24

25 **Abstract**

26 Here we report the discovery of Yaravirus, a new lineage of amoebal virus with a
 27 puzzling origin and phylogeny. Yaravirus presents 80 nm-sized particles and a 44,924
 28 bp dsDNA genome encoding for 74 predicted proteins. More than 90% (68) of
 29 Yaravirus predicted genes have never been described before, representing ORFans.
 30 Only six genes had distant homologs in public databases: an exonuclease/recombinase,
 31 a packaging-ATPase, a bifunctional DNA primase/polymerase and three hypothetical
 32 proteins. Furthermore, we were not able to retrieve viral genomes closely related to
 33 Yaravirus in 8,535 publicly available metagenomes spanning diverse habitats around
 34 the globe. The Yaravirus genome also contained six types of tRNAs that did not match
 35 commonly used codons. Proteomics revealed that Yaravirus particles contain 26 viral
 36 proteins, one of which potentially representing a novel capsid protein with no
 37 significant homology with NCLDV major capsid proteins but with a predicted double-
 38 jelly roll domain. Yaravirus expands our knowledge of the diversity of DNA viruses.
 39 The phylogenetic distance between Yaravirus and all other viruses highlights our still
 40 preliminary assessment of the genomic diversity of eukaryotic viruses, reinforcing the
 41 need for the isolation of new viruses of protists.

42

43 **Significance statement**

44 Most of the known viruses of amoeba have been seen to share many features that
 45 eventually prompted authors to classify them into common evolutionary groups. Here
 46 we describe Yaravirus, an entity that could represent either the first isolated virus of

47 *Acanthamoeba* spp. out of the group of NCLDV's or, in alternative evolutive scenario, it
 48 is a distant and extremely reduced virus of this group. Contrary to what is observed in
 49 other isolated viruses of amoeba, Yaravirus is not represented by a large/giant particle
 50 and a complex genome, but at the same time carries an important number of previously
 51 undescribed genes, including one encoding a novel major capsid protein. Metagenomic
 52 approaches also testified for the rarity of Yaravirus in the environment.

53

54 **Introduction**

55 Viral evolution and classification have been subject of an intense debate, especially
 56 after the discovery of giant viruses that infect protists (1-4). These viruses are
 57 predominantly characterized by the large size of their virions and genomes encoding
 58 hundreds to thousands of proteins, of which a large proportion currently remains
 59 without homologs in public sequence databases (5-9). These coding sequences are
 60 commonly referred as ORFans, and due to the lack of phylogenetic information, their
 61 origin and function still represent a mystery (10-13). Strikingly, the increasing number
 62 of available viral genomes demonstrate that there is a huge set and great diversity of
 63 genes without homologs in current databases, which need to be further explored (10).
 64 Importantly, many amoebal virus ORFan genes have already been proven to be
 65 functional, being expressed and encoding for components of the viral particles (6, 14).
 66 However, the large set of ORFans makes it difficult to predict the biology of viruses
 67 discovered through cultivation-independent methods, such as metagenomics analysis,
 68 reinforcing the need for the complementary isolation and experimental characterization
 69 of new viruses.

70 All currently known isolated amoebal viruses are related to nucleocytoplasmic large
 71 DNA viruses (NCLDV's) (15). This group comprises families of eukaryotic viruses

72 (*Poxviridae*, *Asfarviridae*, *Iridoviridae*, *Ascoviridae*, *Phycodnaviridae*, *Marseilleviridae*
73 and *Mimiviridae*) as well as other amoebal virus lineages including pithoviruses,
74 pandoraviruses, molliviruses, medusaviruses, pacmanviruses, faustoviruses,
75 klosneuviruses and others. NCLDV s have dsDNA genomes and were proposed to share
76 a monophyletic origin based on criteria that include the sharing of a set of ancestral
77 vertically inherited genes (16, 17). From this handful set of genes, a core gene cluster is
78 found to be present in almost all members of the NCLDV s, being composed by five
79 distinct genes, namely a DNA polymerase family B, a primase-helicase, a packaging
80 ATPase, a transcription factor and a major capsid protein (MCP) for which the double
81 jelly-roll (DJR) fold constitutes the main protein architectural class (18, 19). Recently,
82 the International Committee on Taxonomy of Viruses (ICTV) brought forward a
83 proposal for megataxonomy of viruses. The DJR major capsid protein (MCP)
84 supermodule of DNA viruses is present in NCLDV s and other icosahedral viruses that
85 infect prokaryotes and eukaryotes. In addition to the signature DJR-MCPs, the majority
86 of these viruses also encode for additional single jelly roll minor capsid proteins (e.g.,
87 penton proteins) and genome packaging ATPases of the FtsK-HerA superfamily.
88 According to this proposal, the evolutionary conservation of the three genes of the
89 morphogenetic module in the DJR-MCP supermodule, to the exclusion of all other
90 viruses, justifies the establishment of a realm named *Dividnaviria*. Although some
91 NCLDV s, as pandoraviruses, seem to have lost the DJR-MCP gene, their genome
92 present a large set of genes that support their classification into NCLDV s (and
93 *Dividnaviria*, consequently).
94 Here we describe the discovery of Yaravirus, an amoeba virus with a puzzling origin
95 and phylogeny. Yaravirus does not present all the three hallmark genes of *Dividnaviria*,
96 lacking for an identifiable sequence of single jelly roll minor capsid protein. In addition,

97 Yaravirus has an enigmatic genome whose near full set of genes are ORFans. Yaravirus
98 can represent either the first isolated virus of *Acanthamoeba* spp. out of the group of
99 NCLDV. This virus has particles with a canonical size of 80 nm, escaping the concept
100 of large and giant viruses. Thus, Yaravirus expands our knowledge about viral diversity
101 and challenges the current classification of DNA viruses.

102

103

104 **Results**

105 **Yaravirus isolation and replication cycle**

106 A prospecting study was conducted by collecting samples of muddy water from creeks
107 of an artificial urban lake called Pampulha, located at the city of Belo Horizonte, Brazil.
108 Here, by using a protocol of direct inoculation of water samples on cultures of
109 *Acanthamoeba castellanii* (Neff strain, ATCC 30010), we have managed to isolate a
110 new amoebal virus that we named Yaravirus brasiliensis, as a tribute to an important
111 character (Yara, the mother of waters) of the mythological stories of the Tupi-Guarani
112 indigenous tribes (20). Negative staining revealed the presence of small icosahedral
113 particles on the supernatant of infected amoebal cells, measuring about 80 nm diameter
114 (Fig. 1a). Cryo-electron microscopy images of purified particles suggest that Yaravirus
115 particles present two capsid shells, as previously described for Faustovirus (21).
116 At the beginning of infection in *A. castellanii*, Yaravirus particles are found attached to
117 the outside part of the amoebal plasma membrane, suggesting the participation of a host
118 receptor in order to internalize the virions (Fig. 1b). The replication cycle is then
119 followed by the incorporation of individual or grouped Yaravirus particles inside
120 endocytic vesicles, which in a later stage of infection are found next to a region
121 occupied by the nucleus (Fig. 1b-d). The viral factory then takes place and completely

122 develops into its mature form, replacing the region formerly occupied by the cell
 123 nucleus and recruiting mitochondria around its boundaries, likely to optimize the
 124 availability of energy to construct the virions (Fig. 1e). The step corresponding to viral
 125 morphogenesis happens similarly as how it is observed for other viruses of amoeba.
 126 Firstly, it starts by the appearance of small crescents in the electron-lucent region of the
 127 factory (Fig. 1e, Fig. 2a). Next, step by step the virions gain an icosahedral symmetry
 128 by the sequential addition of more than one layer of protein or membranous components
 129 around its structure (Fig. 2a). The constructed virions, with a capsid still empty, start
 130 then to migrate to the periphery of the viral factory where there is the accumulation of
 131 corpuscular electron-dense material (Fig. 1e, Fig. 2b-c). These enucleations are
 132 scattered throughout the periphery of the infected cell and seem to represent different
 133 regions or morphogenesis points where the final step for Yaravirus maturation occurs.
 134 In these regions the capsid of Yaravirus is filled with electron-dense material and the
 135 virus is finally ready to be released (Fig. 2c – red arrow). Sometimes it is also possible
 136 to observe several particles of Yaravirus being packed in the interior of vesicle-like
 137 structures, suggesting a potential release by exocytosis, as observed for other viruses of
 138 amoeba (22, 23) (Fig. 2d). Most of the viral shedding, however, is still represented by
 139 lysis of the amoebal cell, followed by the release of Yaravirus particles, which later
 140 reach the supernatant of the infected culture, or sometimes might get attached to the
 141 debris of the cellular membranes (Fig. 2e). We have also evaluated Yaravirus
 142 replication by concomitantly investigating the decrease of the host cell numbers allied
 143 with the increase of viral genome during infection. Interestingly, during the first hours
 144 of infection, the *A. castellanii* cultures seem to progressively grow until 24 h.p.i,
 145 showing a fastidious character for Yaravirus replication (Fig. 2f). The cells then start to
 146 suffer lysis induced by the virus only after the 72 h.p.i (Fig. 2f). On the same level, from

147 96 h.p.i to 7 days post infection there is no change on the detection levels of Yaravirus
148 genome and the lysis seems to stop, and the remaining trophozoites turn to cysts (data
149 not shown).

150

151 Genome

152 Sequencing of the Yaravirus genome has shown the presence of a double-stranded DNA
153 molecule with a length of 44,924 bp and harboring a total of 74 predicted genes (Fig.
154 3a). Despite a smaller genome than other viruses of amoeba, Yaravirus encodes for six
155 tRNA genes: tRNA-Ser (gct), tRNA-Ser (tga), tRNA-Cys (gca), tRNA-Asn (gtt),
156 tRNA-His (gtg) and tRNA-Ile (aat) (Fig. 3a and c). All of them are co-located on an
157 intergenic region between genes 29 and 30 (Fig. 3a and c). In contrast to tRNA genes in
158 tupanviruses, we did not observe a correlation between the Yaravirus tRNA
159 isoacceptors and the codons most frequently used by the virus or its *A. castellanii* host.
160 The genome has a GC content of 57.9%, which is one of the highest found in any
161 amoebal virus discovered to date. When analyzed gene-by-gene, Yaravirus has a
162 spectrum of GC content that varies between 46% and 65%. The analysis of the
163 intergenic regions of the genome (46% GC content) did not reveal any enriched
164 sequence motifs that might indicate a conserved promoter, opposed to what is observed
165 in many other NCLDV members (24).

166 By considering only the portions of genome related to coding regions, Yaravirus also
167 has a similar coding capacity as observed in other viruses when their genome was first
168 annotated, approximately 90%.

169 Surprisingly, Yaravirus genome annotation showed that none of its genes matched with
170 sequences of known organisms when we compared them at the nucleotide level. When
171 we looked for homology at the aminoacid levels, we found that only two predicted

172 proteins had hits in the Pfam-A database and in total six had distant matches in the nr
173 database. Complimentary prediction of three-dimensional structures of these proteins
174 indicated a potential function of 4 more genes (see the proteomics analysis). Taken
175 together, more than 90% (68) of the Yaravirus predicted genes are ORFans, something
176 not observed for amoebal viruses since the discovery of the pandoraviruses (even after
177 using a more relaxed criteria, BLASTp, e-value $< 10^{-3}$) (Fig. 3b) (25). The six genes
178 whose product has some homology with known protein sequences (Fig. 3b) (Table 1)
179 are homologous to fragments of proteins predicted to have different functions, such as
180 an exonuclease/recombinase bacterial protein (gene 2; best hit: *Timonella senegalensis*),
181 a hypothetical protein (gene 3; best hit: *A. castellanii*), a hypothetical protein (gene 28;
182 best hit: *Acytostelium subglobosum* LBI - a dictyostelid), a packaging ATPase (gene
183 40; best hit: Pleurochrysis endemic virus), a conserved hypothetical protein (gene 46;
184 best hit: Melbournevirus, a marseillevirus strain) and a bifunctional DNA
185 primase/polymerase (gene 69; best hit: *Marinobacter* sp – *Alpha* proteobacteria) (Table
186 1).

187 Phylogenetic analyses were then performed for those different genes (genes 02, 03, 28,
188 40, 46 and 69) after aligning them with protein sequences of similar function belonging
189 to different members of the virosphere and to organisms of the three cellular domains of
190 life. Given the lack of representatives on already known databases other than their best-
191 hits, sequences corresponding to the genes 03 and 28 (both hypothetical proteins) didn't
192 have enough genetic information to be included in a phylogenetic analysis. For analysis
193 corresponding to the gene 02 (exonuclease/recombinase), three major groups were
194 observed to construct the morphology of the tree. Yaravirus was observed to be placed
195 in one of those branches, clustering with some members of Eukarya, specifically with
196 stony coral and insects (Fig. 4). Analyses of gene 40 (virion packing ATPase) revealed

that Yaravirus clustered in a polyphyletic branch, with members belonging to *Mimiviridae* family, bacteria (although many of these sequences seem to represent misclassified NCLDV from metagenome-assembled genomes) and *Pleurochrysis* sp. endemic virus 1a and 2. For the phylogenetic analyses corresponding to gene 46 (hypothetical protein conserved in *Marseillevirus*), Yaravirus clustered with *Marseillevirus* strains. For the last tree, representing analysis for gene 69 (bifunctional DNA primase/polymerase), we have observed that Yaravirus shares a cluster with members of eukaryotes corresponding to the *Streblomastix* and *Phytophthora* groups. However, it should be noted that in a previous study the authors detected sequences of mimivirus genes among the *Phytophthora* parasitic strain INRA-310 genome (26). After all those analyses, it is important to note that although Yaravirus has some genes with representatives in the genome of other organisms, their homology with orthologs is very low (25.24 to 44.12%), highlighting that Yaravirus genome content is essentially novel among the other members of the virosphere (Table 1).

In order to detect sequences related to Yaravirus we surveyed 8,535 publicly available metagenomes in the IMG/M database that have been generated from samples from diverse habitats across our planet (27). We discovered distant homologs of the Yaravirus ATPase (NCVOG0249) with an amino acid homology of up to 33.9% in the metagenomic data, while the closest homolog in the NCBI nr database was that of *Pleurochrysis* sp. endemic virus 1a with 33.1%. In a phylogenetic tree of the viral ATPase the Yaravirus branched within the *Mimiviridae* as part of a highly supported clade made up by its distant metagenomic relatives and three viruses whose genomes were deposited in NCBI Genbank and named *Pleurochrysis* sp. endemic virus 1a, 1b and 2 (Fig. 5). In contrast to known members of the *Mimiviridae*, viral contigs and viral genomes in this clade featured a high GC content with up to 62%. We also searched for

222 proteins similar to the Yaravirus putative MCP but were not able to retrieve closely
223 related sequences in the metagenomic data.

224

225 **Yaravirus proteomics**

226 As aforementioned, most Yaravirus proteins had no detectable homologs in public
227 databases and, from a first perspective, the virus did not encode for capsid proteins. This
228 peculiarity prompted us to have a closer look at the proteins responsible to form the
229 mature particles of Yaravirus. Proteomics revealed a total of 26 viral proteins present in
230 purified particles. We then analyzed the predicted three-dimensional structures of those
231 26 proteins, by using two platforms for domain comparison, the Phyre2 and the Swiss-
232 model tools (28-33). Remarkably, only 4 sequences (genes 11, 12, 41 and 46) were
233 observed to have structural features similar to known proteins (Table 2). That means
234 that almost 90% of its virion proteome consists of ORFans. It is important to mention
235 that the same approach (in silico structure prediction) has been used in parallel to
236 evaluate all of the 74 predicted genes on the genome of Yaravirus, resulting in the
237 discovery of two more genes with structural resemblance with other proteins in public
238 databases (gene 02 and 70) (Table 2).

239 Proteomics data revealed that the most abundant proteins in the viral particles
240 corresponded to genes 41, 46 and 51 (from most to less abundant) (Table 2). While for
241 the third highest expressed protein we were not able to find any structural candidates
242 with known biological function, for sequences represented by the genes 41 and 46 we
243 observed fragments of protein resembling the three-dimensional structure of the capsid
244 of other viruses (Table 2). With a confidence of 97%, a relevant portion (65%) of the
245 gene 41 was found to have a structural convergence with the double-jelly roll domain of
246 the MCP of the Paramecium bursaria Chlorella virus type 1. Gene 46 encoded predicted

247 protein was found to have structural convergence with bacterial secreted protein pcsB
248 and tail needle protein, a portion composed of a long alpha-helix. The function of
249 protein encoded by gene 46 remains to be investigated. Therefore, we were not able to
250 find convincingly any minor capsid protein. It is also important to note that sequences
251 represented by the gene 46 are the same described earlier to be highly conserved
252 (although with unknown function) in marseilleviruses and in medusaviruses (Table 1).
253 Finally, the last two proteins observed in the proteomics which had structural deposits
254 in public databases are represented by the genes 11 and 12, both expressing predicted
255 complement C1-qlike proteins.

256

257 **Discussion**

258 In the last years, amoebal large and giant viruses have frequently been found around the
259 world (5-9, 20, 22, 25, 34-37). Here, we describe Yaravirus brasiliensis, an 80 nm-sized
260 virus with a genome containing a notable proportion of genes (~90%) that have never
261 been observed before. Using standard protocols, our very first genetic analysis was
262 unable to find any recognizable sequences of capsid or other classical viral genes in
263 Yaravirus. This is a relevant feature to highlight the importance of studies related to the
264 isolation of new viral samples, as by following the current metagenomic protocols for
265 viral detection, Yaravirus would not even be recognized as a viral agent (38, 39).

266 According to our knowledge, Yaravirus represents the first virus isolated in

267 *Acanthamoeba* spp. that is potentially not part of the complex group of NCLDVs.

268 Several characteristics unite previously discovered amoebal viruses: large-sized virions,

269 genomes coding for hundreds to thousands of genes and presumably a monophyletic

270 origin that is reflected in the presence of a set of about 20 most likely vertically

271 inherited genes (16, 17). None of these features are present in Yaravirus, and that makes

272 it potentially the first isolate of a novel *bona fide* group of amoebal virus. Of course, we
273 cannot exclude the possibility that Yaravirus may represent a reduced NCLDV,
274 presenting highly divergent or even absent NCLDV hallmark proteins. Recently, a
275 similar case was described for three small crustacean viruses. However, despite their
276 reduced genome when compared to other members of the NCLDV, an important
277 number of hallmark genes were shared with this group, differently as observed for
278 Yaravirus (40). In this scenario, not less exciting, Yaravirus would represent the to-date
279 smallest member of the NCLDVs, both in particle and genome size. The presence of six
280 copies of tRNAs in Yaravirus also impresses when analyzed by the perspective of a
281 selective pressure forcing to maintain these genes in such a small genome, when
282 compared to larger viruses of amoeba. Even more interestingly, none of the isoacceptors
283 related to the Yaravirus tRNAs corresponds to codons of amino acids abundantly used
284 by the virus or the amoeba. Considering the fastidious infection cycle of Yaravirus in
285 *Acanthamoeba*, it is conceivable that in nature a different organism might act as the
286 preferred host of Yaravirus.

287 Most members of the to date isolated giant viruses of amoeba show a capsid specially
288 composed by copies of an MCP related to the D13L of *Vaccinia virus* (14, 41).
289 Pandoraviruses are an exception as they seem to lack a protein shell to protect their
290 genomes (25). Interestingly, even some of the amoeba hosts of these viruses may carry
291 copies of MCP genes, suggesting possible horizontal gene transfer between virus and
292 protist host (42, 43). Even though the Yaravirus capsid does not seem to be homologous
293 to the NCLDV MCP, one of its most abundant proteins features the same architectural
294 double-jelly roll observed in the MCP of giant viruses. This highlights how proteins
295 with completely undescribed sequences might be shaped by evolutionary convergence
296 to play important biological functions (44). Taken together, we can conclude that

297 Yaravirus represents a new lineage of viruses isolated from *A. castellanii* cells. The
298 amount of unknown proteins composing the Yaravirus particles reflects the variability
299 existing in the viral world and how much potential of new viral genomes are still to be
300 discovered.

301

302 **Methods**

303

304 **Origin of samples and viral isolation**

305 In 2017, searching to isolate novel variants of virus-infecting amoebas, we have
306 collected samples of muddy water from a creek of the Pampulha lake, an artificial
307 lagoon located at the city of Belo Horizonte, Brazil (19°51 0.60S and 43°58 18.90W).
308 As soon as they were collected, the samples were quickly taken to our lab and stored at
309 4°C until they were further processed. Following the protocol, 4×10^4 amoebas of the
310 *Acanthamoeba castellanii* Neff strain (ATCC 30010) were seeded in each well of a 96-
311 well plate, inoculating to each one a volume of around 100uL of the collected samples,
312 originally diluted 1:10 in PBS buffer. The plates were then incubated for 7 days at 32°C
313 and observed daily for the appearance of cytopathic effect, what may indicate a
314 probable viral infection. All the content from the wells was then collected and submitted
315 to three processes of freezing and thawing and analysis of the possible isolates by
316 negative staining technique. By the end, the collected content was submitted to another
317 two blind passages in fresh cultures of amoeba, but this time, in 25 cm² Nunc™ Cell
318 Culture Treated Flasks with Filter Caps (Thermo Fisher Scientific, USA) containing
319 around 1 million amoebal cells. After viral isolation, all the following experiments were
320 made by infecting *Acanthamoeba castellanii* cells in a low multiplicity of infection
321 (MOI), given the Yaravirus fastidious replication cycle.

322

323 **Transmission electron microscopy (TEM), TEM tomography, cryo-electron**

324 **microscopy**

325 For resin embedding and transmission electron microscopy (TEM) *Acanthamoeba*
 326 *castellanii* cells infected with Yaravirus were fixed at 20 hours post-infection with 2.5
 327 % glutaraldehyde in 0.1M sodium cacodylate buffer. Cells were washed three times
 328 with a solution of 0.2M saccharose in 0.1M sodium cacodylate. Cells were post-fixed
 329 for 1h with 1% OsO₄ diluted in 0.2M Potassium hexa-cyanoferrate (III) / 0.1M sodium
 330 cacodylate. After washes with distilled water, cells were gradually dehydrated with
 331 ethanol by successive 10 min baths in 30, 50, 70, 96, 100 and 100 % ethanol.
 332 Substitution was achieved by successively placing the cells in 25, 50 and 75 % Epon
 333 solutions for 15 min. Cells were placed for 1 h in 100 % Epon solution and in fresh
 334 Epon 100 % over-night at room-temperature. Polymerization took place with cells in
 335 fresh 100 % Epon for 48 h at 60°. Ultra-thin 70 or 300 nm thick sections were cut with a
 336 UC7 ultramicrotome (Leica) and placed on HR25 300 Mesh Copper/Rhodium grids
 337 (TAAB, UK). Ultra-thin sections were contrasted according to Reynolds (45). Electron
 338 micrographs were obtained on a Tecnai G²⁰ TEM operated at 200 keV equipped with a
 339 4096 × 4096 pixels resolution Eagle camera (FEI)). For tomography, gold
 340 nanoparticles 10 nm in diameter (Ref. 741957; Sigma-Aldrich) were deposited on both
 341 faces of the sections prior to contrasting. Tomography tilt series were acquired on the
 342 G²⁰ Cryo TEM (FEI) with the Explore 3D (FEI) software for tilt ranges of 110° with 1°
 343 increments. The mean applied defocus was −2 µm. The magnification ranged between
 344 3500 and 29,000 with pixel sizes between 3.13 and 0.37 nm, respectively. The image
 345 size was 4096² pixels. The tilt-series were aligned using ETomo from the IMOD
 346 software package (University of Colorado, USA) by cross-correlation (46). The

tomograms were reconstructed using the weighted-back projection algorithm in ETomo from IMOD. The average thickness of the obtained tomograms was $268,40 \pm 64$ nm ($n = 16$). Fiji/ImageJ (NIH, USA) was used for making tomography movies (47).

For cryo-electron microscopy assays, the supernatant of infected cultures of *Acanthamoeba castellanii* was collected after 7 days post-infection and submitted to a first round of centrifugation, at 1500g for 10 min, looking to pellet the cell debris from the virus present on the supernatant. Next, the portion containing the Yaravirus was then submitted to a second round of centrifugation, and the virus was concentrated by ultracentrifugation at 100.000g for 2h. The following steps were previously described by Klose et al (21). Briefly, the μ l of virus solution were placed on glow discharged C-Flat 2/2 grids (EMS) and plunge frozen into liquid ethane using a Gatan Cryoplunge 3. Samples were then imaged on a Talos F200C (ThermoFisher Scientific) equipped with a Ceta camera (ThermoFisher Scientific).

Genome sequence and analysis

The Yaravirus genome was sequenced two times by using the Illumina Miseq platform (Illumina Inc., San Diego, CA, USA) with the paired-end application. The generated reads were then assembled *de novo* by using the software ABYSS and SPADES, with the resulting contigs ordered by the Python-based CONTIGuator.py software. After, gene predictions were made by using the GeneMarkS tool (48). The functional annotation for the Yaravirus predicted proteins was made through searches against the GenBank NCBI non-redundant protein sequence database (nr), considering homologous proteins only the sequences that presented an e-value $< 1 \times 10^{-3}$. For the

370 qPCR assays, the increase in genome replication was assessed in cultures of
371 *Acanthamoeba castellanii* cells infected by Yaravirus in different time points (H4, H6,
372 H8, H12, H24, H72, H96 and H168), using primers which were constructed based on
373 the sequence of the gene 69 of Yaravirus (primers:
374 5'TGCAGCAAGTCGGTCAAGAT3' and 5'AACTTCCACATGCGAAACGC3').
375 Conditions used in the assay were previously described (49).

376 The aminoacid and codon usage data was compared to those presented by
377 *Acanthamoeba castellanii* and by different strains of amoebal viruses. For this, the
378 sequences were downloaded from the NCBI database and analyzed by using the
379 software Artemis 18.0.3. The % of GC content and GC skew have also been analyzed
380 by using the same software. Transfer RNA (tRNA) sequences were identified using the
381 ARAGORN tool.

382 Phylogenetic analyses were performed for the six proteins of Yaravirus holding
383 similarities with other organisms on the NCBI database (Table 1). By using the Clustal
384 W tool in the Mega 10.0.5 software program, aminoacid sequences of these Yaravirus
385 proteins were previously aligned with the corresponding sequences of representatives of
386 the virosphere and from other cellular organisms belonging to the three Domains of
387 Life. All the trees were constructed by using the maximum likelihood evolution method,
388 with the JTT matrix-based model and a bootstrap of 1000 replicates (50).

389

390 **Yaravirus proteomics**

391 In order to identify the proteins that make up Yaravirus particles, thirty 75cm²
392 cell culture flasks (Nunc, USA), containing 7x10⁶ *Acanthamoeba castellanii* cells/flask,
393 were infected with the isolated virus and the cytopathic effect was followed up to 7

d.p.i. After severe amoebal lysis, the content was collected and submitted to a first round of centrifugation, at 1500g for 10 min, looking to pellet the cell debris from the virus present on the supernatant. Then, this viral portion was submitted to a second round of centrifugation, and the virus was concentrated by ultracentrifugation at 100,000g for 2h. To finish, viral pellet was then prepared for a 2D gel electrophoresis and analysis by MALD-TOF and LC-MS/MS as described before by Reteno and colleagues (51)

401

402 **Metagenomic survey**

The Yaravirus ATPase (NCVOG0249) and the putative Major Capsid Protein (MCP) were used to query 8,535 publicly available metagenomes in the IMG/M database (27) using diamond blastp (v0.9.25.126, (52)). Resulting protein hits with more than 30% query and subject coverage and an E-value of at least 1e-5 were extracted from the metagenomic data. In parallel, hmmsearch (version 3.1b2, hmmer.org) was employed to identify and extract ATPases (NCVOG0249) and MCPs from 235 NCDLV reference genomes using specific hidden Markov models (<https://bitbucket.org/berkeleylab/mtg-gv-exp/>). Extracted proteins were then combined with the Yaravirus queries, aligned with MAFFT-linsi (v7.294b,(53)) (ATPase) and MAFFT (MCP) and the resulting amino acid alignments trimmed with trimal (v1.4, -gt 0.9, (54)). Phylogenetic trees were built using IQ-tree (v1.6.12, (55)) with LG+F+R5 (ATPase) and LG+F+R8 (MCP) based on the built-in model select feature (56) and 1000 ultrafast bootstrap replicates (57). The ATPase phylogenetic tree was visualized with iTol (v5, (58)).

417

418 **Data availability**

419 Yaravirus genome and proteomics data will be available upon the manuscript
420 publication.

421

422 **Acknowledgments**

423 We thank our colleagues from IHU (Aix Marseille University) and from Laboratório de
424 Vírus (Universidade Federal de Minas Gerais) for their assistance, specially Said
425 Mougari, Issam Hasni, Lina Barrassi, Priscilla Jardot, Erna Kroon, Claudio Bonjardim,

563 **Figure legends**

564 **Figure 1** - Yaravirus particle and the beginning of the viral cycle. **a** Negative staining of
565 an isolated Yaravirus virion. Scale bar 100nm. **b** Transmission electron microscopy
566 (TEM) representing the beginning of the viral cycle, in which one particle is associated
567 to the host cell membrane and the second one was already incorporated by the amoeba
568 inside an endocytic vesicle. Scale bar 200nm. **c** Detailed image of an incorporated
569 Yaravirus particle in the interior of an endocytic vesicle. Scale bar 100nm. **d** Viral
570 uptake by the amoeba may occur individually but also in groups of particles, as
571 observed in the micrograph. Scale bar 250nm. **e** The viral factory completely develops
572 occupying the nuclear region and recruiting mitochondria around it. Two different
573 regions can be distinct: an electron-lucent region where the virions are assembled as
574 empty shells and a second region formed by several electron-dense points where the
575 genome is packaged inside the particles. Scale bar 500nm.

576

577 **Figure 2** – Yaravirus morphogenesis and release. **a** The virions are assembled by the
578 addition of more than one layer of protein or membranous components around its
579 structure. Scale bar 70nm. **b** The particles then start to migrate to the periphery of the
580 cell where there is the presence of several electron-dense points that function as
581 morphogenetic structures to package the DNA inside the Yaravirus particles (regions
582 inside dashed lines). Scale bar 1000nm. **c** Detailed image of the morphogenetic regions
583 where the DNA (red arrow) is incorporated inside the Yaravirus virion (black arrow).
584 Scale bar 150nm. **d** Sometimes, the final step of viral replication is marked by the
585 particles being packaged inside vesicle-like structures, suggesting a potential release by
586 exocytosis. Scale bar 500nm. **e** Most of the particles, however, are released by cellular
587 lysis and have a high affinity to the membranes of cellular debris. Scale bar 150nm. **f**
588 Graph comparing concomitantly the decrease of host cell numbers (red bars) with the

589 increase of Yaravirus genome during the infection (black line). Replication of viral
590 genome was measure by qPCR and calculated by delta-delta Ct.

591

592 **Figure 3** – Yaravirus genome features. **a** Circular representation of Yaravirus genome
593 highlighting the only six genes (red arrows) which have similarity with aminoacid
594 sequences of other organisms in current databases. Genes with no matches on the
595 databases are represented as green arrows. **b** The percentage of ORFan genes among the
596 complete genome of different viruses of amoeba is represented by the graph with red
597 scale bars. The graph with greenish scale bars represents the absolute number of genes
598 with homologues in databases (non ORFan genes) for each of the same amoebal viruses
599 previously analyzed. **c** All the six Yaravirus predicted tRNAs, as well as their
600 corresponding sequences, are pictured with information about their anticodon (in
601 parenthesis), their nucleotide length, the % of GC content and the position in the
602 intergenic regions of genes 29 and 30.

603

604 **Figure 4** – Phylogenetic tree of the Yaravirus gene corresponding to a probable
605 exonuclease/recombinase, presented in the best-hit *Timonella senegalensis*. Similar
606 genes incorporated in the genome of bacteria (green), eukarya (pink) and other viruses
607 (blue) are also represented.

608 **Figure 5** – Phylogenetic position of Yaravirus and related viral sequences in the
609 *Mimiviridae* based on the viral ATPase (NCVOG0249). The Yaravirus ATPase is
610 highlighted in yellow. Branch support is indicated as colored circles for support values
611 of 90 or below. The tree is rooted at the Poxviruses. Scale bar indicates substitutions per
612 site. GC content of viral genomes and contigs containing NCVOG0249 is shown
613 together with the average GC content of collapsed clades. In addition, environmental
614 origin and assembly sizes of Yaravirus and related viral contigs and genomes are
615 shown. The accession numbers (IMG/M)(REF) of metagenomic sequences are indicated
616 as the numbers before the first dash in the sequence name.
