1. Introduction

Hypercholesterolemia is a major risk factor for the development of cardiovascular disease (CVD). It was reported that hypercholesterolemia contributed to 45% of heart attacks in Western Europe from 1999-2003. Therefore, it is not surprising that hypercholesterolemia has received particular attention from both societies and scientists. To effectively control the development of hypercholesterolemia, both drugs and dietary supplements were exploited. However, many cholesterol-lowering drugs present important side effects, restricting their long-term administration. For this reason, dietary control or supplementation were preferred as complementary therapies, of which probiotics are the one of the most notable. At present, although many probiotic strains have been demonstrated to exert significantly beneficial effects on lowering LDL and total cholesterol (TC), there is still not enough evidence to confirm their clinical efficiency. For one reason, controversial results have been reported attributing to various external factors, such as strains differences, administration dosage, clinical characteristic of subjects, and duration of treatment period. Moreover, studies examining the efficacy of probiotics in reducing cholesterol often do not sufficiently address the mechanism by which they take effects, and which is extensively explicit when a cholesterol-lowering drug was exploited. A comprehensive comparison of probiotic strains with a well-proved cholesterol-lowering drug would provide new insights into the effective use of probiotic strains in the improvement of hypercholesterolemia.

High-fat diet (HFD) induced alteration of gut microbiota has been demonstrated to play a crucial role in the development of hypercholesterolemia. And with the development of research, increasing evidence has demonstrated that the gut microbiome was associated not only with the pathogenesis of disease, but also with the effects of disease treatment and prevention. Accordingly, targeting the gut microbiota using dietary interventions, prebiotics and probiotics have been shown to prevent or alleviate the metabolic diseases in the past few years. Furthermore, many drugs were investigated for their effects on gut microbiota in recent years. Among these, atorvastatin (ATO) is a well proved and commonly prescribed cholesterol-lowering drug. It is an inhibitor of 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase. This enzyme catalyzes the conversion of HMG-CoA to mevalonate, an early and rate-limiting step in cholesterol biosynthesis. Especially, ATO has been recently reported to reverse the alteration of some specific dominant taxa induced by HFD in rats. In this study we compared the hypocholesterolemia effects of 4 cholesterol-degrading probiotics: Pedicoccus acidilactici JQI-5 (JQI-5), Pedicoccus pentosaceus JQI-7(JQI-7), Lactobacillus plantarum LLY-606 (LLY-606) and Lactobacillus plantarum PC-26, with ATO, and investigated the mechanisms by which they exerted hypocholesterolemic effects, focusing on their impact on gut microbiota.

2. Materials and Methods

2.1 Bacterial strains

Pedicoccus acidilactici JQI-5 (JQI-5) and Pedicoccus pentosaceus JQI-7(JQI-7) were isolated from Traditional yoghurt from Inner Mongolia; Lactobacillus plantarum LLY-606 (LLY-606) and Lactobacillus plantarum PC-26 was isolated from Human Intestinal Tract. They were all stored at China General Microbiological Culture Collection Center with a preservation number of CGMCC No. 10512 for JQI-5, CGMCC No. 10511 for JQI-7, CGMCC No. 13984 for LLY-606 and CGMCC No. 12810 for pc-26 respectively. The strains of JQI-5, JQI-7, LLY-606 and pc-26 are respectively cultivated in Man-Rogosa-Sharpe (MRS) broth at 37°C for 24h. After the incubation, the LABs pellet was collected by centrifugation at 12000 g and 4°C for 15 min, and washed twice with cold sterile water. The LABs pellet was finally lyophilized and stored at -80°C for further experiment. The lyophilized LABs were dissolved in distilled water to a concentration of 10⁶ CFU/mL before use.

2.2 Animals and Experiment Design
All interventions and animal care procedures were carried in accordance with the Guidelines and Policies for Animal Surgery of the Institute of Medical Plant Development, Chinese Academy of Medical Sciences & Peking Union Medical College (Beijing, China) and approved by the institutional Animal Use and Care Committee. Seventy specific pathogen-free male golden hamsters aged 6-8 weeks old and weighing 120 ± 20 g were purchased from the Vital River Laboratory Technology Co., Ltd. (Beijing, China), and were housed in stainless steel cages in a temperature-controlled room (22-25°C, 50% to 70% relative humidity) with a 12 h light/dark cycle (light on 7:00 AM), and distilled deionized water was provided continuously. After acclimatization for 1 week, ten hamsters were selected randomly as the normal control diet group (NCD, n = 10) and fed with a normal diet throughout the whole experimental period. Others were fed with a high-fat diet for 2 weeks to generate hypercholesterolemic model. The high-fat diet contained 15% (w/w) lard oil and 0.2% cholesterol and 84.8% normal diet (Beijing HuaFuKang Biotechnology Co., Ltd., Beijing, China).

After the hypercholesterolemic model was successfully established (0th week of probiotic intervention), sixty hyperlipidemic hamsters were randomly divided into the following six groups (n = 10/group): (1) HFD: hamsters on high-fat diet; (2) ATO: hamsters on high-fat diet plus atorvastatin (Pfizer Ltd., Dalian, China); (3) JQI-5: hamsters on high-fat diet plus *Pediococcus acidilactici* JQI-5; (4) JQI-7: hamsters on high-fat diet plus *Pediococcus pentosaceus* JQI-7; (5) LLY-606: hamsters on high-fat diet plus *Lactobacillus plantarum* LLY-606; (6) pc-26: hamsters on high-fat diet plus *Lactobacillus plantarum* pc-26. The atorvastatin was diluted by water at 1 mg/mL using a magnetic stir and was orally administered to ATO group with a dose of 3 mg/kg/day. All probiotic strains were administrated at a dose of 10^8 cfu daily, the NCD and HFD group received the same volume of distilled water by oral administration once a day for eight weeks. The dose of administration of ATO and strains were determined by referring to previous studies and was verified by preliminary experiments.  

### 2.3 Preparation of Blood Samples

Blood samples were obtained from the retro-orbital sinus into prechilled tubes on 0th, 4th and 8th week of probiotic intervention. The serum was separated by centrifugation at 3000 g 4°C for 10 min and stored at -80°C for future analyses.

### 2.4 Analysis of Serum Lipids

Concentrations of serum lipids including TC, triglycerides (TG), HDL-C and LDL-C were determined on 0th, 4th and 8th week using assay kits (BioSino Bio-Technology & Science Inc., Beijing, China) and the AU480 Chemistry analyzer (Beckman Coulter Inc., California, USA).

### 2.5 Inflammation Cytokine Quantification in Serum

Serum concentrations of tumor necrosis factor-α (TNF-α) and interleukin1β (IL-1β) were measured on 8th week using Valukine™ immunoassay kits (R&D Systems, Inc., Minneapolis, USA) according to the manufacturer's instructions using microplate reader (Synergy 2, BioTek, USA). Serum C-reactive protein (CRP) level was determined using radioimmunoassay kit (YingHua Biotechnology Research Institute, Beijing, China) using Radioimmunocounter (XH-6020, Xian Nuclear instrument Ltd., China) on 8th week.

### 2.6 Measurement of Glycemic Metabolism Indices

Serum insulin (INS) concentration was measured using radioimmunoassay kits (YingHua Biotechnology Research Institute, Beijing, China) using Radioimmunocounter (XH-6020, Xian Nuclear instrument Ltd., China) on 8th week. The quantitative determination of glycated hemoglobin A1c (HbA1c) was done according to the procedures in a commercial kit (Nanjing Jiancheng Biotechnology Institute, JiangSu, China) using microplate reader (Synergy 2, BioTek, USA).

### 2.7 Gut Microbiota Analysis

Fresh fecal samples were collected from each group on 8th week and stored at -80°C for DNA extraction. Microbial genome DNA from the fecal samples was extracted using QIAamp DNA stool mini kit (Qiagen Inc, Hilden, Germany) according to the manufacturer's recommendation. The V4 hypervariable region of the 16S rDNA was PCR amplified from the microbial genome DNA which were harvested from fecal samples using universal primer (forward primers: 5'-AYTGGGYDTAAAGNG-3', reverse primers: 5'-TACNVGGGTATCTAATCC-3'). The PCR condition were 94°C for 5 min, followed by 30 cycles of 94°C for 30 s, 58°C for 30 s (annealing) and 72°C for 30 s (extension), and then 72°C for 5 min.
The PCR products were excised from a 1.5% agarose gel and purified by AxyPrep Gel Extraction Kit (Axygen, Scientific Inc., Union City, CA, USA). They were then quantified by PicoGreen dsDNA Assay Kit (Life Technologies Inc., Grand Island, NY, USA) and BioTek Microplate Reader (BioTek Inc., Winooski, VT, USA). Barcoded V4 amplicon was sequenced using the paired-end method by Illumina MiSeq at BGI TechSolutions Co., Ltd (Wuhan, China). Sequences reads with an average quality score lower than 20, ambiguous bases, homopolymer > 7 bases, containing primer mismatches, or reads length shorter than 100 bp were removed. For V4 paired read, only sequences that overlapped longer than 10 bp and without any mismatches were assembled (Tian, Ma et al. 2013). Reads which could not be assembled were removed. Sequences analysis were performed by Uparse (v7.0.1090) and sequences with ≥97% similarity were assigned to the same operational taxonomic units (OTUs). For each representative sequence for each OUT, the GreenGene Database was used based on RDP classifier (v2.2) to annotate taxonomic information. The differences of the dominant species in different groups and multiple sequence alignment were conducted using the MUSLE software to study phylogenetic relationship of different OTUs. Alpha diversity and beta diversity were calculated by QIIME software (v1.80) to evaluate species diversity. Sequence data of this study is available in China Nucleotide Sequence Archive under project No. CNP0000290.

2.8 Determination of SCFAs in Feces

SCFAs were measured according to the method of Wang et al with modifications. 19 0.3g of stool sample were homogenized with a Mini Bead-heater-16 (BioSpec Products, Inc, Bartlesville, OK, USA) in 1mL distilled water. Samples were centrifuged at 12000g for 10min. 800ul supernatant was collected. Then precipitation was rehomogenized in 800UL distilled water and was centrifuged at 12000g for 10min. 700ul supernatant was collected at this time. All together 1500ul supernatant were collected, and these were pooled for SCFA analysis. SCFA levels were measured by high performance liquid chromatograph (LC-2030, Shimadzu Corporation, Japan). Supernatants (20uL) were separated isocratically at a flow rate of 1mL/min at 65 °C on a 250- by 4.6-mm YMC-Pack Pro C18 column (HanKing Instrument & Equipment, Shanghai, China), using 0.025% phosphoric acid and 5% acetonitrile as the mobile phase. The identification and quantification were performed at 210nm. Standard solutions of lactic, acetic and propionate were run separately for identification and quantification of each compound.

2.9 Statistical Analysis

The biodiversity and richness of OUTs were calculated using QIME 1.9 implemented with nonparametric Chao1 and rarefaction analysis. Data was normalized to an equal number of reads per sample, and PCA was performed from the sequences at OUT level with >97% similarity using unsupervised multivariate statistical method. Nonparametric factorial Kruskal-Wallis rank sum test was used were performed to identify significantly different bacterial taxa among different groups. Differences in body weight, cholesterol levels, inflammatory levels and short fatty acid levels were analyzed statistically using IBM SPSS Statistics 22.0 software. The data values are presented as the Mean ± SD. One-way analysis of variance (ANOVA) with Duncan’s test was used to measure the significance of the main effects (p < 0.05) in the variable between groups. Correlations level were calculated using IBM SPSS Statistics 22.0 software.

3. Results
3.1 Effects of probiotics and ATO on gain of body weight induced by HFD

Prior to administration ATO or probiotics, 2 weeks of HFD feeding had induced significant increase in the body weight compared with normal chow diet (NCD) group (Figure 1). After 3 weeks co-administration of ATO, the increase of body weight observed in HFD-ATO group had been prevented. In fact, animals in this group displayed no significant difference in body weight from those in NCD group. However, it was not until the 4th week, the increase in body weight of groups HFD+JQII-5, HFD+JIQ-7, HFD+LLY-606, and HFD+PC-26 started to be attenuated. Even so, the body weight of animals in all these probiotic groups was still significantly higher than that in both HFD+ATO and NCD groups until the 8th week.

3.2 Hypocholesterolemic effects of ATO and probiotic strains

The concentration of serum TC, TG, HDL-C and LDL-C in all groups were assayed at 0th, 4th and 8th week of co-administration. HFD feeding induced significant higher TG, TC and LDL-C compared with NCD (p < 0.05), which indicated that 4 weeks of co-administration of ATO significantly decreased TC, TG and LDL level compared with HFD, and these effects were maintained until the 8th week. However, all the probiotic co-administration groups did not significantly decreased TC or LDL-C level after 4 weeks intervention (Figure 2B and Figure 2C). Nonetheless, 4 weeks of co-administration of probiotic prevented the increase of TG level observed in HFD groups, although it was still significantly higher than in HFD+ATO and NCD groups (Figure 2A).

At the 8th week, the TC level of all probiotic groups started to be significantly lower than the HFD group and to show no difference from the HFD+ATO group. The TG level of all probiotic groups was also decreased to be significantly lower than HFD, but it was still higher than the HFD+ATO (Figure 2A). The effects on the LDL-C was divergent among the probiotic groups at the 8th week of co-administration. Although co-administration of JQII-5, JIQ-7 or LLY-606 decreased the concentration of LDL-C to level comparable to HFD+ATO, it was still higher in HFD+PC-26 than in HFD+ATO (Figure 2C).

These results showed that compared with ATO, probiotic strains used in this study showed mild effectiveness on hypercholesterolemia. Further, the strains of JQII-5, JIQ-7 and LLY-606 were
more significant than PC-26 in the improvement of hypercholesterolemia, especially on reducing the concentration of LDL-C.

3.3 Effects of probiotics and ATO on expression of inflammatory factors

After 8 weeks of co-administration of ATO or probiotics, the expression of inflammatory cytokines was assayed. Just as expected, high-fat diet feeding was accompanied with increased TNF-α ($p < 0.05$), IL-1β ($p < 0.05$) and CRP ($p < 0.05$) (Figure 3). Co-administration of ATO significantly decreased the TNF-α, IL-1β and CRP. In all the four probiotic groups, IL-1β was decreased to the level which was significantly lower than that in HFD group, but higher than in FHD+ATO group.
(Figure 3A). At the same time, co-administration of JQII-5, PC-26 also induced a significantly lower expression of TNF-α (p < 0.05) compared with HFD, but co-administration of JIQ-7 and LYY-606 did not decrease TNF-α (Figure 3B). The CRP concentration of the HFD+JQII-5 and HFD+JQI-7 groups was significantly lower (p < 0.05) than HFD and it was comparable to that in group HFD+ATO (Figure 3C).

The probiotic strains in this study were proved to be able to reduce the expression inflammatory factors induced by high-fat diet, although their effects were not as remarkable as ATO and were divergent among themselves, with JQII-5 and JQI-7 more potential than LLY-606 and PC-26.

3.4 Effect on probiotics and ATO on Glycometabolism

![Figure 4](https://doi.org/10.1101/712083)

Figure 4 Effects of ATO and probiotics on the glycometabolism of golden hamsters. A: HbA1c; B: INS; * * means significant difference from HFD group; ** means different difference from ATO Group (p < 0.05, n = 10).

Compared with NCD group, feeding high-fat diet significantly increased (p < 0.05) INS and HbAc1 concentration, and administration of ATO successfully decreased both INS and HbAc1 (Figure 4). Administration of JQII-5 significantly decreased the INS and HbAc1 to levels comparable to ATO (Figure 4A and Figure 4B). HFD+JQI-7 group also showed significantly lower concentration of HbAc1 and INS compared with HFD group, but not as low as HFD+ATO group. LLY-606 and pc-26 significantly decreased HbAc1 compared with HFD, but not to the level comparable with ATO.

As for the glycometabolism index, the effects of different probiotic strains exhibited more distinct divergence, with JQII-5 more effective than JIQ-7, LLY-606 and PC-26.

3.5 Effect of Probiotics and ATO on Gut Microbiota

3.5.1 Richness and Diversity Indices

After spliced and optimized, 70 samples were delineated into 1358 OTUs at the 97% similarity level with distance-based OTU and richness. The richness and diversity indices of gut microbiota in different groups were listed in Table 1. ATO co-administration did not influence the diversity. The observed species and Chao indices of the HFD+PC-26 group were significantly lower (p < 0.05) than the HFD+JQI-7 and HFD+LYY-606 group and showed no difference from the HFD+JQII-5 group. The ACE and Shannon indices showed no difference among the four single-strain groups. At the same time, the Simpson index of the HFD+JQI-5 and HFD+LYY-606 group was significantly lower (p < 0.05) than the HFD+JQI-7 group and showed no difference from the HFD+PC-26 group.

| Table 1: The OTU richness and diversity indices of different groups. |
|---|---|---|---|---|---|
| Observed species index | Chao index | Ace index | Shannon index | Simpson index |
| NCD | 662.60 ± 18.53<sup>abc</sup> | 761.11 ± 19.46<sup>abc</sup> | 751.04 ± 14.22<sup>abc</sup> | 4.51 ± 0.026 ± 0.09<sup>b</sup> | 0.003<sup>a</sup> |

![Figure 5](https://doi.org/10.1101/712083)
3.5.2 Overall structural change of gut microbiota in response of ATO or probiotics

![Figure 5](https://example.com/figure5.png)

The overall structural changes of the gut microbiota were analyzed using unsupervised multivariate statistical method of PCA. PCA scores plot showed that the gut microbiota of the HFD group present a structural shift from the NCD group (Figure 5). As the figure 5 showed, the communities of all the probiotic groups present a structural shift from the ATO group, and the communities among JQI-7, LLY-606 and PC-26 showed more similarity than they did with JQII-5 group.

HFD significantly increased the relative abundance of the Bacteroidetes ($p<0.01$) (table 2). What is the not expected is that JQII-5 did not change the structure at the phylum level. Except to JQII-5, all the other probiotic and ATO co-administration reversed the shifts in Bacteroidetes and Firmicutes.

3.6 Key phyotypes of gut microbiota modulated by ATO or probiotics
To identify key phyotypes of the gut microbiota responding to HFD, and to compared the key phyotypes response to ATO, JQII-5, JQI-7, LLY-606 and PC-26, nonparametric factorial Kruskal-Wallis rank sum test was used. Linear discriminant analysis scores higher than 2 was considered a higher abundance in the corresponding group than the other group. The relative abundance of significantly different species was showed by linear discriminant analysis scores effect size (LEfSe) taxonomy cladogram (supplementary S1-S5).

First of all, the NCD and FHD groups were compared to find the HFD induced changes in gut microbiota. At the genus level, HFD showed significant selective suppression of Allobaculum, Ruminococcus, Lactobacillus and Prevotella. Nevertheless, it selectively enriched the Bacteroides, CF231, Echerichia, Altispes, Butyrimonas and Enterococcus (Figure 6).

![Figure 6](https://example.com/figure6.png)  
Figure 6 The significantly different species using the nonparametric factorial Kruskal-Wallis rank sum test at a significance level of 0.05. A: LDA score, an LDA score higher than 2 indicated a higher relative abundance in the corresponding group than in the other group; B: LEfSe taxonomy cladogram; different colors suggested enrichment or certain taxa in HFD and NCD groups.

Furthermore, the FHD vs HFD+ATO, and FHD vs HFD+JQII-5, HFD+JQI-7, HFD+LLY-606 or HFD+PC-26 groups were compared to analyze effects of the co-administration of ATO or probiotic strains on the HFD disturbed gut microbiota. The most obviously common reversal by ATO and all probiotic groups, was on the uncharacterized genus CF231 (Figure 7A). This genus was induced by HFD, from less than 0.0001% in NCD to 10.3% in HFD, and it was suppressed by co-administration of ATO or any of the tested probiotic strains. Another common reversed genus in all groups was Bacteroides (Figure 7B). These common reversions on HFD induced dysbiosis of the gut microbiota indicated common effects of ATO and tested probiotics strains.

However, there are specificity in both HFD+ATO and HFD+probiotics groups. The most obvious difference between ATO and probiotic strains is determined by Ruminococcus and Allobaculum. Ruminococcus was reversed by ATO but not by any of the probiotics (Figure 7D), but Allobaculum (Figure 7C) was reversed by all probiotic strains but not by ATO. Furthermore, Allobaculum was
also one of the most dramatically changed genus, which is 7.57% in HFD, 20.79% in JQI-7, 13.85% in JQII-5, 18.29% in LLY-606 and 22.07% in PC-26. In addition to commonly reversed genus, the specific altered genus by individual probiotic strains was analyzed. As shown in Figure 7E, the HFD suppressed *Prevotella* was reversed by JQII-5, but not by any other probiotic strains. And *Bifidobacterium* was enriched only by co-administration of JQI-7 (Figure 7F).

3.7 Effect of Different Probiotics on Lactic Acid and SCFAs in feces

We determined the fecal concentration of SCFAs, including acetic acid, propionic acid, butyric acid and lactate. The results indicated that HFD significantly decreased the fecal concentration of all tested acids. ATO co-administration reversed the decreased acetate and propionate, but not lactate and butyrate (Figure 8). All probiotic strains elevated acetic acid propionate and lactate, but the elevated butyrate was only seen in JIQ-7 and JQII-5.
3.8 Correlation of key phylotypes and blood indicates

To demonstrated whether the key communities of gut microbiota were correlated to hypercholesterolemia, we performed an association analysis by pooling all groups together. In this part we mainly focused on phylotypes that were alerted by HFD and especially those that were reversed by ATO or probiotic strain.

As shown in Figure 9, genus enriched by HFD, such as CF231, *Bacteroides*, *Aitipes* and *Butricimonas* showed positive correlation with IL-1β and INS. The CF231 also showed significant positive correlation to TC (p<0.01) and TG (p<0.01). *Allobaculum*, which was reversed by all probiotic strains but not by ATO, showed negative correlation to TNF-α (p<0.05) and IL-1β (p<0.01). However, what is unexpected is that the ATO altered *Rumoccoccus* showed no significant correlations to any tested factors. Another interesting observation was that, JQI-5 uniquely reversed genus *Prevotella* showed significant negative correlation to CRP (p<0.01), INS (p<0.01) and HbA1c (p<0.01), showing a reflection of the effectiveness of JQI-5 on hypercholesterolemia observed above (Figure 2).

3.9 Correlation among key phylotypes

Then the correlations among the key phylotypes were analyzed. *Alloccum*, which was reversed by all probiotic strains but not by ATO, showed significantly negative correlation to almost all HFD induced genus, including CF231 (p<0.01), *Bacteroides* (p<0.01), and *Butricimonas* (p<0.01), *Enterococcus* (p<0.05) and *Escherichia* (p<0.05) (Figure 10). And it also seemed that all the
HFD induced genus showed positive correlation to each other. These results indicated an indubitable role of *Aliclobacum* in the improvement of disturbed gut microbiota by HFD. Besides, *Aliclobacum* was also the sole correlated genus to *Bifidobacterium* (p<0.05). However, *Ruminooccus*, which was reversed by ATO but not by any of the probiotic strains, was not correlated to any HFD altered genus.

### 4. Discussion

In this study, we found that compared with ATO, all tested probiotic strains showed mild effectiveness on both body weight and hypercholesterolemia of high-fat diet fed golden hamsters. However, after 8 weeks of administration, JQII-5, JIQ-7 and LLY-606 restored the HFD induced TC and LDL to a level comparable with ATO. ATO is a fully proofed and commonly prescribed cholesterol-lowering drug. The comparable effects of these 3 probiotic strains with ATO indicated full potential as a dietary supplementation for hypercholesterolemia. In fact, the effects of probiotic strains on hypercholesterolemia has been observed in many studies. Yet, there is no doubt that vast of further researches are needed and there is still a long way to go.

To provide more solid evidence for their effectiveness on hypercholesterolemia, some factors related to dyslipidemia that are risky to health were also evaluated in this study. Inflammatory is a related state of hypercholesterolemia. TNF-α and IL-1β are well-known markers of inflammation and they have been reported to be elevated in hypercholesterolemic state. Some probiotic strains have been reported to reduce the expression of inflammation cytokines. In the present study, the effectiveness of the tested strains on TNF-α and IL-1β were significant but not as effective as ATO. However, a comparable effect with ATO on CPR was achieved by co-administration of JQII-5 or JQI-7. CPR is a well-known marker of inflammation and it was a dyslipidemia induced risk factor for atherosclerosis, being used as a clinical parameter. The effectiveness on CPR means further potential on improving syndrome induced by hypercholesterolemia.

Hypercholesterolemia is often accompanied by hyperglycaemia, which is also proved in this study by elevated INS and HbA1c in HFD group (Figure 4). And surprisingly, different from the mild effect on dyslipidemia, JQII-5 showed excellent effects on both INS and HbA1c as well as ATO. Higher levels of HbA1c was induced by long term and continuous dysglycemia, and higher levels of INS was an indicator of metabolic disorder in both lipid and glucose. The improvement of JQII-5 means an early influence on regulation of metabolic disorder induced by high-fat diet.

From the comprehensive comparison of ATO with tested probiotic strains, significant, but retarded and mild effectiveness on both body weight, hypercholesterolemia, and inflammation was achieved by probiotic strain. And distinguishing effects on various index was found among the 4 probiotic strains. To provide some possible explanation for their shared and unique effects, the gut microbiota was analyzed. Just as expected, the microbiota structure after co-administration of ATO is markedly different from that of all probiotics strains groups, and the probiotic strain JQII-5 is different from the other 3 strains, indicating the different effects of ATO from probiotic strains and different effects of JQII-5 from the other 3 probiotic strains.

As more and more studies demonstrated the important influence of key communities in the gut microbiota, we investigated the HFD disturbed and ATO or individual probiotic strain reversed key phylotypes at the level of genus. The most obviously common reversion by ATO and all probiotic groups, was CF231 and *Bacteroides*. CF231 was an uncharacterized genus, but it has been reported to be induced by HFD and suppressed by ATO in a previous study just as shown in the present study. And positive correlation of CF231 with TC, TC, LDL, IL-1β, and INS was found in this study, indicating its deleterious role in gut microbiota. *Bacteroides* was found to be more prevalent in western populations who consume higher animal-based diets compared with non-industrialized populations whose diets contain more dietary fibers. A study including 165 older individuals found that higher levels of *Bacteroides* co-abundance group coincided with increased levels of CPR. These shared reversion on HFD induced CF231 and *Bacteroides* indicated an essential and effective role of ATO and tested probiotics strains. *Ruminooccus* is a genus reversed uniquely by ATO and its reversion by ATO was also reported in a previous study. Lower levels of *Ruminooccus* are associated with higher levels of CRP.
and IL-6. However, another study found that the abundance of *Ruminococcus gnavus* was higher in ACDV patients compared with controls. In the present study, *Ruminococcus* was not found to be significantly correlated to any texted index (Figure 9), nor to almost any other genus (Figure 10). Whether the abundance changing of *Ruminococcus* is just a passive effect by ATO, and whether the ATO reversion of *Ruminococcus* would favor gut microbiota to benefit the hypercholesterolemia was still dubious.

One of the most amazing finding in this study is *Allobacum*, which is reversed by all tested probiotic strains and this effect was not shared by ATO. In a previous study, the relative abundance of *Allobacum* was increased by administration of bitter melon powder or by berberine, and the alteration of gut microbiota resulted in improvement of metabolic status in high fat diet-induced obese rats. In fact, high relative abundance of *Allobacum* was reported to be correlated to high H2 concentration in the gut and the portal. And H2 derived from fermentation of saccharides by gut microbiota was reported to suppress hepatic oxidative stress and adipose inflammatory in rats. As oxidative stress was assumed to be an important mechanism initiating inflammatory in obesity and hypercholesterolemia, the probiotic reversing *Allobacum* may improve the oxidative state of body and/or liver, which then help improve the inflammatory state of the body demonstrated in this study. Corresponding to this, a probiotic strain was reported to protect liver injury in rats via anti-oxidative and anti-inflammatory capacity. Besides, different from the ATO induced *Ruminococcus*, *Allobacum* seemed to have significant negative correlation to most of the HFD induced genus, and positive correlation to *Bifidobacterium*. This genus commonly promoted by probiotics showed full chance to favor its host, and its favor is very probably done via favoring the gut microbiota.

In addition to the commonly promoted genus by all probiotic strains, JQI-5 also promoted *Prevotella*. *Prevotella* is associated with plant-rich diets, and its suppression in this study was also supposed to be resulted from the high-fat and relatively low carbohydrates in HFD. Individuals with obesity have a lower abundance of *Prevotella* species in their gut. Increased abundance of certain *Prevotella* species was reported to be associated with low-grade inflammation in systemic diseases, such as rheumatoid arthritis. *Prevotella copri* was found to improve glucose metabolism and insulin sensitivity by a mechanism associated with fermentation of carbohydrates. Consistent with these previous studies, co-administration of JQI-5 was found to be correlated with both inflammatory and glucose metabolism in the present studies (Figure 3 and Figure 4).

5. Conclusions

A comprehensive comparison of the ATO and 4 probiotic strains on high-fat induced hypercholesterolemia was done this study. Compared with ATO, probiotic strains were less effective on body weight, hypercholesterolemia, and inflammation. However, probiotics exert additional favorable effects on gut microbiota, making them excellent complements to cholesterol-lowering drugs like ATO. And these favorable effects were probably made by promoting key phenotypes, such as *Allobaculum* in gut microbiota, which may alleviate oxidative stress. However, the interaction between probiotic strains and targeted genus in gut microbiota is waiting to be confirmed in future study.
