairwise comparisons for non-orthogonal comparisons were conducted when $p<0.05$. We re-ran all of the statistics including litter composition (male vs. female) as a covariate and found no significant effects of litter on any of the variables measured (data not shown).

RNAseq data analysis. Sequencing reads were mapped to the mouse genome (GRCm38.p5) and the Ensembl (releas-84) transcriptome annotation, using HISAT2

[doi: 10.1038/nprot.2016.095]. The mapping rates ranged from 74% to 95%. This resulted in a number of mapped pairs from ~19.5 million up to 40 million (see Supplementary Table QC for more details). The resulting SAM files were converted to BAM formant using SAMtools[63]. The gene expression levels as counts were estimated using featureCounts[64] with the following options: -t exon; -g gene_id; -F "GTF"; -B; -s 0; -p; -a. Raw read counts were filtered requiring more than 1 CPM (counts per million) in at least 25% of the samples and 16214 survived the filter and were considered for further analysis. Conditional Quantile Normalization (cqn package ver 1.16.0)[65] was used to correct for GC bias normalize counts and also to generate normalized RPKM. We next used the sva Bioconductor package [10.1093/bioinformatics/bts034] to identify and correct for latent variables. Hierarchical clustering (using the genes with a sd in expression level above the 95%) pre- and post sva correction show the sample-to-sample relationship and relative clustering (see Supplemental Figure 2). FastQC v0.10.1 and RNA-SeQC (v1.1.8) were used for QC (see Supplemental Table QC).

Differential expression analysis. Differential expressed genes were then inferred using the edgeR pipeline[66], using the trended dispersion to estimate the biological variance and the GLM capability of the package. Nominal p-values from differential expression analysis were FDR corrected, and an FDR cut-off of 0.05 was used for all the tests.

Functional enrichment analysis. ConsensusPathDB[67] was used to test differentially expressed genes for overrepresentation in Gene Ontologies and Canonical Pathways.

Weighted gene co-expression network analysis. We used Weighted Gene Co-expression Network Analysis (WGCNA)[68] for co-expression network analysis using gene expression estimates (as log2(RPKM+1)), separately, from the 25 male samples and the 26 female samples, after cqn and sva correction. We estimated a male and female the co-expression network and modules using the function blockwiseModule, using the bicorr as correlation estimate, a "signed" network type and a minModuleSize=50. The power cut-off was set to 16 for both sets. The analysis produced a male network of 12 modules and a female network of 14 modules, including the grey module of unassigned genes (See WGCNA Summary Data).

Figure Captions

Figure 1. A- Total number of eGFP+ cells in the neocortex. B- Estimated neocortical volume. C- Percentage of radial-like eGFP+ cells. D- Total number of cells expressing GFAP. E- Total number of vimentin+ cells. F- Percent GFP+ coexpressing Ki67. G- Representative mosaic of confocal pictomicrographs at 10x, whole cortex sagittal section (left), zoom on the molecular layer (right). * indicates a significant difference from all other time points; # indicates a significant difference between male and female at that time point. Bars denote group mean and error bars displayed are ± SEM.

Figure 2. Average expression levels in read counts of astroglial-specific genes as identified in Cahoy et al., 2008. Error bars are displayed as ± SEM.

Figure 3. A- Clustered heat map of individual sample gene expression levels from TRAPseq data. B- Represents a heat map of samples manually sorted by sex and age.

Figure 4. A- DEGs between early and late phenotype in males and females. B- Venn diagram displaying overlap in DEGs between females and males. Overlapping gene lists were generated using GeneVenn supported by the University of Southern Mississippi. C, D- Canonical pathways (CPs) for males (C), above (bordered by blue), and females (D) below (bordered by red) generated with the Consensus Path Database-Mouse version MM10 (01-01-2019) supported by the Max Planck Institute for Molecular Genetics using gene set analysis, over-representation analysis. Pathways generated using “pathways database,” using the top 10 called pathways for male and female DEGs from early versus late phenotypes.

Figure 5. A- Graphical representation of DEGs between males and females at each time point. B- Graphical representation of DEGs between time points. C- Total number of COX2+ cells in the frontal cortex. Bars represent group means. Error bars are displayed as ± SEM. D, top panel- Graphical illustration of arbitrary levels circulating gonadal hormones (testosterone, solid lines; estrogen, broken lines) in males (blue) and females (red) overlay with ages examined in the study. D, lower panel- important cortical neurulation events represented by colour saturation. Darker saturation indicates when a process is more active, lower saturation indicates when a process is less active. (Adapted from: Ellis 2004; Gillies and McArthur, 2010; Anderson, 2003; Estes and McAllistter, 2016)

Figure 6- Heatmap of overlap between male and female network. Colorbar represents -log10 of the Bonferroni corrected p-values (after Fisher test) of module-to-module overlap. Higher values imply lower corrected p-values and stronger overlap. The number in the boxed are the number of gene IDs in common between any two modules.
