Abstract

CAPRI Rounds 37 through 45 introduced larger complexes, new macromolecules, and multi-stage assemblies. For these rounds, we used and expanded docking methods in Rosetta to model 23 target complexes. We successfully predicted 14 target complexes and recognized and refined near-native models generated by other groups for two further targets. Notably, for targets T110 and T136, we achieved the closest prediction of any CAPRI participant. We created several innovative approaches during these rounds. Since Round 39 (target 122), we have used the new RosettaDock 4.0, which has a revamped coarse-grained energy function and the ability to perform conformer selection during docking with hundreds of pre-generated protein backbones. Ten of the complexes had some degree of symmetry in their interactions, so we tested Rosetta SymDock, realized its shortcomings, and developed the next-generation symmetric docking protocol, SymDock2, which includes docking of multiple backbones and induced-fit refinement. Since the last CAPRI assessment, we also developed methods for modeling and designing carbohydrates in Rosetta, and we used them to successfully model oligosaccharide–protein complexes in Round 41. While the results were broadly encouraging, they also highlighted the pressing need to invest in (1) flexible docking algorithms with the ability to model loop and linker motions and in (2) new sampling and scoring methods for oligosaccharide–protein interactions.

1 Introduction

2

3   With the explosion in genomic data availability and the ever-increasing accuracy of *in silico*
4   protein folding methods, the ability to computationally model protein assemblies has taken
5   center-stage. Protein-docking methods provide a rapid way to model assemblies, and hence,
6   their progress has been a key focus of computational biophysics. Over the years, various
7   approaches have been developed, each with a different scope and ability to integrate
8   experimental data. Since 2001, a community-wide blind experiment, Critical Assessment of
9   PRediction of Interactions (CAPRI), has been used to assess the state-of-the-art in computational
10 macromolecular docking.[1] Participating groups predict the structure of a complex given the
11 sequences of the constituent proteins, stoichiometry of association, and, in case of homomeric
12 complexes, the point symmetry. Based on their resemblance to the unpublished, experimentally
13 determined structure, the accuracy of the predictions is ranked. With every new round, the
14 organizers add to the complexity of the modeling challenge by introducing more intricate
15 complexes and non-protein macromolecules.

16

17 Our group has continuously evaluated our docking algorithm, RosettaDock[2] in CAPRI, leading to
18 advances such as docking antibodies with loop flexibility,[3] varying protonation states while
19 docking,[4] and interspersing conformational selection with docking.[5] Previous rounds of CAPRI
20 necessitated the creation of protocols for flexible protein assembly and oligosaccharide–protein
21 docking.[6,7] During this latest period with rounds 37 through 45, we developed RosettaDock 4.0
22 to model flexible proteins[8] and refined GlycanDock to predict oligosaccharide–protein
23 interactions.[9] Round 37 was a joint experiment between CAPRI and the Critical Assessment of
24 Structure Prediction (CASP) in which preliminary monomer models submitted by CASP12
25 participants were provided to the CAPRI participants for docking.[10] This round comprised nine
26 symmetric homomers. Based on our performance on these homomers, we developed a new
27 symmetric docking algorithm called Rosetta SymDock2.[11] Rounds 39 and 42 required global
28 docking while predicting the conformation of long, flexible loops. These targets gave us an
29 opportunity to add functionality to dock single-chain camelid antibodies in our antibody docking
30 protocol, SnugDock.[3]

31

32 In this article, we examine the challenge of modeling with the available information, discuss the
33 methodology we used, compare our CAPRI submissions to models made using new techniques,
34 and suggest improvements to improve modeling accuracy.

35

1 Methods and Results

3 We predicted the structures of 23 complexes in CAPRI rounds 37 through 45. We achieved 1 high-
4 quality, 6 medium-quality and 7 acceptable predictions. Table 1 summarizes successfully
5 modeled targets and Table 2 summarizes our failed attempts.

Homomer docking successes

Targets 110–112: Viral fiber head domains

12 The first three targets of round 37 were homo-trimeric fiber head domains from different viruses.
13 Target 110 (T110) was the fiber head domain of raptor adenovirus 1, T111 was that of lizard
14 adenovirus 2, and T112 was that of goose adenovirus 4, and the task was to predict the trimer
15 quaternary structure.

17 Before we docked the models, the organizers provided us with the initial monomer models
18 submitted by CASP12 participants. First, we relaxed all the models using Rosetta FastRelax,[12]
19 clustered those with similar backbone conformations, and chose between one and four
20 monomer backbones for docking. For T110, all homologous proteins had less than 40% sequence
21 coverage and identity. Importantly, all these distant homologs lacked a beta-hairpin predicted by
22 CASP monomer models (residues 358 to 373) present in T110. T111 had a homolog with 94%
23 sequence coverage and 50% identity, which strongly suggested that the native structure would
24 resemble snake adenovirus 1 fiber head (PDB ID: 4D0V)[13]. For T112, the avian adenovirus CELO
25 fiber head (2IUM)[14] came the closest with 59% coverage and 27% identity. For T110, due to the
26 aforementioned beta-hairpin, we performed symmetric global docking simulations with different
27 monomer conformations, with and without the beta-hairpin, using Rosetta SymDock.[15] For initial
28 subunit placement for T111 and T112, we used subunit arrangements derived from their
29 respective homologs and refined the complexes using fixed-backbone refinement of SymDock.
30 Between 10,000 and 50,000 models per monomer were generated for all three targets.

32 For T110, the crystal structure (PDB ID: 5FJL)[16] is shown in in Figure 1A (gray). The native structure
33 did indeed possess a beta-hairpin as predicted, which is highlighted in red. On the superposed
34 complex, the root-mean-square deviation of the C_α atoms ($RMSD_{C\alpha}$) of the predicted beta-hairpin
35 was 1.4 Å from the native. Our best model (yellow) recovered 67% of the native contacts across
36 the subunits and had a root-mean-square deviation of ligand backbone atoms (Lrmsd) of 2.35 Å
37 and a root-mean-square deviation of interface backbone atoms (Irmsd) of 1.73 Å from the native,
38 which were the lowest values among all of the models submitted by all of the groups. The
39 presence of a close homolog made T111 an easy target with multiple groups, including us,
40 predicting high-quality models. The crystal structure of the target is still unreleased, but we
41 assume it to be similar to snake adenovirus 1 fiber head (4D0V). In Figure 1B, our best model is
42 shown in orange superimposed on the gray crystal structure of the homolog. Conversely, the
43 absence of close homologs made T112 difficult to model both in the monomeric state and in the

3

1 trimeric state. No group achieved a medium- or high-quality prediction. The Lrmsd and Irmsd of
2 our best model was 5.8 Å and 2.9 Å, respectively and hence, it was classified as acceptable. The
3 crystal structure of the target is still unreleased and no close homolog is available for a visual
4 comparison.
5
6
7 ## Target 118: Fructose bisphosphatase homo-octamer
8
9 T118 was a refinement challenge involving fructose 1,6-bisphosphatase from *Thermus*
10 *thermophilus*. Although the organism is a hyperthermophile, we were not provided any
11 temperature information about this target. A close homolog structure of fructose 1,6-
12 bisphosphatase from a thermo-acidophilic archaeon, *Sulfolobus tokodaii* with 100% sequence
13 coverage, 46% identity, and the same D4 symmetry (3R1M)[17] was available.
14
15 We extracted symmetry information from the aforementioned homolog, arranged the monomer
16 models and refined the complex using fixed-backbone refinement of SymDock. Figure 1C shows
17 our best model in color and the crystal structure of the homolog in gray. The crystal structure of
18 the target is yet to be released. The model recovered 41% of the native contacts with Lrmsd and
19 Irmsd values of 1.7 Å and 1.0 Å, respectively, and hence, was classified as a medium-quality
20 model.
21
22
23 ## Target 119: Archaeal halo-thermophilic alcohol dehydrogenase
24
25 T119 challenged us with atypical modeling conditions. The homo-dimeric protein, alcohol
26 dehydrogenase, was from a halo-thermophilic archaeon expressed in a halo-mesophilic
27 expression system. The behavior of this enzyme is pH dependent: in the pH range of 9.6–10.2, its
28 oxidative reaction peaks, whereas at pH of 6.4, reduction reaction is dominant.[18] We were asked
29 to predict the structure of the complex at pH 10.
30
31 First, we relaxed and selected monomer models from CASP12 participants. The closest
32 homologous homo-dimer that we found was alcohol dehydrogenase 2 from the bacteria
33 *Zymomonas mobilis* (3OWO)[19]. The two subunits of the homolog had extensive cross-beta sheet
34 interactions along the N-termini. The N-termini interaction served as a hinge, where a small error
35 in the backbone would result in a drastically different rigid-body conformation. Unfortunately,
36 this region of the target protein was predicted to be disordered and was different in all monomer
37 models. As a result, we had to partly truncate the N-terminus. We followed a two-pronged
38 approach to model this target: on the one hand, we explored the homo-dimeric conformational
39 space using the standard SymDock protocol; on the other hand, we sampled different residue
40 protonation states at pH 10 with a variant of RosettaDock called with Rosetta pHDock[4]. We
41 produced 10,000 docking models with each method and chose the most symmetric proteins
42 interacting at the N-terminus for pHDock.
43

1 Figure 1D shows our best model in yellow, the crystal structure in gray, and the N-terminus of
2 the crystal structure in red. Despite missing key interactions at the N-terminus, we were able to
3 predict the rough placement of the subunits correctly, and hence our best model was adjudged
4 acceptable. The model predicted 61% of the native contacts with Lrmsd and Irmsd values of 9.9
5 Å and 3.0 Å, respectively. This large difference of RMSD values arises from the aforementioned
6 hinge motion, where a small change in the N-terminus backbone leads to large changes globally.
7 The best model across all groups was a medium-quality model.
8
9
10 Target 136: Lysine decarboxylase homo-decamer
11
12 T136 was the homo-decameric lysine decarboxylase, LdcA from *Pseudomonas aeruginosa*. Close
13 homologs were available for the complex in the form of lysine decarboxylase, LdcI from *E. coli*
14 (5FKZ) and arginine decarboxylase, AdiA (2VYC) from *Salmonella typhimurium*. The wing domain
15 of the subunits was given to be significantly different to the homologs leading to different inter-
16 subunit contacts. As the subunit arrangement was likely to be similar to its homologs, the
17 challenge of this complex was to model the wing domain correctly within the confines of the D5
18 symmetry. Another issue was the sheer size of the protein: ten subunits each with 750 residues
19 making extensive interfaces with other subunits makes it the largest CAPRI target to date,
20 requiring high-memory workstations for docking.
21
22 We started by modeling the monomer using the online server, Robetta,[20] which produced
23 convergent conformations for the wing domain that were distinct from the homologs. Drawing
24 on symmetry information from the homologs and arranging the subunits accordingly led to steric
25 clashes at the wing domain. All fixed-backbone refinement efforts using SymDock failed to
26 produce a plausible structure free of clashes. Instead, SymDock refinement resulted in an
27 unrealistic inter-subunit distance by expanding the complex to relieve the clashes. We
28 conjectured that the monomers needed to be relaxed in the context of the complex, and not
29 independent of it. We achieved this by superimposing ten copies of each monomer model onto
30 each of the subunits of the homolog, AdiA and then relaxing one of the monomers with the other
31 nine copies present. On doing so and then docking the context-refined monomers, we were able
32 to obtain structures where the wing domain readily fits into the given symmetry without steric
33 clashes. Figure 1E shows our model for LdcA with the wing domains of five subunits highlighted
34 in darker hues against lighter tints of the rest of the subunit. We predict that each wing domain
35 contacts two neighboring wing domains and well as a neighboring chain. Our scoring model
36 (based on our prediction model) was adjudged to be the highest quality for any group (medium
37 quality overall) and recovered 60% of the native contacts with Lrmsd and Irmsd of 2.4 Å and 1.7
38 Å, respectively.
39
40
41

5

1   Post-hoc analysis of the performance of SymDock2 on CAPRI targets

2

3   We noticed a pattern of error whereby when starting from the symmetric arrangement of a
4   homolog, Rosetta SymDock protocol would expand the overall size of the complex to relieve
5   inter-chain clashes. This phenomenon progressively worsened for higher order symmetries.
6   Given the same set of inputs, we tested (post-CAPRI) whether SymDock2[11] improved the quality
7   of the models for three of the complexes where this error was observed, *viz.* T110, T118, and
8   T136.

9

10   For T110, the best model amongst the 10 top-scoring models had the same overall classification
11   as our original submission, medium-quality. However, its inter-subunit distance of 23.7 Å was 2%
12   smaller than the native (5FJL) structure's distance of 24.2 Å. This reversed the trend of the best
13   structure from SymDock, which had a 4% larger inter-subunit distance of 25.0 Å. The cause of
14   this compression is not because the individual monomers are closer to the native; in fact, the
15    $RMSD_{C\alpha}$ of the monomers in SymDock was 1.1 Å compared to 1.2 Å after SymDock2. The tighter
16   fit was achieved by subtle backbone changes during SymDock2's flexible backbone refinement.

17

18   We observed a big improvement for T118, where most of SymDock2's 10 top-scoring models
19   were high-quality (using monomer model superposition to a close homolog, 3R1M, to
20   approximate native). The best structure from SymDock2 recovered 73% of the "native" contacts
21   while having a sub-angstrom Lrmsd. Had we submitted this structure during CAPRI, it would have
22   been the best structure across all groups. Moreover, the inter- subunit distance of the SymDock2
23   model was 40.3 Å compared to 43.3 Å in the SymDock model and 39.0 Å in the homolog. Thus,
24   the SymDock2 model expands by just 3% relative to the homolog and presumably recovers
25   additional inter-chain contacts compared to the SymDock model, which expands by 11%.
26   Supplementary Figure S1A highlights the similarity of the SymDock2 model to the "native" and
27   Figure S1B compares the SymDock and SymDock2 models and the distance between monomers.

28

29   As we could not generate a feasible structure for T136 using SymDock, a direct comparison is not
30   possible. Instead, first, we had relaxed the monomer in context of its partners and then used that
31   monomer with SymDock. The inter-subunit distance for the best-scoring model was 62.2 Å, a 1%
32   increase over the distance of 61.6 Å in a close homolog (2VYC). With SymDock2, we could
33   generate models starting from the initial homology-modeled monomers with the best-scoring
34   model having an inter-subunit distance of 63.1 Å, which was 2% more than the homolog. Thus,
35   with better packing of interfaces due to flexible backbone refinement, SymDock2 resolves the
36   problem of complex expansion in SymDock and thus, significantly outperforms SymDock on
37   CAPRI targets.

38

39

40

1 ## Homomer docking failures
2
3 ### Target 114: Ljungan virus protein
4
5 T114 was the homodimeric-protein 2A2 from Ljungan virus. The function of this protein is
6 unknown. We were provided with monomer models from CASP12 participants. We relaxed the
7 models and chose five top-scoring, distinct models for docking. We found no homologs from
8 which to extract symmetry information, and hence, we performed a global search of C2
9 configuration space to generate 50,000 models for each monomer structure. None of the models
10 submitted by us or any predictor was adjudged to be correct. As the experimental structure of
11 this protein has not been released yet, we could not determine the reason(s) for failure.
12
13
14 ### Target 116: Bifunctional histidine kinase
15
16 T116 was two domains (Dhp and CA) of the homo-dimer, CckA of *Caulobacter crescentus*. We
17 identified several homo-dimeric histidine kinase homologs with 97% or more sequence coverage
18 and 25% or more identity, like those from *E. coli* (4GCZ)[21] and *Geobacillus stearothermophilus*
19 (3D36)[22]. Each homolog had a different relative orientation of the Dhp and CA domain
20 equivalents, indicating that this target could only be successfully docked if the domains were
21 correctly oriented in the monomers.
22
23 Models from CASP12 participants had a variety of different relative orientations of these two
24 domains depending on the homolog template they chose. Using monomers with two different
25 orientations, we generated 25,000 global docked models per orientation. Unfortunately, the
26 relative orientations of the two CckA domains were very different from all available homologs as
27 shown in Supplementary Figure S2B. Without a good monomer conformation, we, as well as all
28 the other predictors, failed to dock the dimer correctly.
29
30
31 ## Heteromer docking successes
32
33 ### Target 120: Group 1 dockerin–cohesin complex
34
35 In anaerobic bacteria, the cellulosome assembly digests plant fibers. The assembly of this
36 complex involves the binding of different enzyme-borne dockerin proteins (Doc) to cohesin
37 modules of the non-enzymatic protein, scaffoldin (Sca). As different groups of dockerins have
38 significantly different cohesin-binding interfaces, they have different binding modes for every
39 cohesin.[23] Moreover, within the same species, each dockerin binds cohesins promiscuously and
40 with different binding modes. Furthermore, single residue changes can affect binding,
41 compounding the challenge of identifying the correct mode.[24] T120 was a hetero-dimer of ScaB3
42 cohesin with Doc1a from *Ruminococcus flavefaciens*.
43

1   We started with homology models from CASP12 participants and relaxed them. Next, we
2   searched for homologous complexes to create an initial placement of the monomers. A complex
3   of group I dockerin and ScaB from *Acetivibrio cellulolyticus* (4UYQ)[25] provided a starting point
4   despite low homology with the individual proteins—the cohesin had 24% sequence coverage
5   with 33% identity and the dockerin had 79% coverage with 37% identity. Starting from an initial
6   structure where the monomers were aligned to the homologous complex, we docked the target.
7   While docking the proteins, we used an ensemble of 10 relaxed monomer models for each
8   partner to explore alternate backbone conformations.
9
10 Figure 2A shows our best model in green (cohesin) and blue (dockerin) against the crystal
11 structure in gray. This model was adjudged to be acceptable; no other group submitted a higher-
12 ranking model. The bulge in the crystal structure of cohesin (highlighted in red) was not present
13 in any of the homology-modeled cohesins. This bulge changed the rigid-body conformation of
14 the dockerin and resulted in the dockerin having an Lrmsd of 4.9 Å.
15
16
17 Target 122: Human IL-23–receptor complex
18
19 For T122, we were asked to model the interaction between IL-23 and its receptor, IL-23R. Several
20 crystal structures of IL-23 were available in the Protein Data Bank.[26] A disulfide bond held
21 together its two subunits, IL-23A and IL-23B and hence, we expected their bound state to remain
22 largely unchanged. We modeled the receptor, IL-23R using Modeller[27] based on multiple
23 sequence alignment of homologs with manual input on the alignment of loop regions. In addition,
24 we also used models from Robetta,[20] which used a different homolog as its template.
25
26 From the variety of models obtained, it was apparent that the receptor might have inter-domain
27 flexibility between its three domains. This flexibility ruled out the possibility of global docking. A
28 literature survey revealed that the binding site observed in other cytokine/cytokine receptor
29 complexes in this family was likely used to bind IL-12Rβ1, which was not the receptor chain we
30 were modeling, and not IL-23R.[28] Based on prior experimental experience on IL-23 interactions,
31 a collaborator (Jamie Spangler) advised us that the interaction was likely between the D1 domain
32 of IL-23R and IL-23 with the conserved Trp-156 on IL-23B serving as the 'lightning rod'. Using this
33 information, we obtained a starting state and locally docked the receptor against the cytokine
34 heterodimer while constraining the conserved tryptophan residue to contact the receptor. This
35 was the first target for which we used RosettaDock 4.0, and as a result we were able to efficiently
36 dock 65 receptor backbone conformations to 56 cytokine backbone conformations.
37
38 Figure 2B shows our best model superimposed on the crystal structure (5MZV, in gray)[29]. The
39 conserved tryptophan of IL-23B is highlighted in red. This model was able to capture the rough
40 binding mode along with the tryptophan lightning rod interaction. With 22% of the native
41 contacts recovered and an Irmsd of 0.7 Å, our model was adjudged acceptable. None of the
42 models of IL-23R (yellow) had $RMSD_{C\alpha}$ under 4.2 Å because of the different orientations of the
43 three domains and as a result the Lrmsd of the model was 16.8 Å. The best model across all the
44 CAPRI groups was a medium-quality model with 40% of the native contacts.

8

1   ## Target 125: NKR-P1–LLT1 hetero-hexamer

2   T125 was the complex between the extracellular domains of natural killer cell surface receptor,
3   NKR-P1 and a cell surface ligand, LLT1. It presented a three-step docking challenge: first, a dimer
4   of NKR-P1 had to be modeled, then the LLT1–NKR-P1 hetero-trimer complex had to be
5   determined, and finally, two of these hetero-trimers had to be docked together to construct the
6   hetero-hexamer.

7

8   For NKR-P1, we generated dimer models by symmetric docking of the monomer models of NKR-
9   P1 obtained from Robetta. We chose seven dimer configurations for further docking. We then
10   modeled the NKR-P1 dimer–LLT1 complex by global docking of the models using ClusPro followed
11   by local refinement in Rosetta. A structure of LLT1 dimer was already available (4QKH); we used
12   this as a reference to assemble the complex model. This step also filtered out trimer
13   configurations that clashed with each other. Finally, we locally refined three candidate
14   complexes, generating 5,000 models each.

15

16   Our best model captured 40% of the native contacts on the LLT1–NKR-P1 with an Irmsd of 0.969
17   Å and Lrmsd of 1.971 Å and was classified as medium-quality. On *post ex facto* analysis, the
18   closest docked conformation had an $RMSD_{C\alpha}$ of 4.7 Å from the crystal structure of NKR-P1
19   homodimer (5MGS). As a result, we, as well as other predictors, could not predict the full
20   hexamer correctly.

21

22

23   ## Target 133: Colicin DNase–immunity protein complex

24

25   T133 was a colicin E2 DNase–Im2 complex designed to change partner specificity from the native
26   complex. The crystal structure of the native colicin E2 DNase–Im2 was available (3U43).[30]
27   However, the organizers informed us that the mutations led to an altered binding mode.
28   Therefore, the challenge of this target was recognizing changes in the binding mode brought
29   about by the mutations. The designed colicin, E^{Des3} had mutations in 17 of the 132 positions while
30   the immunity protein Im^{Des3} had 15 of its 85 positions mutated, most of which were situated in a
31   loop. Three residues, identified as native-sequence hotspots for binding (Y54 and Y55 on Im2 plus
32   F86 on E2),[30] were not changed. After mutating and refining the structures of the mutant
33   proteins, we explored different conformations of the Im^{Des3} loop with the mutations (residues
34   20–35) and closed the loop with kinematic closure.[31] For E^{Des3}, we obtained a variety of backbone
35   conformations using Rosetta Backrub.[32] We then docked an ensemble of E^{Des3} conformations
36   with an ensemble of Im^{Des3} conformations while constraining the three hotspot residues to
37   interact.

38

39   Figure 2C shows our best E^{des3} (green)–Im^{Des3} (blue) model (submitted as our 14th model)
40   superimposed with the crystal structure (gray) of E^{des3}– Im^{Des3} complex (6ERE)[33]. Unfortunately,
41   we predicted larger backbone changes (yellow) than were actually a part of the design (red). The
42   hotspot residues (orange sticks) interact as predicted. This medium-quality model predicts 42%

1 of native contacts with 2.2 Å Irmsd and 4.1 Å Lrmsd. We only submitted acceptable structures in
2 our top ten.
3
4

5 ## Heteromer docking failures
6

7 ### Target 113: Contact-dependent toxin–immunity protein complex

8 In T113, we were asked to model the interaction between the C-terminal domain of the toxin,
9 CdiA-CT, and its cognate immunity protein, CdiI2 from *Cupriavidus taiwanensis*. We started with
10 monomer models from the CASP12 predictors. We observed variability in the CdiA-CT models
11 and consequently chose nine that had convergent secondary structure signatures for further
12 modeling. There was less variability in CdiI2 models, but for the eleven-residue N-terminal tail.
13 We chose three models with significantly different tail conformations from each other to hedge
14 our bets. As we could not find a homologous complex, we searched the global conformational
15 space using ClusPro[34] and chose the binding mode compatible with most of the monomer
16 conformations. Restricting our search to the local space around this mode, we then docked the
17 ensemble of nine CdiA-CT backbone with three CdiI2 backbones to generate 15,000 models. As
18 we could not predict this tail conformation correctly in the model, we predicted the rigid body
19 conformation of CdiA-CT incorrectly (see Supplementary Fig S2A). The best model across all
20 groups was classified as acceptable.
21
22

23 ### Target 117: Pins–Insc tetramer

24 T117 was the tetrameric complex of two molecules of Pins, a cell polarity determining protein
25 and two molecules of Insc, an adapter protein. A structure of the Pins monomer was available
26 (3SF4). For the structure of Insc, we relied on models from CASP12 participants. Owing to the
27 absence of close homologs, we obtained a variety of different models, which we then relaxed
28 and clustered by similarity. The models that clustered most tightly still had a variety of
29 conformations of the first 35 (N-terminal) residues, which we consequently truncated. Based on
30 literature,[35] we decided to construct a homo-dimer of hetero-dimer model, where we first
31 docked the Insc to Pins, generating 50,000 models, then selected an ensemble of 15 distinct top-
32 scoring dimers, and finally we symmetrically docked the dimers, starting from four distinct
33 orientations, and generating 50,000 models for each orientation.
34
35 The crystal structure of the complex (5A7D, see Supplementary Fig S2C) is a homo-dimer of two
36 hetero-dimers as we predicted, but is not symmetric. The primary contacts of Insc in each hetero-
37 dimer unit occur in the thirty-residue unfolded N-terminal peptide, Insc^{PEPT}. As a result, there is
38 a large amount of conformational flexibility in the hetero-dimer subcomplex with the two
39 subcomplexes in the crystal structure having significantly different conformations. We had
40 truncated this peptide and hence could not model either the hetero-subcomplex or the whole

1 complex correctly. This was arguably the hardest challenge of round 37 because it involved not
2 only multi-body docking, but also predicting the interactions of an unfolded peptide stretch with
3 large conformational flexibility. No CAPRI team submitted an acceptable or better model.
4

5 Targets 123 & 124: PorM–camelid nanobody complex

6 T123 and T124 comprised the N- and C- terminal domains (respectively) of PorM, a periplasmic
7 member of the type IX secretion system found in *Porphyromonas gingivalis*, in complex with
8 nanobody chaperones. In their presence, the N-terminal domain crystallized as a monomer
9 whereas the C-terminal domain crystallized as a dimer. Generally, nanobodies recognize antigens
10 primarily by interactions in three variable loops called H1, H2 and H3. The H3 loop is the longest
11 and most flexible loop, and as a result it is the primary determinant of binding. Thus, we modeled
12 the constant core of the nanobody and the H1 and H2 loops from available homologs and then
13 we generated 1,000 models with different H3 loop conformations using RosettaAntibody.[36,37] In
14 T123, $PorM_{N-term}$ in complex with nb02, the H3 loop was 12 residues long, whereas in T124,
15 $PorM_{C-term}$ dimer in complex with nb130, the H3 was 21 residues long.
16

17 For T123, we obtained $PorM_{N-term}$ models from Robetta. For T124, we obtained $PorM_{C-term}$
18 monomer conformations from Robetta and docked them together symmetrically to attain a
19 dimer configuration. In both cases, no homologs were available as templates and hence the
20 monomers were modeled *de novo* from sequence, which was a source of error. Using the lowest-
21 scoring PorM models, we searched for suitable nanobody-binding regions by global docking using
22 ClusPro. We then refined the distinct binding modes obtained from ClusPro while simultaneously
23 sampling various nanobody variable loop conformations using SnugDock,[3,36] a variant of
24 RosettaDock specialized for docking antibodies.
25

26 For T123, the $PorM_{N-term}$–nb02 complex, we did not produce an acceptable model or better. Since
27 the structure is not yet released, we cannot analyze the reason for our failure. Only one
28 acceptable solution was submitted across all participants. T124, the $PorM_{C-term}$ dimer–nb130,
29 complex involved multiple challenges: modeling monomers without templates, predicting their
30 dimeric form and then docking the nanobody correctly (see Supplementary Figure S3A). All our
31 $PorM_{C-term}$ monomeric models were incorrect. Although we were able to model the nb02 H3 loop
32 within 2.4 Å $RMSD_{C\alpha}$, all our complex models had an Lrmsd of more than 18 Å. As a result, we, as
33 well as all the other participants, failed to model this complex correctly.
34

35 Targets 131 & 132: CEACAM1–HopQ complex

36 T131 and T132 were the complexes of *Helicobacter pylori* adhesins HopQ1 and HopQ2,
37 respectively, bound to the N-terminal domain of cell adhesion molecule CEACAM1. Multiple
38 structures were available for the N-terminal domain of CEACAM1 (2GK2, 4QXW, 4WHD, and
39 5DZL).[38,39] For T131, the structure of HopQ1 was available with four loops missing at the putative
40 binding interface (5LP2).[40] Using this structure as a template, complete models were obtained

1   from Robetta. Robetta produced different conformations for the two longest loops (residues
2   135–148 and 245–255), which suggested potential flexibility. A mutation study indicated that
3   residues Y34 and I91 of CEACAM1 are essential for HopQ binding.[41] The authors of the study also
4   conjectured that the first long loop of HopQ1 is involved in binding CEACAMs. We modeled the
5   missing loop using fragment insertion and closed the loop with cyclic coordinate descent.[42] Using
6   an ensemble of 200 different loop conformations for the first HopQ1 loop and constraints to
7   ensure CEACAM1 Y34 and I91 contact HopQ1, we generated 10,000 models each from two
8   different starting states. For T132, we modeled the structure of the HopQ2 monomer based on
9   its homology to HopQ1 using Rosetta Remodel.[43] We followed a similar protocol for HopQ1 loop
10   conformation sampling (for a slightly shorter loop of residues 135–144) and docking.
11
12   In both the cases, our loop modeling methods failed to provide the necessary bound
13   conformation, often producing extended loops, instead of the compact structure in the crystal.
14   As a result, the rigid-body orientation of CEACAM1 was completely incorrect. The two CEACAM1
15   residues predicted to be at the interface were indeed found to be there and are shown as salmon
16   sticks in Supplementary Figure S3B.
17
18   While we did not predict the structure correctly, we did successfully refine and score structures
19   submitted by another group. Our best refined model was classified as acceptable with 27% of
20   native contacts predicted, Lrmsd and Irmsd of 11.8 Å and 3.2 Å, respectively. This demonstrates
21   that the *REF2015* score function[44] can recognize the near-native structure. Therefore, the
22   outstanding challenge is to sample the conformation *de novo*.
23
24

25   Protein–Oligosaccharide docking

26   Targets 126–130: Arabino-oligosaccharide binding to proteins

27   In round 41 of CAPRI, we modeled the interaction between arabino-oligosaccharide ligands of
28   different lengths and the arabinose sensor, AbnE, or the arabinanase, AbnB — two important
29   components of the L-arabinan-utilization system of *Geobacillus stearothermophilus*. Specifically,
30   T126–129 challenged us with the docking of 1,5-α-L-arabinohexose (A6) through 1,5-α-L-
31   arabinotriose (A3), respectively, to AbnE. T130 involved the docking of A5 to a catalytic mutant
32   (E201A) of AbnB.
33
34   We modeled AbnE from homologs with 95% or more sequence coverage and 25% or more
35   identity using Modeller[27] and relaxed the models in Rosetta.[45] Additionally, we obtained models
36   from the Robetta server.[20] One of the homologs that we used to model the target, the maltose-
37   binding protein GacH from *Streptomyces glaucescens*, exists in two conformations: an unliganded
38   open conformation and a closed, ligand-bound conformation.[46] From all the aforementioned
39   protein models, we used the conformation closest to the ligand-bound GacH conformation to
40   model T126–129. As the chemical description of arabinose was absent in Rosetta, we
41   programmed the required geometry, partial charge, and chemical connectivity information to
42   model arabinose ligands with the RosettaCarbohydrate framework.[9] To obtain a starting

1 structure, we superimposed the AbnE model and A4 onto maltotetraose-bound GacH (3K00)[46],
2 changing the backbone torsion angles of A4 to best align with maltotetraose. For A5 and A6, we
3 added arabinose units to the non-reducing end of the ligand. For A3, we removed an arabinose
4 unit from the non-reducing end.
5
6 To simultaneously dock the glyco-ligands and explore their backbone conformations, we used
7 the new GlycanDock protocol in Rosetta.[9] In this protocol, the glyco-ligand undergoes small
8 backbone motions along with rigid-body moves to dock into a protein cavity. These perturbations
9 are alternated with side-chain repacking and energy minimization in torsion space for the
10 residues at the protein–glycan interface. For each target, we obtained 15,000 initial docked
11 models without any constraints to relieve clashes and to broadly sample the rigid-body
12 conformational space. From the models where the ligands moved less than 5 Å RMSD from the
13 starting structure, *i.e.*, those that stayed in the binding pocket of AbnE, we selected the one with
14 the lowest interaction energy as the starting model for the final simulation. For the final docking
15 simulation, we added constraints to hold the glyco-ligands within the putative binding pocket of
16 AbnE and generated another 15,000 models. The range of conformations explored by A6 in T126
17 is exemplified in Figure 3A. We predicted medium quality models for T129 and acceptable-quality
18 models for T127 and T128. During scoring, we recognized acceptable models for T126–T129, thus
19 validating the score function.
20
21 For T130, the crystal structure of A3 bound to the E201A mutant of the glycosidase AbnB was
22 already available (3D5Z). The active site of this enzyme is a long groove with a bridge connecting
23 the brinks under which the ligand can slide (see Figure 3B). The enzyme cleaves glycosidic linkages
24 indiscriminately[47] as the groove offers no steric obstruction at either end to hold the substrate in
25 place. Consequently, although a structure was available with A3, we could not *a priori* predict
26 how the A5 ligand would position itself. Extending the A3 in either direction provided us with
27 starting coordinates for three unique starting states. We generated 10,000 docked models each
28 from the three starting states using GlycanDock while constraining the A5 ligand to the active site
29 groove. Figure 3B shows the best predicted conformation of A5 (in green) superimposed on the
30 crystal structure of AbnB$_{E201A}$ (light gray)–A5 (dark gray) complex (6F1G). The structure is a
31 medium-quality model with 63% of the contacts being recovered with an Irmsd of 1.58 Å and an
32 Lrmsd of 4.22 Å.
33
34
35 Post-hoc analysis of GlycanDock sampling and scoring
36
37 Compared to the crystal structure (6F1G), the three A5 structures we used as input for the T130
38 prediction round had a high fraction of native contacts (0.267, 0.367, and
39 0.633, respectively). We examined the failure of Rosetta GlycanDock to produce a high-quality
40 structure despite having favorable starting states by investigating the Rosetta scoring function
41 and an updated sampling algorithm in the version of GlycanDock under development.
42
43 To test scoring, we refined the crystal structure to generate 50 models. All models had sub-
44 Angstrom RMSDs (purple triangles in Supplementary Figure S4) with interaction scores more

13

1 favorable than those of the submitted models; the lowest-scoring model had a score of -
2 24.9 units for the crystal refinement versus -13.9 units for the submitted models. This
3 result suggests that, had it been sampled, the Rosetta scoring function would have correctly
4 identified a near-native structure.
5
6 Despite having favorable starting conformations and a score function that discriminates near-
7 native models, the previous version of GlycanDock failed to sample native-like states. The
8 primary reason was that the first step of the algorithm randomized glycan backbone torsions as
9 well as the rotation of the glycan about the protein, both of which disrupted favorable starting
10 structures. As a result, this initial perturbation is not as extensive in the updated version.
11
12 To diagnose our current limitations, we tested two aspects of sampling—the rigid-body
13 orientation sampling and the glycan backbone conformation sampling—individually at first and
14 then, simultaneously. To remove any bias from the protein backbone conformation in the crystal,
15 we used the protein backbone that we used for the prediction round. As a best-case scenario, we
16 aligned the crystal structure of the A5 glycan in the protein groove as observed in the crystal
17 structure. We generated 500 models by perturbing the glycan conformation
18 (0.5 Å translation, 7.5° rotation, and backbone torsion perturbation between ± 12.5°) and then
19 refining it. As expected, we successfully generated and discriminated near-native decoys even
20 when starting with structures with an average Lrmsd of 1.98 Å (Supplementary Figure S4A). Next,
21 we examined rigid-body sampling by moving the A5 crystal structure away from the binding
22 pocket by assigning it *de novo* coordinates. Starting with this orientation and employing the same
23 protocol, we generated high-quality models with RMSDs similar to those observed in crystal
24 structure refinement (Supplementary Figure S4B). To examine glycan backbone sampling, we
25 aligned the three input A5 structures used for the prediction round in the protein groove as in
26 the crystal structure and generated 1000 docked models for each input. We were unable to
27 obtain any high-quality models; all models had Lrmsd greater than 2 Å (Supplementary Figure
28 S4C). Finally, we tested both rigid-body and backbone sampling simultaneously by placing the
29 three input A5 structures used for the prediction outside the binding groove and then docking.
30 We achieved similar results as in the previous case (Supplementary Figure S4D). These results
31 suggest GlycanDock adequately samples rigid-body orientations but fails to do so for glycan
32 backbone conformation. Thus, the key to successfully dock glycans lies in sampling relevant
33 glycan backbone torsion.
34

Discussion

Previous rounds of CAPRI led to the development of niche protocols like SnugDock[3] to model antibody–antigen binding and pHDock[4] to dynamically sample residue protonation states while docking.[6] In rounds 37–45, we utilized these specialized methods while also encountering challenges that require overhauls of the core methodology for general problems such as global docking with flexibility, global docking of symmetric homomers, and oligosaccharide–protein docking. We modeled backbone flexibility by incorporating a pre-generated ensemble of backbone conformations during docking. With RosettaDock 4.0,[8] we sampled over fifty conformations for each partner to successfully model T122. Despite having an efficient backbone sampling algorithm, we failed to model T131 and T132 due to the absence of conformations where the interacting loops were in near-bound conformation. These failures highlight the need for ensemble generation methods that sample loop conformations broadly.

As many of the targets were symmetric homomers with varying degrees of homology to existing structures, we were able to thoroughly assess the Rosetta SymDock protocol. When homologs were present, we could borrow the symmetric arrangement from the homolog as a template, as we did to successfully model targets 110, 111, 112, 118, and 119. However, even in those cases, the proximity of the monomer backbone to the template monomer backbone determined the overall quality of the models. For example, the monomer model of T111 had a 0.8 Å $RMSD_{C\alpha}$ from the template and was our only prediction to be classified as high-quality. While one would expect that the more closely related a template is, the better the model will be, we noticed a systematic pattern of error in tightly-packed, higher order complexes. The method of induced fit successfully used for T136 inspired the flexible-backbone refinement strategy of the new symmetric docking protocol, Rosetta SymDock2.[11]

For only the second time in CAPRI, we encountered oligosaccharide–protein complexes. Five targets in round 41 gave us an opportunity to work with the recently-developed RosettaCarbohydrate framework,[9] especially the GlycanDock application therein. Oligosaccharides have many more degrees of freedom than peptides, often featuring an additional mobile backbone torsion angle, multiple mobile side chains, and sometimes flexible rings. GlycanDock samples these mobile dihedrals while performing rigid-body transformations to place the oligosaccharide in a binding pocket and simultaneously repacking the side chains of contacting protein residues. We recognized deficiencies in the sampling of GlycanDock, and ongoing developments focus on optimizing its conformation sampling capabilities for a variety of glyco-ligands. Certain glycosidic linkages have been observed to populate limited regions of torsion space and for these linkages, glycosidic torsion angle preferences and crystal structure-based statistics have been calculated and collected.[48,49] For the arabinose–arabinose linkages present in T130, linkage torsional statistics have not yet been collected, nor have the linkage-conformation energies been calculated. These data, when incorporated into glycan docking algorithms, could narrow the search space in glycan conformation sampling.[9,49] In addition, some groups that participated in round 41 included a term in their scoring function to encourage individual arabinose units to remain in a parallel stacking orientation with nearby aromatic residues in the active site. This type of protein–carbohydrate interaction, known as a CH–π

15

1 interaction, has been well characterized in carbohydrate-binding proteins and is understood to
2 play an important role in carbohydrate binding and recognition.[50,51] The Rosetta software suite
3 does not currently employ a scoring term to encourage this type of geometry-driven
4 intermolecular interaction, and it might help further discriminate native-like oligosaccharide–
5 protein interactions.
6
7 With fourteen successful predictions and two additional scoring successes, our performance in
8 the rounds evaluated thus far was commensurate with other leading groups in the rounds we
9 participated. Of our nine docking failures, we believe, retrospectively, that we had the sampling
10 techniques available in Rosetta to better model targets 113, 126, 131, and 132. On the other
11 hand, targets 114, 116, 117, 123, and 124 required blind prediction tools that do not yet exist
12 and as a result, they did not elicit a successful model from any predictor. Broadly, the challenges
13 that caused the most failures were docking with large conformational changes and multi-body
14 docking (especially higher order heteromers). These community-wide failures highlight the
15 massive gaps that still need to be addressed to fulfill the overarching goal of reliably modeling
16 entire interactomes.[52–54]

Table 1: **Summary of targets successfully modeled**. The table lists the round, target number, name of the complex, the nature of the challenge, the methods used to model the complex, and the evaluation metrics for the best model that we submitted. The metrics are f_{nat}: the fraction of native contacts recovered, Lrmsd: root-mean-square-deviation of the backbone atoms from the native ligand after superimposing the receptor, Irmsd: root-mean-square-deviation of the backbone atoms of the interface after superposition to the bound interface, and quality: high-quality (***), medium-quality (**), acceptable (*), or incorrect (-) as evaluated by the CAPRI organizers.

Round	Target. Interface #	Complex Name	Challenge	Method(s) Used	f_{nat}	Lrmsd (Å)	Irmsd (Å)	Quality
						Best Model Evaluation		
37	110	Fibre head domain of raptor adenovirus 1	Symmetric docking based on homolog	SymDock local refinement	0.67	2.35	1.73	**
	111	Fibre head domain of lizard adenovirus 2	Symmetric docking based on homolog	SymDock local refinement	0.75	0.98	0.73	***
	112	Fibre head domain of goose adenovirus 4	Symmetric docking based on homolog	SymDock local refinement	0.38	5.81	2.90	*
	118.1	Fructose bisphosphatase	Symmetric docking based on homolog	SymDock local refinement	0.41	1.72	1.07	**
	119	Alcohol dehydrogenase	pH-dependent symmetric docking based on homolog	SymDock local refinement, pHDock	0.61	9.92	2.99	*
	120	Group 1 dockerin–cohesin complex	Local docking based on homomer	RosettaDock with ensembles	0.25	4.96	3.80	*
39	122	IL-23–receptor complex	Multi-body docking, global docking	RosettaDock with ensembles	0.22	16.86	0.70	*
40	125.1	NKR-P1–LLT1 complex	Multi-body docking, symmetric global docking	ClusPro, RosettaDock with ensembles, SymDock	0.40	1.97	0.97	**
41	127	1,5-α-L-arabinopentose bound to AbnE	Oligosaccharide docking	GlycanDock	0.11	6.78	2.99	*
	128	1,5-α-L-arabinotetrose bound to AbnE	Oligosaccharide docking	GlycanDock	0.15	7.79	2.94	*
	129	1,5-α-L-arabinotriose bound to AbnE	Oligosaccharide docking	GlycanDock	0.48	2.78	1.84	**
	130	1,5-α-L-arabinopentose bound to AbnB$_{E201A}$	Oligosaccharide docking	GlycanDock	0.63	4.22	1.58	**
43	133	Designed colicin E2–Im2 complex	Loop modeling, docking based on homolog	KIC, RosettaDock with ensembles	0.45	5.58	4.26	*
45	136.1	Lysine decarboxylase	Symmetric docking based on homolog, complex size	Constrained relax, SymDock local refinement	0.58	2.70	1.68	**

Table 3.2: Summary of targets modeled incorrectly. 'Best in CAPRI' corresponds to the model evaluation of the best model submitted by all CAPRI predictors (not scorers). The description of the other headers is the same as in Table 1.

Round	Target. Interface #	Complex Name	Challenge	Method(s) Used	f_{nat}	Lrmsd (Å)	Irmsd (Å)	Best in CAPRI
						Best Model Evaluation		
37	113	CDI toxin–immunity complex	Flexible loop, global docking	ClusPro, RosettaDock with ensembles	0.06	18.33	11.43	*
	114	Ljungan virus protein	Low-quality monomer, symm. global docking	SymDock with ensembles	0.01	47.75	10.83	-
	116	Bifunctional histidine kinase	Variable domain linker, symmetric global docking	SymDock with ensembles	0.09	36.02	11.86	-
	117.2	Pins–Insc complex	Partial monomer unfolding, multi-body docking	RosettaDock with ensembles, SymDock	0.00	80.39	36.13	-
39	123	PorM$_{N-term}$–nb130 complex	Loop flexibility, global docking	RosettaAntibody, SnugDock, ClusPro	0.16	18.53	5.06	*
	124.2	PorM$_{C-term}$–nb02 complex	Loop flexibility, global docking	RosettaAntibody, SnugDock, ClusPro	0.00	27.42	14.15	-
41	126[a]	1,5-α-L-arabinohexose bound to AbnE	Oligosaccharide docking	GlycanDock	0.00	11.24	4.27	**
42	131	CEACAM1–HopQ1 complex	Loop flexibility, global docking	CCD + fragments, RosettaDock with ensembles	0.04	39.28	11.61	*
	132[a]	CEACAM1–HopQ2 complex	Loop flexibility, global docking	CCD + fragments, RosettaDock with ensembles	0.00	34.79	10.42	**

[a] During the scoring round, we refined and scored models of other predictors to obtain acceptable structures.

**A**

B

C

D

E

Fig 1: (A) **T110:** Our best model (** rating) of the fibre head domain of raptor adenovirus 1 (yellow) superimposed on the crystal structure (gray). Predicting and modeling the beta-hairpin in the native structure (red) was crucial to prediction success. The Lrmsd of 2.35 Å was the best among all groups. (B) **T111:** Our high-quality model (***) of the fibre head domain of lizard adenovirus 2 (orange) superimposed on the crystal structure of a close homolog (gray), snake adenovirus 1 fibre head. (C) **T118:** Our best model (**) of fructose 1,6-bisphosphatase (color) superimposed on the crystal structure of a close homolog (gray). (D) **T119:** Our best model (*) of alcohol dehydrogenase dimer (yellow) superimposed on the crystal structure (gray). The model is missing cross-beta interactions between the subunits at the interface (red). (E) **T136:** Our model (**) of LdcA decamer where the five subunits on top are displayed in different colors. For each subunit, the wing domains are highlighted in brighter hues. The Lrmsd of 2.44 Å was the best among all groups.
Fig 2: (A) **T120:** Our best model (*) of group I dockerin (blue)–cohesin (green) complex superimposed on the crystal structure (gray). A bulge in the cohesion (red) was not modeled correctly leading to a small error in the rigid body orientation of the dockerin. (B) **T122:** Our best model (*) of the complex of the two chains of IL-23, viz. IL-23A (green) and IL-23B (blue) with IL-23R (yellow) superimposed on the crystal structure (grey). The lightning rod interaction via the conserved Trp-156 (red) to IL-23R domain 1 (D1) was correctly predicted. IL-23R model had large errors in the relative orientation of the three domains. (C) **T133:** A 14th-ranked model (**) of Im^{Des3} (blue) bound to E^{Des3} (green) superimposed on the crystal structure of the complex (gray). The Im^{Des3} loop (red) is modeled inaccurately (yellow). This alters the rigid body orientation of Im^{Des3} by pushing it 'down'. The hotspot resides across the interface in the wild-type (orange), *viz.* Y54-Y55 Im2 and F86 on E2 still interact in the model of the designed complex.
Fig 3: (A) **T126:** Range of ligand conformations sampled by 1,5-α-L-arabinohexose (green/yellow/pink) in the binding groove of AbnE (gray). (B) **T130:** The best predicted conformation of 1,5-α-L-arabinopentose (green) on AbnB$_{E201A}$ (gray), with f_{nat} = 63%. The crystal structure (dark gray) is shown for comparison.
