11 Running title: Transposons diversify the neural transcriptome

12 Keywords: Transposon expression; alternative splicing; transcriptional heterogeneity; single-
13 cell transcriptomics.

14 **Abstract**

15

16 Somatic transposition in neural tissue could contribute to neuropathology and individuality,
17 but its prevalence is debated. We used single-cell mRNA sequencing to map transposon
18 expression in the *Drosophila* midbrain. We found that neural transposon expression is driven
19 by cellular genes. Every expressed transposon is resident in at least one cellular gene with a
20 matching expression pattern. A new long-read RNA sequencing approach revealed that
21 coexpression is a physical link in the form of abundant chimeric transposon-gene mRNAs.
22 We identified 148 genes where transposons introduce cryptic splice sites into the nascent
23 transcript and thereby produce many additional mRNAs. Some genes exclusively produce
24 chimeric mRNAs with transposon sequence and on average transposon-gene chimeras
25 account for 20% of the mRNAs produced from a given gene. Transposons therefore
26 significantly expand the neural transcriptome. We propose that chimeric mRNAs produced
27 by splicing into polymorphic transposons may contribute to functional differences between
28 individual cells and animals.

29 Introduction

30 Transposons comprise almost half of every eukaryote genome (Britten and Kohne, 1968;
31 International Human Genome Sequencing Consortium et al., 2001; Ketchum et al., 2000)
32 and their mobilization in the germline contributes to chromosome evolution. Non-heritable *de*
33 *novo* transposon activity in neural tissue has been proposed to contribute to functional
34 heterogeneity in the brain and to neurological disease (Baillie et al., 2011; Coufal et al.,
35 2009; Evrony et al., 2012; Kazazian, 2011; Kazazian and Moran, 2017; Muotri et al., 2005;
36 Schauer et al., 2018). However, it is difficult to faithfully map rare *de novo* transposon
37 insertions using whole-genome DNA sequencing (Baillie et al., 2011; Evrony et al., 2012,
38 2016; Perrat et al., 2013; Treiber and Waddell, 2017; Upton et al., 2015). A growing number
39 of studies have therefore correlated the development of neurodegeneration in animal models
40 with changes in transposon expression (Guo et al., 2018; Krug et al., 2017; Li et al., 2013; Li
41 et al., 2012; Sun et al., 2018). Using expression as a proxy for mobility could be misleading
42 because high-level transposon expression does not appear to result in elevated *de-novo*
43 somatic transposition in the brain (Evrony et al., 2012, 2016; Treiber and Waddell, 2017). It
44 is therefore important to understand what controls the expression of transposon-derived
45 sequences in the brain and whether their elevated expression relates to neural function.

46

47 An early study of the human LINE-1 (L1) promoter demonstrated that its activity was heavily
48 influenced by flanking cellular sequences, and concluded that expression of a given L1
49 depended on its location in the genome (Lavie et al., 2004). Such a locus specific model
50 could more generally explain the apparent cell-type restricted nature of transposon
51 expression and mobilization in the brain. So far, studies of somatic transposon expression
52 have either focused on single transposon families or have been based on bulk sequencing
53 of tissues or cultured cells (Chung et al., 2019; Faulkner et al., 2009; Li et al., 2013; Philippe
54 et al., 2016; Rangwala et al., 2009). However, answering this question on a brain- and
55 genome-wide scale requires a means to relate the cellular expression of each transposon in
56 the genome to that of their neighboring genes. Recent technical developments in whole-

57 genome DNA sequencing and high-throughput single-cell transcriptomics of complex tissues
58 now make this possible (Macosko et al., 2015).

59

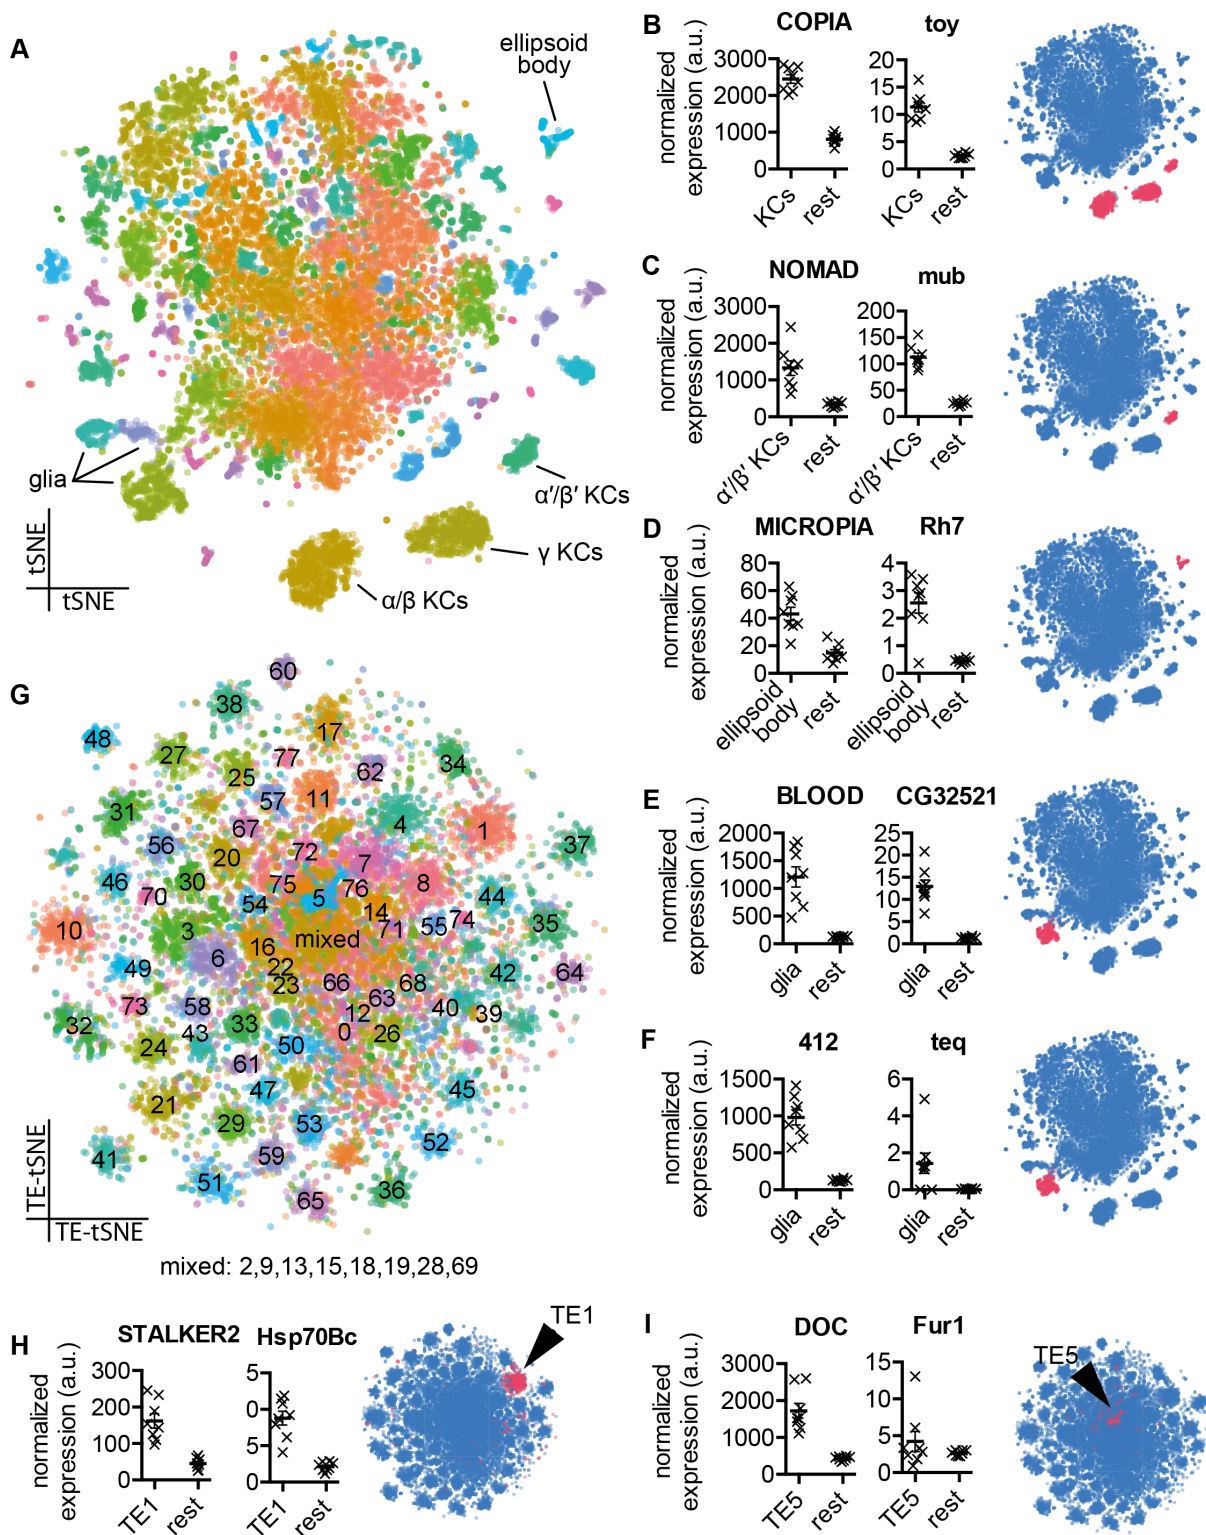

60 Here we used single-cell transcriptomics to map transposon expression to individual cells in
61 the *Drosophila* midbrain. We found that many transposons are expressed with cell-specificity
62 that is often highly correlated to that of a neighboring gene. A more detailed analysis
63 revealed that >90% of transposon expression can be linked to co-expression with a host
64 gene, indicating that these genes are the main driver of somatic transposon expression.
65 Long-read sequencing showed that the transposon and neighboring gene are alternatively
66 spliced together becoming part of the same chimeric mRNAs. Sometimes all mRNAs
67 produced from a particular gene in which a transposon resides include transposon
68 sequence. Therefore, transposons produce genome-wide diversification of cellular
69 transcripts. Analysis of sequencing data produced from other fly strains demonstrated large
70 differences in their chimeric transcriptomes. Inter-strain and individual differences in
71 transposon complement therefore constrain the cellular specificity and likelihood of
72 transposon-directed pathology.

73 **Results**

74 **Single-cell transcriptomics reveals cell-type restricted transposon expression**

75 The *Drosophila* genome contains 112 families of transposons and the number of an
76 individual type varies from a few to hundreds of copies (Kaminker et al., 2002). Conventional
77 single-cell RNAseq (scRNAseq) analysis pipelines typically discard sequencing reads that
78 align to multiple genomic loci, and so they overlook transposon expression. We therefore
79 devised an analysis pipeline to map the expression of all transposons within scRNAseq
80 data. We masked all repetitive sequences in the reference genome and then added a single
81 copy of the consensus sequence for every known transposon to the masked genome. In
82 essence this produces a *Drosophila* reference genome with one copy of each type of
83 transposon. We first used this modified reference genome to map transposon expression
84 onto single cells of the midbrain prepared from a fly strain expressing mCherry in $\alpha\beta$ Kenyon
85 cells (KCs) of the mushroom body (MB); from here called $\alpha\beta$ Cherry flies. We found evidence
86 for expression of both the sense and the antisense strand of most transposons, which
87 comprised 76.2 and 23.8% (\pm 1.7% SD) of all transposon expression, respectively
88 (Supplemental figure 1). We first performed principal component decomposition of cellular
89 genes and clustered cells from the midbrain by constructing a k-Nearest-Neighbor graph on
90 the Euclidean distances in the PCA space, optimizing the modularity using the Louvain
91 algorithm (Butler et al., 2018). This analysis grouped cells into many discrete clusters. We
92 next assigned many of these clusters to cell types in the midbrain using the expression
93 patterns of known marker genes (Croset et al., 2018) (Figure 1a). Displaying the expression
94 of individual types of transposons on the cluster plot revealed that some transposons are up-
95 regulated in specific cell types. For example, the long-terminal repeat (LTR)
96 retrotransposons COPIA and NOMAD showed elevated expression in the $\alpha\beta$, $\alpha'\beta'$ and γ
97 Kenyon Cells (KCs) classes (Figure 1b, first graph) and $\alpha'\beta'$ KCs (Figure 1c, first graph),
98 respectively. Other LTR retrotransposons such as MICROPIA were upregulated in the
99 ellipsoid body (Figure 1d, first graph) whereas BLOOD and 412 were higher in glia (Figure
100 1e,f, first graphs).

105 expression levels. Colors represent cell clusters (at SNN resolution of 3.5). **B-F** Mean
106 expression of transposons and neighboring cellular genes in the relevant cell groups in 8
107 biological replicates and tSNE representation of cell-type restricted expression. **B** COPIA
108 and *twin-of-eyeless* (*toy*) in all Kenyon Cell (KC) classes. **C** NOMAD and *mushroom-body*
109 *expressed* (*mub*) in α' β' KCs. **D** MICROPIA and *Rhodopsin 7* (*Rh7*) in the ellipsoid body **E**
110 **and F** BLOOD and *CG32521*, and 412 and *tequila* (*teq*) in glia. Values represent the mean
111 normalized number of unique molecular identifiers (UMI's) in an average cell from each cell
112 type, and from the rest of the midbrain. Error bar indicates standard error of mean (SEM).
113 Note that transposon- and gene levels were normalized separately. Blue schematic shows
114 location of cell cluster (pink) in tSNE plot. **G** Two-dimensional reduction of 14,804 *Drosophila*
115 midbrain cells, based exclusively on transposon expression levels. Colors represent cell
116 clusters (at SNN resolution of 3.5). **H and I** Mean expression of STALKER2 and *Hsp70Bc*
117 and DOC and *Furin 1* (*Fur1*) in their relevant transposon clusters and the position of the
118 cluster in the overall transposon-based tSNE (indicated in pink).

119 **Transposon expression correlates with that of cellular genes they are inserted within.**

120 Transposons could be elevated in specific cell types because they are inserted in genes that

121 are highly expressed in the same cells. To test this hypothesis, we re-used our previously

122 published high-coverage gDNA sequence of $\alpha\beta$ Cherry flies. We mapped all the germline

123 transposon insertions in these flies using TEchim, a new custom-built transposon analysis

124 program. TEchim first generates long nucleotide contigs from either gDNA or cDNA

125 sequencing reads, then creates in-silico paired-end reads and screens them for cases where

126 one in-silico end maps to a cellular gene and the mate read maps to a specific transposon.

127 Since these paired-end reads are derived from contiguous sequences, TEchim permits one

128 to subsequently refer back to the original long reads to determine the precise nucleotide

129 sequence of the transposon-gene breakpoints. Using TEchim, we found copies of COPIA,

130 NOMAD, MICROPIA, BLOOD and 412 inside the genes *twin-of-eyeless (toy)*, *mushroom-*

131 *body expressed (mub)*, *Rhodopsin-7 (Rh7)*, *CG32521* and *tequila (teq)*, respectively. The

132 expression of each of these genes mirrored the expression pattern of the transposon they

133 harbored (Figure 1b-f, second graphs). The expression of these transposons in the brain of

134 $\alpha\beta$ Cherry flies therefore appears to be driven by their relevant host genes.

135

136 We next tested whether all transposons exhibit patterned expression throughout the

137 midbrain. We re-clustered the single-cell data of the fly using only transposon expression.

138 This generated 78 cell clusters that mostly contained cells from all 8 biological replicates in

139 the data (Figure 1g, Supplemental figure 2). This result suggests that transposon expression

140 is stereotyped across samples derived from different flies collected from the same strain. We

141 then analyzed the expression of cellular genes across the transposon clusters and found

142 many clusters also preferentially expressed certain genes. For example, the cluster of cells

143 expressing the LTR of STALKER2 was enriched for cells that also expressed the *Hsp70Bc*

144 gene (Figure 1h), and cells in the DOC-positive cluster showed increased expression of

145 *Furin1 (Fur1)*. By referring back to the gDNA, we found that $\alpha\beta$ Cherry flies harbor a copy of

146 STALKER2 within *Hsp70Bc* and a copy of the LINE-like DOC element inside *Fur1*. Again,

147 these data suggest that expression of STALKER2 and DOC is driven by a neighbouring
148 gene.

149

150 **Quantitative analysis reveals high fidelity transposon-gene co-expression**

151 Our gDNA analysis also revealed many transposon insertions inside genes that were more
152 broadly expressed across the brain. In total, we identified 1952 germline transposon
153 insertions within genes. Of these, 881 cases were inserted in the sense direction to the open
154 reading frame of the gene and 1071 were in the antisense orientation (Supplemental Table
155 1). To quantify the correlated expression of transposons and cellular genes we devised a
156 method based on the established Hardy-Weinberg principle for quantifying linkage
157 equilibrium of two alleles in population genetics (Lewontin and Kojima, 1960) (Figure 2a).
158 We first binarized our scRNAseq data to generate the equivalent of bi-allelic traits in a
159 population. We then calculated the proportion of cells expressing a specific transposon,
160 multiplied it by the proportion of cells expressing a certain gene, and then subtracted this
161 value from the proportion of cells that expressed both the transposon and the gene. We
162 termed this value the Coexpression Disequilibrium, CD. We also normalized these CD
163 values to account for the variable abundance of each transposon and gene in every
164 transposon-gene pair and repeated the analysis for all transposon-transposon and gene-
165 gene pairs. These normalized values were then ranked within each of the 8 biological
166 replicates. P-values were corrected for multiple comparisons and describe the probability
167 that a transposon-gene pair would have such a highly ranked CD value across multiple
168 replicates if they were expressed independently.

Figure 2

169

170

171 **Figure 2. Transposons are co-expressed with neighboring genes.**

172 **A** Schematic and formulae describing the calculation of Co-expression Disequilibrium

173 values. **B** Examples of transposon-gene pairs that are neighboring in the genome and co-

174 expressed across the midbrain. Pink bar represents the total transposon expression.

175 Examples are selected from the most highly expressing transposons. See Supplemental

176 Table 2 for entire list of correlated transposon-gene pairs. **C** Graph illustrating that more

177 neighboring genes are correlated with their resident transposons than if transposons are

178 randomly assigned to genes.

179 We combined the list of all germline transposon insertions in $\alpha\beta$ Cherry flies with the
180 scRNAseq data generated from the same population of flies and calculated the CD values
181 between every transposon and the gene in which it was inserted. We tested every
182 transposon that contributed at least 0.1% of the overall transposon expression in our
183 midbrain $\alpha\beta$ Cherry fly samples. This cut-off left 59 different transposons, 34 of which were
184 expressed in both the sense- and the antisense direction, 22 only in sense, and 3 only in
185 antisense (Figure 2b, Supplemental Table 2). For 56 of these transposons we found at least
186 one copy inside a gene that exhibited a correlated expression pattern (Benjamini-Hochberg
187 corrected p-val >0.05). For those cases where the transposon was inserted in the same
188 orientation as the transcription unit of the gene the expression of the sense strand of the
189 transposon correlated to that of the gene. In contrast, the antisense strand of reverse
190 orientation transposons was correlated with the host gene. Importantly, the average number
191 of correlated genes for each transposon was significantly less if equivalent values were
192 calculated using random assignment of transposons to host genes (Figure 2c). These
193 analyses therefore demonstrate that the genomic locus strongly influences the expression
194 patterns of almost all transposons in the fly brain. We did not identify a neighboring gene
195 with a correlated expression pattern for the transposons TART-A, P-element and
196 HMSBEAGLE. This is expected for TART-A, which is a telomeric retrotransposon, and for P-
197 element, which is a remnant of transgenic intervention in $\alpha\beta$ Cherry flies. It is conceivable
198 that the HMSBEAGLE retrotransposon is the only element that is expressed independently
199 of a cellular gene. However, despite our high coverage sequence of $\alpha\beta$ Cherry flies we may
200 have missed a germline HMSBEAGLE insertion that sits near a gene that is driving its
201 expression.

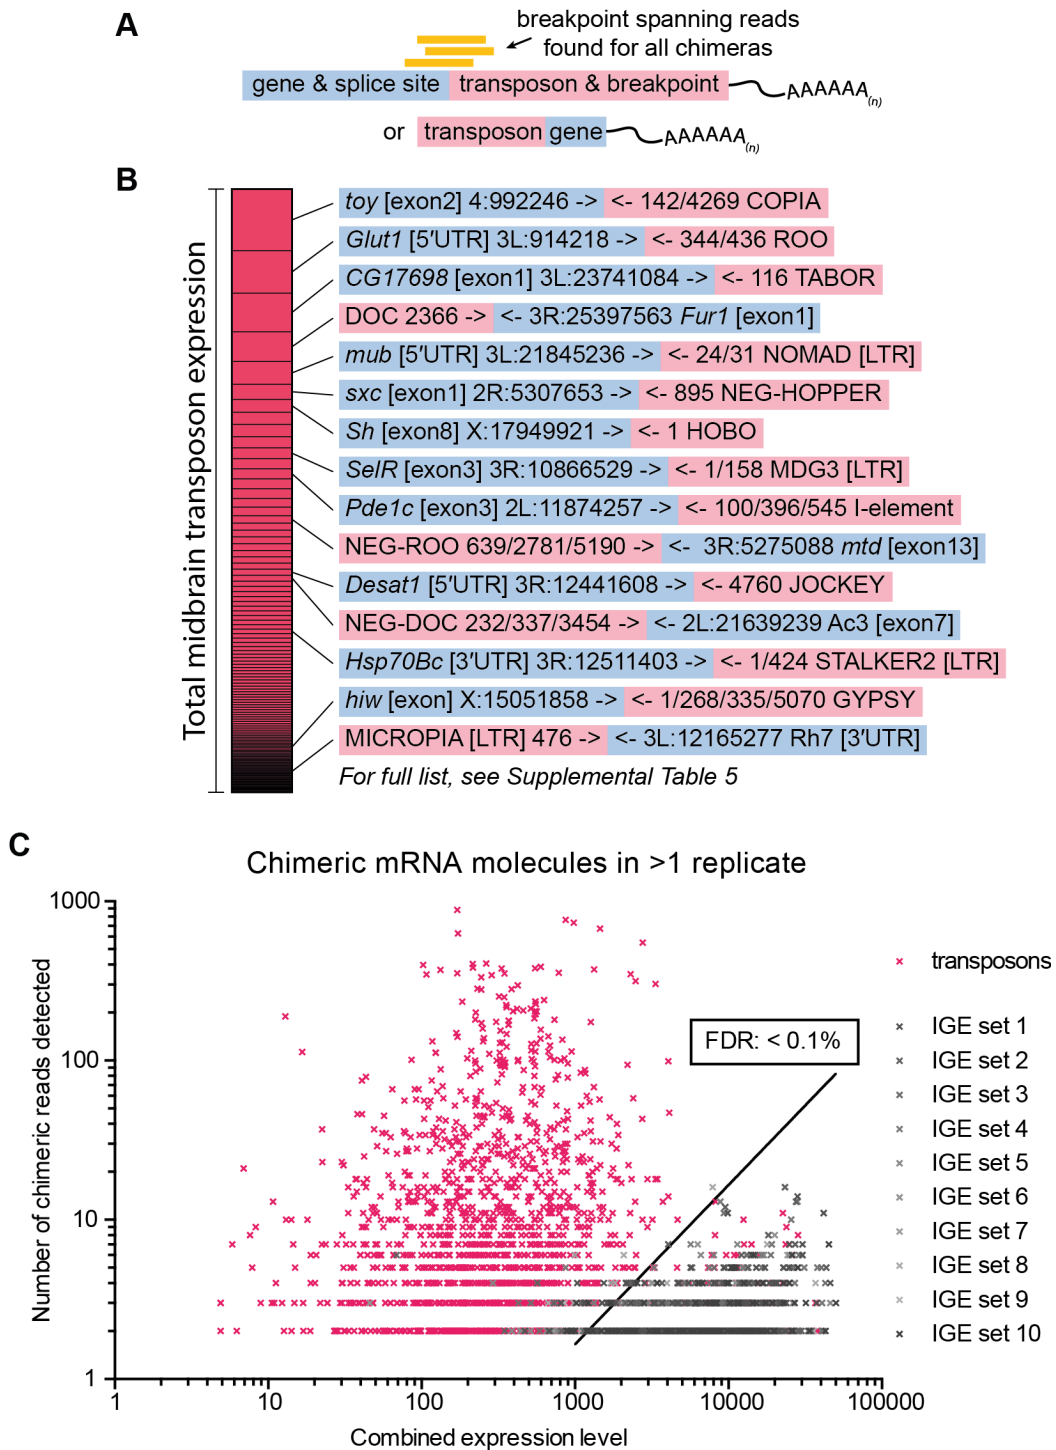

202

203 **Transposons are exonized into cellular mRNAs**

204 Recent work has shown that mRNAs from the *Arc* gene contain transposon-like sequence in
205 the coding sequence and 3' UTR (Pastuzyn et al., 2018; Zhang et al., 2015). We therefore
206 tested whether chimeric mRNAs might occur more broadly and extend to all transposons.

207 We extracted mRNA from $\alpha\beta$ Cherry fly heads and generated 250 basepair long reads which
208 were screened using TEchim for chimeric reads. We also incorporated a function in TEchim
209 that maintains strand-specificity of the input reads which enabled us to unambiguously
210 assign chimera to cellular genes. This analysis revealed that a large number of transposons
211 inside introns lead to the formation of chimeric mRNAs. In total, we found chimeric mRNA
212 from 887 transposon insertions (Figure 3a, Supplemental Table 3). Chimera included
213 sequences from LTR, LINE-like and DNA transposons attached to mRNAs from genes
214 involved in a broad range of biological processes. For example, we found sequence from the
215 LTR-retrotransposon Gypsy in transcripts of the ubiquitin gene *Ubi-P5E* and of the neuron
216 specific ubiquitin ligase *highwire (hiw)*, the non-LTR element DOC in *Fur1*, encoding a
217 synaptic membrane bound protease, and the TIR element HOB0 attached to transcripts
218 from *Shaker*, which encodes a voltage-gated potassium channel (Izquierdo, 1994; Kaplan
219 and Trout, 1969; Roebroek et al., 1991; Wan et al., 2000).

Figure 3

221 **Figure 3. Chimeric transposon-gene mRNA is abundant in the midbrain.**

222 **A** Schematic of the structure of chimeric mRNA molecules, and illustrating the data
223 representation in **B**. **B** Examples of transposon-gene pairs that form chimeric mRNA. The
224 blue box contains the gene name, the section of the gene that forms a chimera and the
225 breakpoint, which is always the endogenous exon-intron junction. The red box contains the
226 transposon name, and the breakpoint(s) on the transposon. Note that for consistency,
227 transposon breakpoints are always taken from the sense orientation, starting from the core
228 transposon sequence, unless specifically indicated as [LTR]. Examples shown here are the
229 same transposon-gene pairs as in Figure 2b. For the entire list of chimera, see
230 Supplemental Table 5. **C** Graph showing the number of chimeric reads, and the combined
231 expression levels of each transposon-gene pair (pink), as well as for all 10 sets of IGE-gene
232 pairs (grey). Combined expression levels are the square root of the product of reads in both
233 transcripts of a transposon/IGE-gene pair. IGEs were used to calculate a threshold for a
234 False Discovery Rate that is less than 0.1%.

235 Previous studies of chimeric sequencing reads have established that *in vitro* amplification of
236 genetic material often leads to chimeric amplification artefacts (Evrony et al., 2016; Treiber
237 and Waddell, 2017). It was thus important to account for similar errors in our data. We
238 therefore calculated the rate of these artefacts in our mRNA data by selecting 10 sets of 167
239 exons (with each set providing a number of sequences corresponding to the 112 different
240 transposon types and 55 LTRs) with matching expression levels in the brain. These exons
241 lack the ability to relocate in gDNA so we refer to them as immobile genetic elements (IGEs).
242 Since IGEs should only occur as single copies in the gDNA from $\alpha\beta$ Cherry, chimeric reads
243 between IGEs and other genes most likely represent amplification artefacts. We found the
244 rate of generating IGE chimeras was directly correlated to the expression level of the IGE
245 and the gene that it formed a chimeric molecule with. Critically, the IGE chimera rate was
246 substantially lower than that of chimera formed between genes and transposons. We
247 therefore used the rate of IGE chimera to filter the transposon chimera detected using
248 TEchim, defining a false discovery rate (FDR) of 0.1% (Figure 3b, Supplemental Table 3). All
249 examples of chimeric transcripts that are presented in detail in this study have supporting
250 evidence that exceeds this FDR.

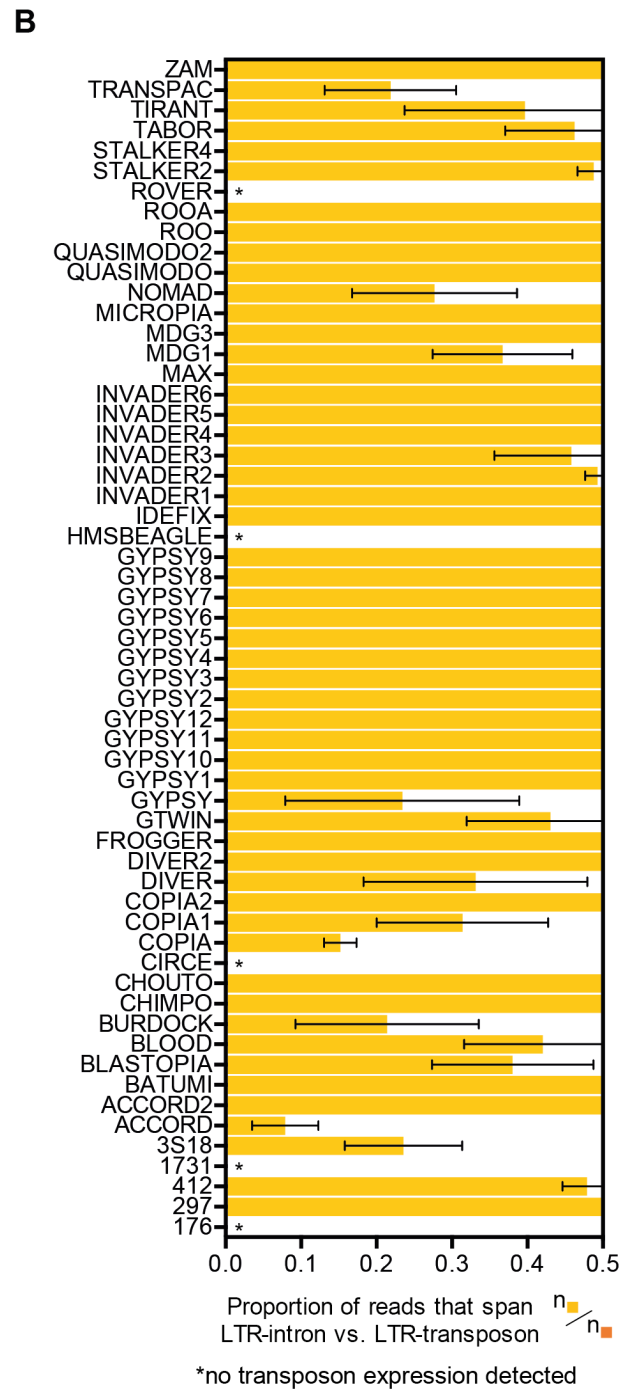

251

252 **LTR retrotransposon expression is predominantly non-autonomously**

253 Given that transposon expression was highly correlated with at least one neighboring gene,
254 we hypothesized that all transposon expression in the brain might occur as co-expression
255 with cellular genes. To test this, we focused on LTR retrotransposons. We quantified the
256 number of reads that spanned an LTR-gene breakpoint, and compared it to the number of
257 reads that crossed the LTR-transposon breakpoint within the transposon (Figure 4a).
258 Autonomously expressed, full-length transposons only generate the latter type of read, whilst
259 non-autonomous expression should generate both kinds of reads, at varying proportions.
260 We found that around 95% of the highly expressed LTR transposons produced a roughly
261 equivalent number of gene-transposon and LTR-transposon reads, suggesting that LTR

262 transposons are expressed as chimeras with cellular genes, rather than being autonomously
263 expressed (Figure 4b, Supplemental Table 4).

Figure 4

265 **Figure 4. LTR retrotransposon expression is predominantly non-autonomous**

266 **A** Illustration showing method of calculating the percentage of chimeric transcripts vs.
267 autonomously expressed transposon transcripts. Non-autonomous expression should result
268 in an approximate value of 0.5 for reads spanning the LTR section of transposons and the
269 intron of a neighboring gene over the number of reads spanning the LTR and the core
270 section of the transposon. In contrast, autonomous expression would not result in LTR-gene
271 spanning reads. **B** List of all LTR transposons analyzed in our mRNA data. We identified
272 LTR-gene spanning reads for every LTR transposon that is expressed in the midbrain. Error
273 bars represent standard deviation. Values have been capped at 0.5 in this graph. However,
274 some transposons produced a much higher number of LTR-gene reads (see Supplemental
275 Table 4).

276 **Many transposons introduce cryptic alternative splice-sites into cellular genes**

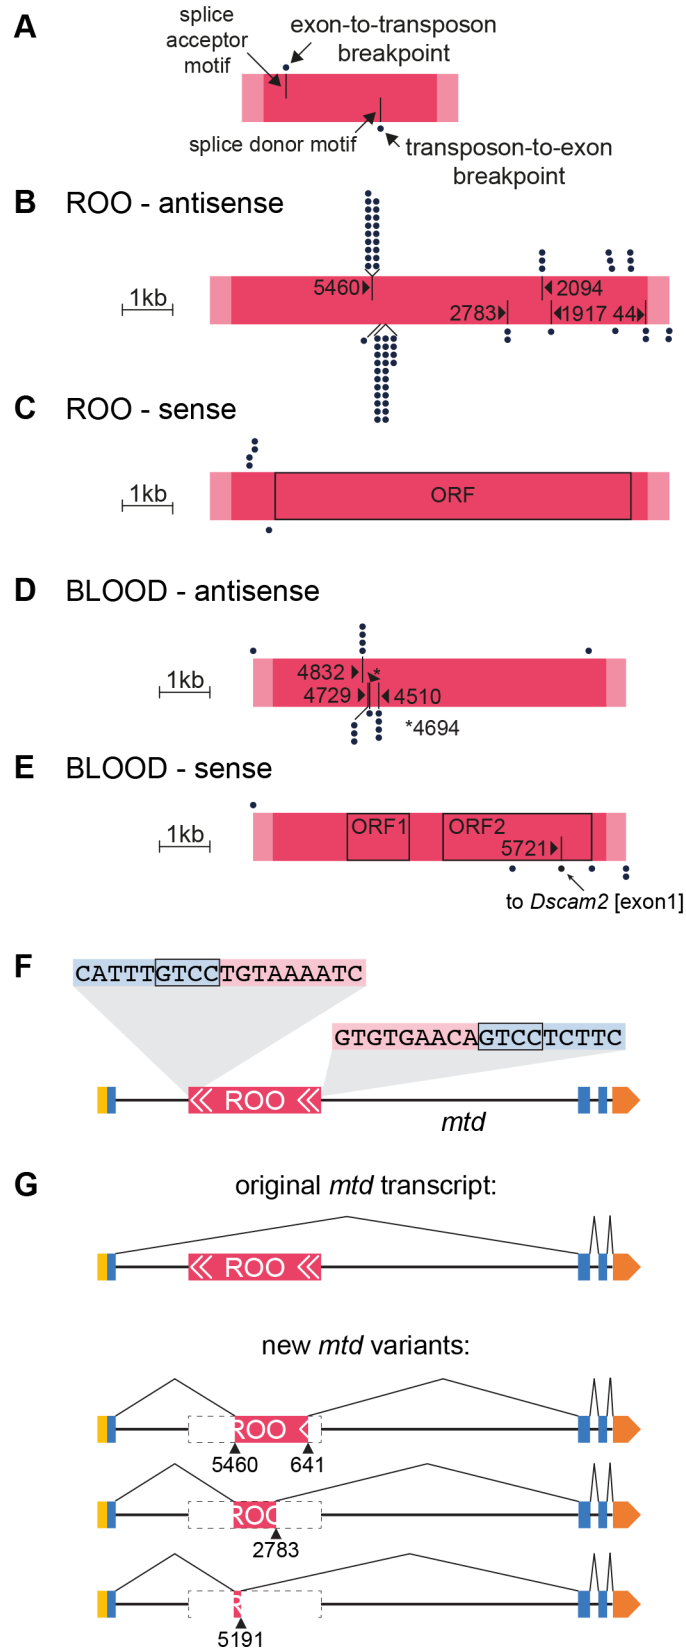

277 Given the abundance of reads that span a gene-transposon breakpoint, we next investigated
278 the structure of these transcripts in more detail. Our transposon mapping identified 887 loci
279 with a germline transposon insertion in the intron of a gene. For each of these we found
280 mRNA molecules where one section mapped to the beginning or end of the transposon and
281 the other section corresponded to the flanking intronic sequence. These reads could
282 represent nascent unspliced chimeric pre-mRNAs from which transposon-derived sequence
283 could be removed by splicing to yield intact host mRNAs, and full-length transposon
284 sequences. However, we also found 148 examples where breakpoint-spanning reads
285 indicate that specific sections of transposon sequence are spliced into host-gene transcripts
286 (Supplemental Table 5).

287

288 Analysis of the breakpoints inside transposons at these 148 sites revealed that chimera are
289 formed at conserved locations in each type of transposon. For example, in cases where an
290 antisense ROO resided within an intron, we found transcripts where the 3'-end of an
291 upstream exon had formed a new phosphate bond to a section of ROO at positions 5460
292 and 2094 at 19 and 3 different genomic loci, respectively, and also at several additional
293 breakpoints with lower frequency (Figure 5a,b). In addition, we identified transcripts where
294 sections of ROO were bound to the 5'-end of a downstream exon. We found breakpoints at
295 position 5191 from 24 genes, two at 2783, and several others at unique positions (note that
296 the numbering runs backward because it relates to the forward orientation of ROO).

297 Whereas intronic antisense ROO provides gene-transposon breakpoints for 28 exons, and
298 transposon-gene breakpoints for 33, intronic sense ROO only introduced 4 and 1 (Figure
299 5c). Similarly, the LTR BLOOD also introduced more breakpoints when it was inserted in the
300 antisense orientation relative to the host gene (14 vs. 6, Figure 5d,e).

Figure 5

302 **Figure 5. Transposons introduce splice sites at conserved locations.**

303 **A** Illustration of the labelling scheme in panels **B-E**. The pink bar represents the transposon;
304 light pink ends indicate the LTRs and the dark pink the core sequence. The positions of the
305 dots above the bar represent the site on the transposon where an upstream exon splice
306 donor site has merged. Every dot represents a different gene. Black lines in the top half of
307 the pink bar represent splice acceptor (SA) motifs in the transposon. Dots below the pink bar
308 indicate the location of breakpoints on the transposon that are spliced to upstream exonic
309 SA sites of different genes. Bars in the lower half indicate splice donor (SD) motifs. **B-E**
310 Representations of sense- and antisense ROO and BLOOD (to scale), with all breakpoints
311 to SA and SD sites of neighboring genes. Note that the frequently used site on antisense
312 ROO at position 5191 is a non-consensus SD site, which lacks the expected GT motif at the
313 immediate breakpoint. The sequence around 5191 resembles the consensus SD motif,
314 although the GT is a GC. Compare TTTGGCAAGTT to motif in Supplemental figure 3a. **F**
315 Illustration of antisense ROO insertion in the *mustard* (*mtd*) gene. Only one isoform of *mtd* is
316 shown. Yellow box represents the 5'UTR, blue boxes are exons, orange box the 3'UTR,
317 pink represents ROO transposon with white arrows indicating the LTRs. Breakpoint-
318 spanning gDNA reads reveal Target Site Duplication (TSD, inset). **G** Schematic of original
319 *mtd* transcript, and of three new splice isoforms.

320 We screened the transposon sections around breakpoints for consensus splice- acceptor
321 (SA) and donor (SD) sequence motifs and found many cases where the gene-to-transposon
322 chimera had been formed at SA consensus motifs, and transposon-to-gene chimera at SD
323 motifs (Stephens and Schneider, 1992) (Supplemental figure 3, Supplemental Table 6). For
324 example, all breakpoints in antisense BLOOD that were formed with more than one exon
325 were precisely located at the predicted SA and SD splice site (Figure 5d). Interestingly, we
326 did not find a consensus SD motif at the transposon-gene breakpoint at position 5191 of
327 antisense ROO, although it frequently provided 5'- sequence to transposon-gene chimeric
328 RNAs. However, the sequence around position 5191 matched the consensus motif, with the
329 exception of a GT-to-GC conversion (see Supplemental figure 3). Taken together, our
330 analysis revealed that transposons introduce many alternative splice sites, which are
331 recognized by the host cell spliceosome to combine cellular exonic sequences with sections
332 of transposon sequence.

333

334 We also identified cases of alternative splicing to different sites within the same transposon
335 insertion. Again using ROO as an example, $\alpha\beta$ Cherry flies harbor a reverse orientation ROO
336 in the intron between exons 10 and 11 of the pan-neurally expressed *mustard* (*mtd*) gene,
337 which to date has only been implicated in fly innate immunity (Wang et al., 2012) (Figure 5f).
338 RNAseq revealed a complex collection of *mtd* splice variants that incorporated different
339 fragments of ROO (Figure 5g). SD sites upstream of this ROO came from the end of either
340 *mtd* exon 11 or 13. and these spliced in to the corresponding SA at position 5462 within
341 ROO (Figure 5g). We also found three different SD sites (at positions 641, 2784 and 5191)
342 within ROO, which spliced out to the closest downstream SA (exon 6) of *mtd*. Therefore, this
343 ROO element substantially increases the *mtd* mRNA isoform repertoire. Without ROO the
344 *mtd* locus can express 23 isoforms whereas with ROO it can generate 68 differentially
345 spliced mRNAs.

346

347 We identified 147 other genes whose transcript diversity was similarly increased by
348 transposon insertions. These alternative transcripts incorporate 43 different transposon
349 families which each introduce cryptic SA and/or SD sites into host genes (see Supplemental
350 Table 5). For example, we found a sense insertion of BLOOD inside the *Dscam2* gene which
351 encodes the transmembrane Down Syndrome cell adhesion molecule 2. Chimeric reads
352 indicate that transcription of *Dscam2* is frequently initiated in BLOOD, which is then spliced
353 into exon 33 (the second exon) of the gene. This splicing event combines ORF2 of BLOOD
354 with the remaining exons of *Dscam2* and correctly aligns the reading frames of the two
355 transcripts, generating a novel N-terminus (Supplemental figure 4). We also observed cases
356 where transposon chimera resulted in exon skipping (e.g. the above mentioned ROO in *mtd*
357 and 412 inside *tequila*, Supplemental figure 5). Most transposon chimera resulted from
358 intronic insertions, but we also detected one case where a HOBO insertion resided in the
359 exon of the *CG31705* gene. This HOBO introduced a cryptic SA site which was spliced to
360 the upstream SD from the first exon, creating a truncated *CG31705* transcript (Supplemental
361 figure 6). Together these data show that a broad range of *Drosophila* transposons are
362 alternatively spliced into mRNAs producing many more isoforms of a large number of
363 neurally expressed genes.

364

365 **Alternative splicing into and out of transposons can be highly penetrant**

366 Chimeric transcripts could be inconsequential to a cell if they only constitute a small
367 percentage of the overall transcript repertoire of a given gene. We therefore quantified the
368 percentage of mRNAs produced from a transposon harboring gene that include transposon
369 sequence. To do this we analyzed sites where transposons were spliced into an exon-intron
370 junction of a gene. For each gene we counted the number of reads spanning transposon-
371 exon boundaries, and the number of reads that spanned the exon immediately up- and
372 downstream of the transposon insertion (Figure 6a). This analysis showed that for some
373 genes, all derived mRNAs contained transposon sequences. For example, all spliced copies
374 of the isoform B of the Allatostatin A receptor 1 (*AstA-R1*) contained a section of ROO, and

375 every transcript of *Piezo-like (Pzl)*, a gene encoding a predicted mechanosensitive ion
376 channel, ended in the I-element instead of exon 1 (Hu et al., 2019; Larsen et al., 2001). All
377 mRNAs retrieved from *Mec2* contained TRANSPAC as the most 5' sequence, suggesting
378 that transcripts might initiate within the TRANSPAC transposon and spliced to the SD of
379 exon 2 of *Mec2*. On average, transposons contributed to 14% of transcripts derived from a
380 specific gene (Figure 6b, Supplemental Table 7). Insertions in genes on the X chromosome,
381 resulted in a higher average percentage of chimeric transcripts (27% vs. 13% for the rest of
382 the genome) and a larger number of cases where 75% or more of transcripts were chimeric.
383 Insertions on the X chromosome are hemizygous in male flies and our samples were
384 generated by pooling an equal number of male and female flies. The increased chimera rate
385 on the X might therefore reflect the smaller number of different X chromosomes when
386 compared to the rest of the genome. For example, we found that the X-linked *cacophony*
387 (*cac*) gene, which encodes a voltage-gated calcium channel, harbored a sense-orientation
388 BLASTOPIA (Smith et al., 1996). This transposon insertion resulted in 54.7% of *cac*
389 transcripts being truncated in $\alpha\beta$ Cherry fly samples, potentially missing the last 8-11 coding
390 exons, suggesting that many flies in this strain are likely mutant for the *cac* gene
391 (Supplemental figure 7). Another interesting example on the X chromosome of $\alpha\beta$ Cherry
392 flies is *Beadex (Bx)* which encodes a long-term memory relevant LIM-type transcription
393 factor (Hirano et al., 2016). A sense NOMAD insertion gives rise to at least two new *Bx*
394 transcript isoforms (Supplemental figure 8), which constitute 9.8% of all *Bx* transcripts.

Figure 6

395

396

397 **Figure 6. High penetrance of transposon-containing splice isoforms.**

398 **A** Schematic showing method used to calculate the frequency of transposon chimera
 399 produced from a given gene. The number of reads that span the exon-transposon junction
 400 were divided by the total number of reads that map beyond the exon-intron junction (exon-
 401 transposon reads plus reads that partially map to the exon immediately downstream of the
 402 transposon insertion. **B** Examples of chimeric transposon-gene transcripts detected in fly
 403 heads. Many genes are almost exclusively expressed as chimeric transcripts with
 404 transposon sequence. See Supplemental Table 7 for complete list.

405 **Splicing into transposons is common and varies between strains**

406 The transposon complement is highly variable between fly strains. We therefore tested
407 whether other fly strains express chimeric gene:transposon mRNAs by analyzing three
408 previously published mRNA sequencing data sets (Croset et al., 2018; Daines et al., 2011;
409 MacKay et al., 2012). Although these prior studies generated shorter paired-end RNAseq
410 reads, than those collected here, we were still able to find chimeric mRNAs in all three data
411 sets (Supplemental Table 8). Some transposon:gene chimera were conserved across all
412 strains, whilst others appeared to be strain-specific. 318 of the 887 chimera identified in our
413 $\alpha\beta$ Cherry flies were present in at least one of the three other data sets, whereas 120 of
414 those occurred in at least three of the four strains. Chimera that were not detected in data
415 from other strains could either reflect genomic heterogeneity between the tested fly strains,
416 or the absence of evidence could result from lower sequencing coverage. Nevertheless,
417 these results demonstrate the prevalence of cellular mRNAs containing transposon
418 sequence.

419 **Discussion**

420 Somatic transposition in neurons has been proposed to contribute to age-dependent
421 neuronal decline in wildtype and disease models of *Drosophila* and (Li, e al., 2013; Guo et
422 al., 2018; Sun et al., 2018). Although the frequency of neural transposition is debated,
423 expression is a prerequisite for movement. Therefore, transposons can only mobilize in cells
424 that express full-length elements, or transposon mRNAs that encode enzymes permitting
425 other elements to move in *trans*. It is therefore important to understand how transposon
426 expression is controlled in the brain. Here, we combined single-cell expression data from the
427 *Drosophila* midbrain with high-coverage gDNA sequence data of the same fly strain and find
428 that the majority, if not all, expressed transposon sequences are parts of chimeric mRNAs
429 with cellular genes.

430

431 Transposons residing in introns have previously been shown to contribute novel exons to
432 several genes (Nekrutenko and Li, 2001). In addition long non-coding (lnc) RNAs frequently
433 contain transposon sequences (Kapusta et al., 2013). We found transposon exonization to
434 be highly prevalent in the *Drosophila* brain. Transposons within the coding regions of genes
435 and those in introns dramatically increase the transcript repertoire by introducing new splice
436 variants. At this stage it is difficult to definitively determine the whole-genome functional
437 consequences of splicing into transposons because we most often only retrieve the
438 sequence across the splice junctions. Furthermore, although each transposon has a known
439 consensus sequence individual copies are highly polymorphic. Nevertheless, our
440 sequencing shows that transposon exonization often truncates and/or changes the amino
441 acid sequence of the encoded gene products, potentially changing protein structure and
442 function. We did also identify several examples where the inclusion of transposon sequence
443 conserved the reading frame of the host gene, likely generating a novel chimeric protein.
444 Amongst the 148 transposon harboring genes identified in this study, there are several that
445 we have described in detail for which the observed locus disruption and altered expression
446 would be expected to have significant consequences for neural function. Flies harboring

447 HOBO in *Sh* and BLASTOPIA in *cac* might exhibit altered voltage-gated currents, whereas
448 those with ROO in *AstA-R1* will respond differently to the modulatory Allatostatin A
449 neuropeptide (Larsen et al., 2001; Smith et al., 1996). We also described insertions of 412 in
450 *teq* and NOMAD in *Bx*, two genes which have been implicated in long-term memory
451 formation (Didelot et al., 2006; Hirano et al., 2016).

452

453 Some transposons provide more splice sites than others. Our analysis of the abundant ROO
454 retrotransposon (found in sense orientation inside 48 genes, and in antisense orientation
455 inside 59 genes in our strain) provides a good example, and the insertion in *mtd* exemplifies
456 the extended variance transposons can introduce to cellular transcription units. Interestingly,
457 antisense insertions of ROO provide more potential SA and SD sites than sense orientation
458 ROO. Insertions of ROO that are sense to the expression of the host gene were found to be
459 mainly part of pre-mRNA, from which functional reverse transcriptase could potentially be
460 translated. In contrast, antisense ROO introduces over 10 times more cryptic splice sites
461 (compare Figure 5b and c).

462

463 mRNA molecules that contain transposon sequences might be susceptible to short-
464 nucleotide mediated gene-silencing (Malone and Hannon, 2009), as recently reported for
465 LINE-2 containing mRNAs and LINE-2 derived microRNAs in humans (Petri et al., 2019).
466 This would provide a challenge for the cells expressing transposon-targeting piRNAs in
467 differentiating between chimeric transcripts and full-length transposon sequences. It is worth
468 noting that transposon-directed piRNAs have been identified in the fly brain (Li et al., 2009).
469 It is therefore conceivable that transposon sequence permits cellular mRNAs to be
470 selectively regulated. In addition, transposon sequence might confer the capacity to be
471 specifically trafficked within the cell, and even between cells (Ashley et al., 2018; Pastuzyn
472 et al., 2018).

473

474 The process of transposable elements acquiring new cellular functions that benefit the host
475 cell is called transposon exaptation (Gould and Vrba, 2013). Several examples of exaptation
476 events during the evolution of eukaryotes have been reported. How these functional
477 transitions occur is, however, not fully understood (Joly-Lopez and Bureau, 2018). Stress-
478 induced transposon mobilization has been observed in many species, and it has been
479 hypothesized that these mobilization events trigger the formation of new transposon-gene
480 chimera. Our results reveal a new mechanism by which transposons participate in the
481 generation of new gene variants. We show that transposons do not need to mobilize in order
482 to form chimeric mRNA molecules. Instead, the cellular gene splicing machinery frequently
483 uses intronic transposon insertions to increase transcriptional diversity.

484

485 Transposon sequences in the gDNA can deliver enhancer elements to cellular genes and
486 thereby influence their expression. However, our results do not support the idea that
487 transposons provide enhancer sequences contributing to neural expression of neighboring
488 genes. If this was the case, we would expect to have found that cellular genes that harbor
489 the same type of transposon are more likely to be expressed in the same cells. Our data
490 instead show that transposon expression is dictated by the genes they are inserted within.
491 This is further supported by the fact that many genes that share transposon insertions with
492 neurally expressed genes were not expressed in the brain.

493

494 Our studies also introduce important practical concerns for the analysis of transposon
495 expression in somatic tissue and disease models. Several previous studies have used
496 Quantitative PCR (qPCR) to measure levels of transposon expression in mutant flies and
497 disease models. Since qPCR probes are usually not designed to cross transposon-gene
498 breakpoints, they cannot distinguish autonomous transposon expression from chimeric
499 mRNA (Guo et al., 2018; Li et al., 2013; Sun et al., 2018). Similarly, standard RNA
500 sequencing protocols rely on the alignment of cDNA fragments to the reference genome and
501 would not identify chimeric reads as non-autonomous transposon expression (e.g. De Cecco

502 et al., 2013). Baseline and changing cell-specific expression of host genes that form
503 chimeric transcripts with transposons can therefore be misinterpreted as cell-restricted
504 autonomous transposon expression and mobilization.

505

506 Our data also constrain somatic transposition. If all transposon expression depends on the
507 neighboring host gene, only cells expressing that host gene can be susceptible to
508 transposition of that element. This would mean that GYPSY could only be active in glia, if
509 the fly strains being studied harbor a copy of GYPSY in a glial-expressed gene (Krug et al.,
510 2017). Interestingly, although we found sense GYPSY sequences in mRNAs for 14 different
511 genes, we did not detect glial GYPSY expression in our $\alpha\beta$ Cherry flies.

512

513 Analysis of RNA-seq data from other fly strains suggests that more than half of the chimeric
514 transposon transcripts we identified in $\alpha\beta$ Cherry flies are unique to this strain. This finding
515 alone demonstrates the incredible heterogeneity of the transposon complement between
516 strains. In addition, our prior genome sequencing revealed large differences between
517 individual $\alpha\beta$ Cherry flies (Treiber and Waddell, 2017). Given the broad range of target genes
518 that we have identified to form chimeric mRNA with transposable elements, it will be
519 important to understand the functional consequences of fixed and variable transposons
520 inside genes for the host organism. Nevertheless, it seems highly likely that polymorphism of
521 transposon load and the distribution of transposons across the host genome could contribute
522 towards heterogeneity of neural function, and neurological pathology, between individual
523 animals.

524 **Methods**

525

526 **Fly strains**

527 All experiments were performed on $\alpha\beta$ Cherry flies, which were generated by crossing
528 MB008b females (Aso et al., 2014) with w^- ; +; UAS-mCherry males. Flies were raised on
529 standard molasses food at 25°C, 40-50% humidity and 12 h:12 h light-dark cycles.

530

531 **Long-read mRNA sequencing**

532 For RNA extraction, groups of ~50 flies were frozen in liquid nitrogen and vortexed for 6 x 30
533 s to separate heads from abdomens. Heads were isolated using a sieve. To avoid gDNA
534 contamination, mRNA was purified with a combination of protocols. Samples were first
535 processed with a column-based kit (RNeasy Mini kit, Qiagen, UK), including the optional on-
536 column DNaseI digestion. Next, mRNA was extracted from total RNA using oligo-dT
537 magnetic beads (NEB, Ipswich, MA) and the mRNA was purified again using the RNA
538 columns. Finally, sequencing libraries were generated using oligo-dT magnetic beads from a
539 strand-specific mRNA library preparation kit (TruSeq, Illumina, San Diego, CA), with 17
540 cycles of PCR amplification. Fragmentation was optimized to obtain ~350nt long fragments.
541 Whole-genome sequencing was performed on a HiSeq 2500, with 250nt paired-end reads.
542 We mapped the long reads using MRTemp, as previously described (Treiber and Waddell,
543 2017).

544

545 **Single-cell read alignments**

546 The *Drosophila melanogaster* reference genome release 6.25 was used for all sequence
547 alignments. Transposon reference sequences were taken from Repbase (Jurka, 2000;
548 Kaminker et al., 2002). Repetitive sequences in the *Drosophila* reference genome were
549 masked using Repeatmasker (Smit et al.). Single-cell sequencing data was processed with
550 a custom-built data processing pipeline, which is available on GitHub. The masked reference

551 genome, as well as a gene reference file (refFlat) with all genes and each unique reference
552 transposon sequence is provided as supplemental data.

553

554 **Single-cell data analysis**

555 Digital Gene Expression (DGE) matrices were generated as previously described (Butler et
556 al., 2018). Rscripts can be downloaded as supplemental file 1. In summary, DGE's were
557 filtered (≥ 800 UMIs, ≥ 400 features) and 8 replicates were merged. Gene and transposon
558 expressions levels were normalized separately. Marker genes were taken from Croset et al.
559 (2018).

560

561 **Co-expression analysis**

562 Co-expression was quantified by calculating the Co-expression Disequilibrium (CD, see
563 main text). The R-code snippet is available through GitHub. For the statistical analysis, a
564 non-parametric test was performed. CD values between every gene- and transposon
565 combination were ranked within each biological replicate, p-values were calculated using the
566 student t-test and corrected for multiple comparisons using the Benjamini-Hochberg
567 correction. In addition, CD values were calculated for every tested transposon with a set of
568 10 randomly assigned genes (or transposons).

569

570 **Mapping germline transposon insertions in the fly**

571 Germline transposon insertions were mapped with single-nucleotide resolution using
572 previously published gDNA data from the $\alpha\beta$ Cherry fly strain and MRTemp (Treiber and
573 Waddell, 2017). A new, purpose-built, multi-functional sequence analysis pipeline called
574 TEchim was developed. TEchim has 5 key functions: 1. generation of support files, including
575 a masked reference genome and endogenous intron-exon junctions. (input files: reference
576 genome, list of genes, list of transposon sequences). 2. alignment of un-stranded genomic
577 DNA sequence data of multiple sequencing lanes and multiple biological replicates,
578 detection of chimeric sequence fragments with single-nucleotide resolution, and the

579 generation of summary output tables. 3. alignment of stranded cDNA data, detection of
580 chimeric fragments, quantification of reads 4. generation of matching immobile genetic
581 elements (IGE, see main text), analysis of these IGEs. These data are then used to
582 determine sample-specific detection thresholds. 5. Quantification of LTR-gene and LTR-
583 transposon reads (see Figure 4). Detailed descriptions and manuals are available on Github.

584

585 **Splice acceptor (SA) and donor (SD) motif analysis**

586 SA and SD motifs in the *Drosophila melanogaster* reference genome were generated by
587 randomly selecting 500 known SA and SD sites from exons and screening for motifs in these
588 sequences using the MEME suite (Bailey and Elkan, 1994) (Supplemental figure 3). These
589 motifs were then searched in sequence sections across transposon-gene breakpoints using
590 FIMO (Grant et al., 2011).

591

592 **Data from previously published studies**

593 Raw single-cell sequencing reads from Croset et al. (2018) was obtained from the NCBI
594 Short Read Archive (SRA <https://www.ncbi.nlm.nih.gov/sra>) with the accession number:
595 PRJNA428955. Genomic DNA data from Treiber and Waddell (2017) was obtained from the
596 Dryad Digital Repository (<https://doi.org/10.5061/dryad.fd930>).

597 **Data Access**

598 All processed data is presented in Supplemental Tables 1-8. All raw sequencing data
599 generated in this study have been submitted to the NCBI SRA with the BioProject ID
600 PRJNA588978. Custom-built software packages can be accessed via GitHub
601 (<https://github.com/charlieforia/TEchim> and
602 <https://github.com/charlieforia/scHardyWeinberg>)

603

604 **Acknowledgements**

605 We are grateful to other members of the Waddell group for discussion. CT was supported by
606 a Wellcome Trust DPhil studentship. SW is funded by a Wellcome Principal Researcher

776

777 **Supplemental figures**

778

779

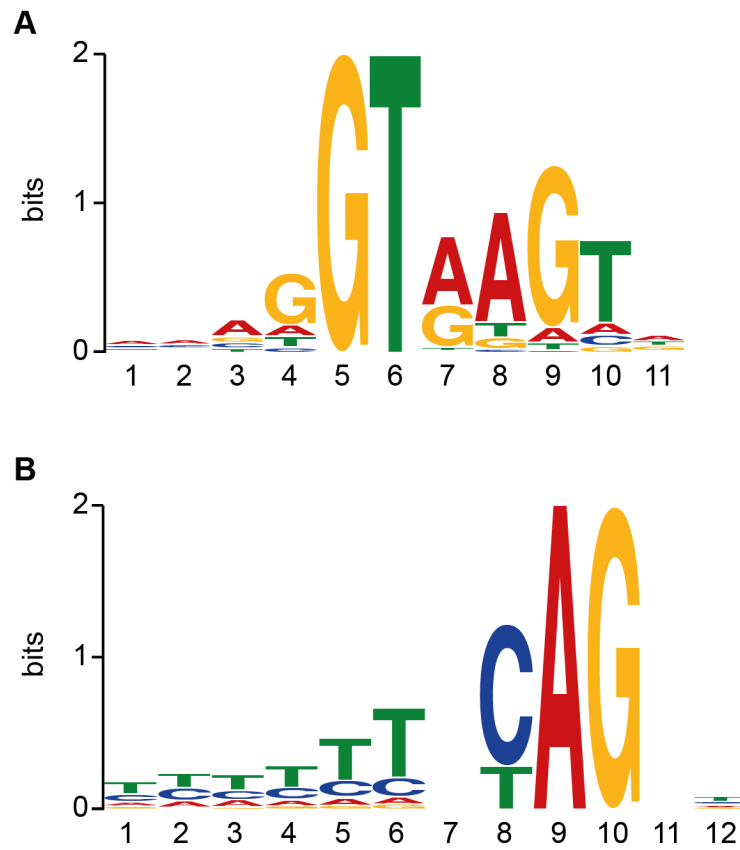

780 **Supplemental figure 1. Sense strand transposon transcripts are twice as abundant as**
781 **antisense strand transcripts in the *Drosophila* midbrain.**

782 Graph showing mean expression levels across the entire midbrain of all sense and
783 antisense transposon sequences. Each data point (cross) represents one biological
784 replicate.

Supplemental figure 2. Transposon expression patterns are stereotyped across biological replicates.

tSNE based on transposon expression levels showing all 8 biological replicates. Each replicate contributes cells to each cluster.

791

792

793 **Supplemental figure 3. Splice acceptor and donor motifs.**

794 **A** Splice acceptor motif, taken from 500 randomly chosen exon-intron junctions of

795 *Drosophila* genes. **B** splice donor motif.

original *Dscam2* transcript:

new *Dscam2* variant:

*in frame with BLOOD ORF2

796

797

798 **Supplemental figure 4. Sense BLOOD insertion in *Dscam2*.**

799 Schematics of *DScam2* mRNAs produced from locus containing BLOOD. Top shows the
800 nascent transcript spliced around the intronic full-length sense BLOOD insertion. Bottom
801 illustrates a new mRNA splice isoform, which reads through in frame from the ORF2
802 sequence of BLOOD into exon 2 of *DScam2*. The breakpoint in BLOOD is a consensus SD
803 motif. 23.2% of all *Dscam2* transcripts in fly heads are chimeric with BLOOD.

original *teq* transcripts:

new *teq* variants:

804

805

806 **Supplemental figure 5. Sense 412 insertion in *tequila*.**

807 Schematics of *teq* mRNAs produced from locus containing full-length sense orientation 412

808 insertion. Top, original transcripts of *teq* splicing around 412. Bottom, and new *teq* splice

809 isoforms that include 412 sequence. 83.9% of *teq* transcripts contain 412 transposon

810 sequence. In addition, 22.4 % of 412 containing mRNAs skip exon 5 of *teq*. In 0.5% of cases

811 exons 2-5 are skipped.

original *CG31705* transcript:

new *CG31705* variants:

812

813

814 **Supplemental figure 6. Antisense HOBO insertion in *CG31705*.**

815 Schematic of *CG31705* mRNAs produced from locus containing exonic antisense HOBO

816 insertion. Transcripts containing unspliced HOBO and two additional new splice isoforms

817 that are generated by alternative splicing into HOBO are shown.

818

819

820 **Supplemental figure 7. Sense BLASTOPIA insertion in *cacophony*.**

821 Schematic *cac* transcripts produced from locus containing a full-length intronic sense

822 BLASTOPIA insertion (the orientation is 5' (left) to 3' (right)). A regular *cac* transcript is

823 produced by splicing around the BLASTOPIA insertion and a new truncated *cac* isoform

824 results from splicing into BLASTOPIA. The *cac* gene is on the X chromosome, and 54.7% of

825 *cac* transcripts in the fly head are truncated by splicing into BLASTOPIA.

original *Bx* transcript:

new *Bx* variants:

9.8% new variant

826

827

828 **Supplemental figure 8. Sense NOMAD insertion in *Bx*.**

829 Schematic showing mRNAs produced from locus containing sense intronic NOMAD
830 insertion. Original transcript of *Bx* is generated by splicing around NOMAD. New splice
831 isoforms contain fragments of NOMAD. 9.8% of transcripts that start with the *Bx* 5'UTR are
832 spliced into NOMAD.
