21

22

23 **Summary**

24 The effects of short-term extreme events on tree functioning and physiology are still rather
 25 elusive. European beech is one of the most sensitive species to late frost and water shortage.
 26 We investigated the intra-annual C dynamics in stems under such conditions.
 27 Wood formation and stem CO₂ efflux were monitored in a Mediterranean beech forest for
 28 three years (2015–2017), including a late frost (2016) and a summer drought (2017).
 29 The late frost reduced radial growth and, consequently, the amount of carbon fixed in the stem
 30 biomass by 80%. Stem carbon efflux in 2016 was reduced by 25%, which can be attributed to
 31 the reduction of effluxes due to growth respiration. Counter to our expectations, we found no
 32 effects of the 2017 summer drought on radial growth and stem carbon efflux.
 33 The studied extreme weather events had various effects on tree growth. Even though late
 34 spring frost had a devastating impact on beech radial growth in the current year, trees fully
 35 recovered in the following growing season, indicating high resilience of beech to this stressful
 36 event.

37

 39 resilience, stem carbon efflux, wood formation.

40 **Introduction**

41 Even small changes in the mean or variation of a climate variable cause disproportionately
 42 large changes in the frequency of extreme weather events, recognized as major drivers of
 43 current and future ecosystem dynamics (Frank *et al.* 2015). In the near future, the
 44 Mediterranean region is predicted to be the most vulnerable of the European regions to global
 45 change (Schröter *et al.* 2005). Changes in temperature and precipitation regimes may increase
 46 drought risk (Schröter *et al.* 2005), which can negatively affect physiological performance
 47 (Rezaie *et al.* 2018), as well as the growth and competitive strength (Peuke, Schraml, Hartung

48 & Rennenberg 2002) of common beech, one of the most important and widespread
49 broadleaved trees in Europe.

50 Increasing spring temperatures can trigger earlier leaf unfolding (Gordo & Sanz 2010;
51 Allevato *et al.* 2019), which in turn results in a higher risk that young leaves are exposed to
52 late spring frost (Augspurger 2013), especially at higher elevations (Vitasse, Schneider,
53 Rixen, Christen & Rebetez 2018). Temperatures below -4°C can kill the developing new
54 shoots and leaves, thus reducing the photosynthetic area and ultimately the trees' growth. In
55 the case of late frost, depending on the intensity of damage, the formation of new leaves
56 requires a high amount of reserves (Dittmar, Fricke & Elling 2006; D'Andrea *et al.* 2019).

57 Tree stems play an important role in the carbon balance of forest ecosystems (Yang, He,
58 Aubrey, Zhuang & Teskey 2016). Part of the carbon (C) fixed by photosynthesis is allocated
59 to the stem, and some is respired by stems and emitted into the atmosphere. Radial growth –
60 an often used proxy for the overall allocation of C to the stem (Bascietto, Cherubini &
61 Scarascia-Mugnozza 2004; Cuny *et al.* 2015; Chan, Berninger, Kolari, Nikinmaa & Hölttä
62 2018) – is largely related to the process of wood formation, which can be divided into five
63 (main) developmental phases: *i*) cambial cell division; *ii*) cell enlargement; *iii*) secondary wall
64 deposition and, *iv*) cell wall thickening (lignification); while *v*) in the case of vessels and
65 fibres, also genetically-programmed cell death or *apoptosis* (Prislan, Čufar, De Luis & Gričar
66 2018). The whole process is sensitive to many factors, such as leaf phenology (Michelot,
67 Simard, Rathgeber, Dufrêne & Damesin 2012), temperature (Begum, Nakaba, Oribe, Kubo &
68 Funada 2007), drought (Linares, Camarero & Carreira 2009), tree-size and social status
69 (Rathgeber, Rossi & Bontemps 2011) and tree vigour (Gričar, Krže & Čufar 2009).

70 As also reported by Damesin (2002), stem respiration may represent up to 1/3 of the overall
71 above ground respiration and 1.4% of the annual carbon assimilation. However, field
72 measurements of actual stem respiration (RS) are difficult if not impossible (Teskey, Saveyn,

Steppe & McGuire 2008), and the most commonly measured proxy, stem CO₂ efflux (ES), is likely to underestimate local respiration (Trumbore, Angert, Kunert, Muhr & Chambers 2013). Previous studies have reported a strong correlation between RS and ES, with ES ranging between 82–94% and 86–91% of RS in *Populus deltoides* W.Bartram ex Marshall (Saveyn, Steppe, Mc Guire, Lemeur & Teskey 2008) and *Dacrydium cupressinum* Lamb stems (Bowman *et al.* 2005), respectively. Another study using O₂ uptake, as an alternative proxy for actual respiration, and comparing it to traditionally measured ES, showed that ES on average underestimated RS by about 41% (CO₂ was not emitted locally at the point of measurement) (Hilman *et al.* 2019). ES and RS are different because part of the CO₂ produced by respiration is not released directly through the bark into the atmosphere, but is dissolved in xylem sap and is carried upward by the transpiration stream (Bloemen *et al.* 2014). In addition, ES is affected by CO₂ deriving from root respiration, which is also carried upward into the stem (Bloemen, McGuire, Aubrey, Teskey & Steppe 2013). Moreover, part of respired CO₂ can be fixed in xylem storage pools (Ubierna *et al.* 2009). A recent global estimate showed that the stem CO₂ efflux (ES) alone, from boreal to tropical forests combined, was 6.7 (± 1.1) Pg C yr⁻¹, accounting for 11% and 20% of global forest ecosystem gross primary production (GPP) and net primary production (NPP), respectively (Yang *et al.* 2016). ES is influenced by many factors, such as air temperature (Yang *et al.*, 2016), growth rate (Damesin, Ceschia, Le Goff, Ottorini & Dufrêne 2002), distribution and turnover of living cells (Collalti *et al.* 2019), nitrogen concentration (Ceschia, Damesin, Lebaube, Pontailier & Dufrêne 2002) and tree social class (Guidolotti, Rey, D'Andrea, Matteucci & De Angelis 2013). Both RS and ES are also affected by growth respiration (R_G), which provides the energy for synthesizing new tissues; and by maintenance respiration (R_M), which maintains existing living cells (Ceschia *et al.* 2002). Separating ES into these components allows further investigation of stem carbon budgeting and tissue costs (Chan *et al.* 2018).

Despite the crucial role of extreme events and increasing attention on their prospective increasing role in future climate scenarios, information on the effect of short-term extreme events on tree functioning is still fairly elusive (Carrer, Brunetti & Castagneri 2016; Gazol *et al.* 2019). In this respect, not much is known about the interaction between wood formation (xylogenesis) and ES. At the seasonal timescale, the capacity of micro-coring technique to identify phenological phases of wood formation allows to attribute metabolic costs to each one of them (Meir, Mencuccini & Coughlin 2019).

A deeper investigation of this link is crucial, especially in the context of climate change, associated with increased frequency of extreme weather events (e.g., drought and late frost), which may greatly modify the contribution of these processes to the C cycle.

In this context, we monitored xylogenesis, together with ES and overall growth, in a mature Mediterranean beech forest (*Fagus sylvatica* L.) from 2015 to 2017 – a period characterized by a spring late frost (2016) and a summer drought (2017) – with the objective of unravelling the intra-annual C dynamics in stems under different climatic conditions and in response to extreme weather events. On the hypothesis that extreme weather events would alter the stem C dynamics at both tree and stand scales, we investigated tree scale physiological processes; specifically, of growth (xylogenesis) and respiration (proxied by stem CO₂ efflux), and then upscaled to stand-scale growth and C emission related to this process. We hypothesized that: 1) cambial activity and radial growth may have ceased soon after leaf death due to the 2016 spring late frost; 2) second leaf re-sprouting starts at the expense of stem growth; 3) the 2017 summer drought would have negatively impacted stem biomass production and effluxes; and that, 4) climatic variability and extreme weather events are important factors in C dynamics on tree and stand scales.

Material and methods

Study site and description of weather events

The measurements were carried out between 2015 and 2017 on a long-term monitored beech stand (*Fagus sylvatica* L.) located at Selva Piana (41°50'58" N, 13°35'17" E, 1,560 m elevation), close to Collelongo (Abruzzi Region, Italy) in the Central Apennines. The site, established in 1991 and since 2006 part of the long-term ecological research (LTER) network, is located in a 3000 ha forest included in the wider forest area of the external belt of Abruzzi National Park. In 2017, the stand density was 725 trees ha⁻¹, the basal area was 45.77 m² ha⁻¹ with a mean diameter at breast height (DBH) of 28.5 cm, and a mean tree height of 23 m. Mean tree age in 2013 was estimated to be about 110 years. Site topography is gently sloping and the soil is humic alisol with a variable depth (40–100 cm), developed on calcareous bedrock (Chiti *et al.* 2010). The climate is of Mediterranean mountain type, during the period 1989 – 2014 the mean annual temperature was 7.2°C, and the mean annual precipitation was 1178 mm, of which ~10% falls in summer (Guidolotti *et al.* 2013).

In the night between the 25th and 26th of April 2016 (Day of Year, DOY 115), a spring late frost occurred in Central and Southern Italy, causing leaf damage in many beech stands (Bascietto, Bajocco, Mazzenga & Matteucci 2018; Greco *et al.* 2018; Nolè, Rita, Ferrara & Borghetti 2018; Allevato *et al.* 2019). At the Selva Piana site, the air temperature reached – 6°C at canopy level, destroying the whole-stand canopy and leaving the trees without leaves for almost two months (Bascietto *et al.* 2018; D'Andrea *et al.* 2019).

In the summer of 2017, a widespread positive temperature anomaly affected Central Italy and the Balkans, with a duration ranging from 20 to 35 days (Rita *et al.* 2019). In the same year, annual precipitation was 950 mm, with only 54 mm of precipitation throughout the entire summer; while only 1 mm of rain and a mean air temperature (23.9 °C) ~ 2°C warmer than

the long-term average (1989–2014) characterized August 2017, leading to a Standardized Precipitation Evapotranspiration Index (SPEI) > 1.5 during the vegetative season (Fig. 1).

Tree selection, wood formation dynamics, xylem phenology and C fixation

Sampling was performed on five trees that were selected for their similarity, with a site tree ring chronology following the methodology described in Rezaie *et al.* (2018) and as done in other studies on wood formation and stem CO₂ efflux (e.g. Ceschia *et al.*, 2002; Damesin *et al.*, 2002; Gruber *et al.*, 2009; Delpierre *et al.*, 2019). Microcore collection and ES measurements were carried out from April 2015, before leaf unfolding, until November 2017, when the trees had completely lost their leaves.

Microcores (2 mm diameter and 15 mm long) were extracted from each tree at 1.1–1.7 m above ground using a Trephor tool (Rossi, Menardi, Fontanella & Anfodillo 2005). Microcores were collected 15, 12, and 14 times in 2015, 2016, and 2017, respectively. To avoid wound effects, cores were sampled at a distance of at least 5 cm from each other. The microcores, containing bark, cambium, newly developing xylem and 1–2 older xylem rings, were immediately stored in formaldehyde-ethanol-acetic acid solution (FEA) in the field. Cross-sections of the microcores were prepared following the standard methodology (Prislan, Gričar, De Luis, Smith & Cufar 2013) and were photographed in high definition under a Leica DM 4000 microscope (Leica Microsystems, Wetzlar, Germany) using transmission and polarized light. Histometrical analyses were performed on images taken with a Leica DFC 280 digital camera using the LAS (Leica Application Suite) image analysis system (Leica Microsystems, Germany). On each photographed cross-section, the number of cambium cells was counted and the widths of the developing xylem were measured along three radial directions.

The dynamics of xylem formation were analysed by fitting the Gompertz function to xylem increments (Prislan *et al.* 2018; Rathgeber, Santenoise & Cuny 2018), corrected for the

previous tree ring width (Camarero, Guerrero-Campo & Gutierrez 1998; Oladi, Pourtahmasi, Eckstein & Bräuning 2011), as follows:

$$y = \alpha \exp \left[-e^{(\beta - kt)} \right] \quad (1)$$

where y is the cumulative ring width (μm) at time t (day of the year), α is the final asymptotic size representing the annual potential growth, β is the x-axis placement parameter and k is the rate of change parameter.

For each tree and monitoring year, the following phenological xylem formation phases were recorded: *i*) cambium *reactivation*, *ii*) beginning of cell *enlargement* (bE); *iii*) beginning of cell wall *thickening* (bW); *iv*) beginning of cell *maturation* (bM); *v*) *cessation* of cell enlargement (cE); and *vi*) cessation of cell wall thickening and *lignification* (cW). The date of cambium reactivation was assessed as the average between dates when an increase of cambium cells was observed (i.e., from 3-4 to 6-7 cells in a radial row) (Čufar, Prislan, De Luis & Gričar 2008; Deslauriers, Rossi, Anfodillo & Saracino 2008). Phases of xylem growth and ring formation were computed using logistic regression, spanning from the 50% probability that phenophases have started or ended (Rathgeber *et al.* 2018). Based on phenological phases, the durations of key wood formation phases were calculated: *i*) the overall duration of the enlargement period ($dE = cE - bE$); *ii*) the duration of the wall-thickening period ($dW = cW - bW$); and *iii*) the total duration of wood formation (i.e., the duration of xylogenesis) ($dX = cW - bE$). Data were analysed using the CAVIAR (v2.10-0) package (Rathgeber *et al.* 2018) built for R statistical software (R Development Core Team 2018).

Starting from the detailed time-resolved data from tree microcores, the annual C fixed in the stem (SG_t) was estimated for each of the sampled tree, as follows:

196

$$197 \quad SG_t = \frac{0.46 \times (BS_t - BS_{t-1})}{\Delta t} \quad (2)$$

198

199 where SG_t is the amount of C fixed in the stem per year expressed in $Mg\ C\ yr^{-1}$, 0.46 is the
200 carbon content of the woody tissues (Scarascia-Mugnozza, Bauer, Persson, Matteucci &
201 Masci 2000), BS_t and BS_{t-1} are the stem biomass in Mg of Dry Matter (DW) of at the
202 beginning and at the end of each sampling year, Δt is the time variation (one year).

203 The site-specific allometric equation for beech used for BS was that proposed by Masci
204 (2002):

205

$$206 \quad BS = \frac{283.734 \times DBH^{2.134}}{10^6} \quad (3)$$

207

208 Where BS is in Mg DW, and DBH is the diameter (in cm) at 1.30 m ($R^2 = 0.96$, p -value <
209 0.01).

210 Upscaling to stand scale was performed according to the following equation:

$$211 \quad SG = SG_t \times n \times \frac{d_{avg}}{d_{st}} \quad (4)$$

212 with SG expressed in $Mg\ C\ ha^{-1}\ yr^{-1}$, n being the number of trees per hectare, d_{avg} the average
213 diameter (cm) and d_{st} the diameter of the sampled tree (cm).

214

215 *Stem CO₂ efflux (ES)*

216 Two PVC collars (10 cm diameter and 5 cm high, one facing north and one south) were fixed
217 on each tree with flexible plastic ties and sealed leak tight with Terostat (Henkel KgaA,
218 Germany). When present, bark mosses and lichens were removed. Stem CO₂ efflux was
219 measured with a portable IRGA (EGM 4, PP-System, Hitchin, UK), equipped with a closed-

dynamic chamber (SRC-1, PP-System, Hitchin, UK), which was tightened. Each measurement consisted of a 120-second loop, in which the CO₂ concentration inside the chamber was measured every 5 seconds. During measurements, the CO₂ concentration typically increased by 10 to 50 μmol mol⁻¹. ES measurements were performed 16, 12, and 12 times in 2015, 2016, and 2017, respectively.

Stem CO₂ efflux (ES) was calculated as:

$$ES = K_{CO_2} \div V_{mol} \times \frac{V_{cuv}}{A} \quad (5)$$

where ES is the stem CO₂ efflux per unit surface area (μmol m⁻² s⁻¹), K_{CO_2} (μmol mol⁻¹ s⁻¹) is the slope of the regression between CO₂ concentration and time during measurements, V_{mol} , the molar volume, is the volume occupied by one mole of CO₂ (m³ mol⁻¹), at the air pressure (measured by built-in sensor of the EGM-4) and air temperature (T_{air} in °C) at the measurement time, A is the exposed lateral surface area of the stem (m²), and V_{cuv} is the sum of SRC-1 and collar volumes (m³).

An exponential function was used to assess the relationship between ES and T_{air}

$$ES = a \times e^{T_{air} \times b} \quad (6)$$

and ES overall temperature sensitivity for a 10 °C increase (Q_{10}) was calculated according to Gruber *et al.* (2009) as:

$$Q_{10} = 10^{K_T \times 10} \quad (7)$$

where K_T is the regression slope taken from linear regression of log₁₀ of ES versus T_{air} .

From the wood formation and xylem phenology analysis described above, we identified wood (w) and non-wood (nw) formation periods for each tree, making it possible to divide the measured ES into two groups, ES_w and ES_{nw} . According to Eq. 5, we calculated for each group the specific CO_2 efflux at a base air temperature of $15^\circ C$ (ES_{15w} and ES_{15nw}) and the specific Q_{10} (Q_{10w} and Q_{10nw}).

During the non-wood formation period, ES_{nw} ($\mu mol\ m^{-2}\ s^{-1}$) was constituted only by the effluxes derived by maintenance respiration (ES_b , $\mu mol\ m^{-2}\ s^{-1}$), which was calculated as:

$$ES_{nw} \equiv ES_b = ES_{15nw} \times Q_{10nw}^{\frac{(T_{air}-15)}{10}} \quad (8)$$

During the wood formation period, ES_w ($\mu mol\ m^{-2}\ s^{-1}$), which is affected by both maintenance and growth respiration, was calculated as:

$$ES_w = ES_{15w} \times Q_{10w}^{\frac{(T_{air}-15)}{10}} \quad (9)$$

We assumed that ES_b and its relationship with air temperature was also valid during the wood formation period, although this approach does not account for the acclimatisation of maintenance respiration to temperature during warmer periods (Collalti *et al.*, 2018 and references therein). However, there are contrasting hypotheses on the magnitude of acclimatisation (Carey *et al.*, 1997; Stockfors & Linder, 1998). Under the above-mentioned assumptions, we calculated the stem CO_2 efflux due to growth respiration, ES_g ($\mu mol\ m^{-2}\ s^{-1}$), as:

$$ES_g = ES_w - ES_b \quad (10)$$

270

271 The daily C effluxes of the whole stem were obtained by integrating, over the entire stem
272 area, the effluxes through equation 7, 8, 9, using half-hourly T_{air} values measured at the site.

273 The stem area was calculated as follow:

274

$$275 \quad LA = 0.464 \times DBH - 2.083 \quad (11)$$

276

277 where LA is the stem lateral area (m^2) ($R^2 = 0.828$, $p\text{-value} < 0.01$, for more details on the
278 equation see additional material Methods S1). Using DBH, we considered the measurement at
279 1.30 m to be representative of the whole stem, even though contrasting effects of height on
280 stem CO_2 effluxes have been reported (see Damesin *et al.*, 2002; Katayama *et al.*, 2019).

281 Annual values of each of the C fluxes of the five sampled trees (TES, TESb, TESg, see Table
282 1 for definitions) were obtained by summing up the daily values.

283 On the assumption that the selected trees were representative of the stand, annual values of
284 each of the fluxes at stand scale (AES, AESb, AESg, $\text{Mg C ha}^{-1} \text{ yr}^{-1}$, see Table 1 for
285 definitions) were calculated:

286

$$287 \quad AES_x = 10^{-6} \times TES_x \times n \times \frac{d_{\text{avg}}}{d_{\text{st}}} \quad (12)$$

288

289 where TES_x was the effluxes at tree level (TES, TESb, TESg, g C yr^{-1}), n is the number of
290 trees per hectare, d_{avg} is the average diameter (cm) and d_{st} is the diameter of the sampled tree
291 (cm).

292 ***Meteorological and phenological data***

293 For the period 1989-2014, FLUXNET2015 release half-hourly air temperature and
294 precipitation were used (Reyer *et al.* 2019). For the period of the study (2015-2017),

measured data were gap filled using downloaded data by the ERA5 database of the European Centre for Medium-Range Weather Forecasts (ECMWF) (<https://www.ecmwf.int/en/forecasts/datasets/archive-datasets/reanalysis-datasets/era5>), according to FLUXNET 2015 release equations.

The Standardized Precipitation Evapotranspiration Index (SPEI), considered the most appropriate index for the Mediterranean climate (Vicente-Serrano *et al.* 2013), was used to assess the magnitude of the drought in 2017. This index is based on the difference between precipitation and potential evapotranspiration (PET), computed according to Hargreaves' equation. The 3-month SPEI was calculated for the site for the period 1989-2017, using the SPEI package in R.

Leaf phenology was monitored using the MODIS Leaf Area Index product (LAI, MOD15A2H, <https://modis.gsfc.nasa.gov/>) with 8-day temporal resolution and 500- meter spatial resolution. The date of onset of photosynthetic activity (green up) and the date at which plant green leaf area peaked at its annual maximum (maturity) were assessed through the rate of change in the curvature of the fitted logistic models (Zhang *et al.* 2003).

Statistical data analysis

Descriptive parameters of growth and xylem phenology were tested using one-way repeated measures analysis of variance, with years as factor, followed by post-hoc (Holm-Sidak method). An exponential equation was used to evaluate the relationship between ES and T_{air} . Differences among ES parameters (Q_{10} and ES_{15}) were tested using two-way repeated measures Anova (two factor repetition), using year and period (non-wood formation, wood formation) as predictive factors. Multiple comparisons were performed by the Holm-Sidak method. Linear regressions were used to assess the relationship between tree ring widths (TRW) and mean annual ES. We tested data normality and constant variance using the

Shapiro-Wilk test and the Spearman rank correlation between the absolute values of the residuals and the observed value of the dependent variable.

Results

Wood formation dynamics

The date of onset of photosynthetic activity, based on leaf area index (LAI) dynamics, differed among the study years, occurring at DOY 118, 95 and 127 in 2015, 2016 and 2017, respectively. In all three years, cambium reactivation occurred after leaf unfolding at DOY 123 ± 4 , 118 ± 8 , 138 ± 6 in 2015, 2016 and 2017, respectively (Fig. 2). In 2016, cambium cell production also continued after the late frost event, but at considerably lower rates.

Different intra-annual growth patterns were observed during the three study years, especially in the year of the late frost (2016, Fig. 3, Table 1). In 2016, the maximum growth rate (rx) ($F = 8.469$, p -value = 0.014) was lower and was reached 3 weeks earlier (tx) ($F = 22.667$, p -value < 0.001) than in the other two years. The different intra-annual growth patterns also resulted in significantly narrower tree rings in 2016 ($230.12 \pm 1.54 \mu\text{m}$) ($F = 13.272$, p -value < 0.01) than in 2015 ($1312.17 \pm 196.15 \mu\text{m}$) and 2017 ($1234.80 \pm 269.32 \mu\text{m}$).

Differences were also observed for the beginning, cessation, and duration of wood formation phases (Fig. S2). The beginning of the enlargement phase occurred earliest in 2016 and latest in 2017 ($F = 34.789$, p -value < 0.001). In contrast, the cessation of this phase was observed latest in 2015 ($F = 17.155$, p -value < 0.01). Consequently, the duration of the enlargement phase was longer in 2015 (110 ± 22 days) than in 2016 (82 ± 4 days) and 2017 (78 ± 4 days) ($F = 8.025$, p -value = 0.01).

The beginning of the wall thickening phase did not differ among the years ($F = 4.188$, p -value = 0.06). The cessation of this phase occurred latest in 2015 ($F = 69.167$, p -value < 0.001). The duration of the wall thickening phase was thus shorter in 2016 (57 ± 5 days) than in 2015 (99

± 6 days) and 2017 (75 ± 4 days) ($F = 26.561$, p -value < 0.001). We also observed a delay in the beginning of cell maturation in 2016 (at DOY 200 ± 4) with respect to 2015 (at DOY 178 ± 4) and 2017 (at DOY 176 ± 2) ($F = 11.650$, p -value < 0.01). The overall duration of wood formation was longer in 2015 (128 ± 5 days) than in 2016 (98 ± 8 days) and 2017 (97 ± 8 days) ($F = 12.561$, p -value < 0.001).

Stem CO₂ efflux (ES)

During the monitoring period (April 2015 – November 2017), the measured ES ranged between $0.16 \pm 0.03 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ (December 2015) and $3.01 \pm 0.40 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ (August 2017) (Fig. 5). Mean ES measured in 2016 ($0.68 \pm 0.19 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$) was lower ($F = 24.476$, p -value < 0.01) than in 2015 ($1.11 \pm 0.40 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$) and 2017 ($1.29 \pm 0.30 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$).

In each year, ES was strongly related to air temperature through the standard exponential function (Fig. 6). The relation was confirmed at different aggregation levels of measurements (whole year, wood formation and non-wood formation periods; see also Table S1 in Supporting Information).

Average Q_{10} was 2.71 ± 0.15 , 2.11 ± 0.18 and 2.68 ± 0.15 , in 2015, 2016 and 2017, respectively. The Q_{10} parameter was not strongly affected by the sampling year (p -value = 0.059), although the values in 2016 were 22% lower than in the other two years. Wood formation affected the Q_{10} parameter ($F = 31.563$, p -value < 0.01) with Q_{10w} and Q_{10nw} calculated to be 3.06 ± 0.15 and 1.93 ± 0.14 ($t = 5.571$, p -value < 0.01), respectively. This difference was confirmed for all of the sampled years.

ES_{15} was also affected by the different conditions of the monitoring years ($F = 7.094$, p -value = 0.01) with mean values in 2016 ($0.63 \pm 0.07 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$) lower than in 2015 ($0.93 \pm 0.12 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$) and 2017 ($0.82 \pm 0.12 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$). Similar to Q_{10} , the wood formation period also affected ES_{15} , with ES_{15w} ($0.84 \pm 0.22 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$) higher than

ES_{15nw} ($0.73 \pm 0.02 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$, $F = 7.094$, $p\text{-value} = 0.01$). Furthermore, during the wood formation period, ES_{15w} was higher in 2015 ($1.03 \pm 0.07 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$) and 2017 ($0.90 \pm 0.07 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$) than in 2016 ($0.60 \pm 0.09 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$). No differences among years were found for ES during the non-wood formation periods.

Annual ES for individual trees, per unit of lateral surface area, ranged between $112 \text{ g C m}^{-2} \text{ yr}^{-1}$ in 2016 (tree 4) and $349 \text{ g C m}^{-2} \text{ yr}^{-1}$ in 2017 (tree 2). Average total ES for all sampled trees was lower in 2016 ($182 \pm 25 \text{ g C m}^{-2} \text{ yr}^{-1}$, $F = 12.007$, $p\text{-value} < 0.01$) than in 2015 ($258 \pm 27 \text{ g C m}^{-2} \text{ yr}^{-1}$) and 2017 ($233 \pm 35 \text{ g C m}^{-2} \text{ yr}^{-1}$).

The estimated contribution of maintenance respiration to ES for individual trees ranged between $112 \text{ g C m}^{-2} \text{ yr}^{-1}$ in 2016 (tree number 4 showed no growth) and $284 \text{ g C m}^{-2} \text{ yr}^{-1}$ in 2017 (tree number 2), and was lower, on average, in 2016 ($169 \pm 21 \text{ g C m}^{-2} \text{ yr}^{-1}$) than in 2015 ($211 \pm 18 \text{ g C m}^{-2} \text{ yr}^{-1}$) ($q = 5.104$, $p\text{-value} = 0.017$).

Likewise, the estimated contribution of wood formation to ES for individual trees varied between 0 in 2016 (tree number 4) and $70 \text{ g C m}^{-2} \text{ yr}^{-1}$ in 2015 (tree number 2) and was significantly lower ($F = 8.144$, $p\text{-value} = 0.012$) on average in 2016 ($14 \pm 5 \text{ g C m}^{-2} \text{ yr}^{-1}$) than in 2015 ($48 \pm 9 \text{ g C m}^{-2} \text{ yr}^{-1}$) and 2017 ($39 \pm 8 \text{ g C m}^{-2} \text{ yr}^{-1}$). In relative terms, the contribution of wood formation to ES was estimated to be $18 \pm 2\%$, $9 \pm 3\%$ and $16 \pm 3\%$ in 2015, 2016 and 2017, respectively, with the remaining CO₂ efflux originating from maintenance respiration.

Radial growth and stem C effluxes

During the study period, annual average measured ES and tree ring widths were closely related (Fig. 5). Seasonal patterns of ES were similar in the three years, but with different amplitudes (Fig. 8). Moreover, ES_b, the stem C effluxes affected by maintenance respiration, showed a similar pattern among the three years. We observed a time-lag between the time of maximum growth rate (tx) and maximum ES values of 23 ± 2 days, 31 ± 2 days and 29 ± 1

days in 2015, 2016 and 2017, respectively. Differences between years were not significant ($F = 3.317$, p -value = 0.07).

From tree to stand level

Annual stand-level stem C emissions (AES) were lower in 2016 (1.58 ± 0.22 Mg C ha⁻¹ yr⁻¹) than in 2015 (2.24 ± 0.24 Mg C ha⁻¹ yr⁻¹) and 2017 (2.02 ± 0.27 Mg C ha⁻¹ yr⁻¹) (Table 3). Annual stem C effluxes due to maintenance respiration (AESb) in 2015 (1.47 ± 0.19 Mg C ha⁻¹ yr⁻¹) were lower than in 2016 (1.82 ± 0.16 Mg C ha⁻¹ yr⁻¹); AES due to growth respiration (AESg) was lower in 2016 (0.11 ± 0.04 Mg C ha⁻¹ yr⁻¹) than in 2015 (0.42 ± 0.08 Mg C ha⁻¹ yr⁻¹) and 2017 (0.34 ± 0.06 Mg C ha⁻¹ yr⁻¹). The contribution of AESg to the annual stem effluxes was 19%, 7% and 16% in 2015, 2016 and 2017, respectively.

The amount of carbon fixed in the stem biomass (SG) was lower in 2016 (0.48 ± 0.13 Mg C ha⁻¹ yr⁻¹) than in 2015 (2.78 ± 0.41 Mg C ha⁻¹ yr⁻¹) and 2017 (2.50 ± 0.49 Mg C ha⁻¹ yr⁻¹). At the studied beech forest, the mean C construction cost of wood, defined as the slope of the relationship between AESg and SG at tree level ($R^2 = 0.849$, p -value < 0.01, see Supporting Information Fig.S3), was 0.2 g C emitted per g C fixed. On an annual scale, this parameter was 0.15 ± 0.01 for 2015, 0.24 ± 0.05 for 2016 and 0.14 ± 0.02 for 2017.

Discussion

Cambial activity and radial growth are not entirely linked to leaf phenology

To the best of our knowledge, this is the first time that the effects of a spring late frost with a subsequently close summer drought on the wood formation dynamic of beech have been described.

In all three years, cambium reactivation and wood formation occurred within 1-3 weeks after leaf development, confirming the tight dependence of radial growth on leaf phenology and photosynthesis in diffuse-porous species (Čufar *et al.* 2008; Michelot *et al.* 2012).

Nevertheless, in diffuse-porous trees, stem conductivity to water occurs in several outermost growth rings and is not limited to the youngest formed xylem, as found in ring-porous species (Schume, Grabner & Eckmüller 2004). Hence, in beech allocation to the current year wood, it is not as decisive as in ring-porous species, and newly formed photosynthates at the beginning of the season are preferably used for other crucial processes, such as foliage and fine root growth. At the same site, Matteucci (1998) analysed in parallel net ecosystem exchange (NEE) and carbon allocation to foliage and stem radial growth, finding that the latter started approximately 15 days after photosynthesis exceeded respiration (i.e., NEE was negative). Until then, net absorbed carbon was allocated mostly to foliage growth. This can be related to the C allocation hierarchy, which identifies newly developing leaves as the main C sink at the beginning of the growing season (Capioli *et al.*, 2013; Collalti *et al.*, 2016; Merganičová *et al.*, 2019). Interestingly, and even counter to our expectations, in 2016, the cambium remained active at low rates even after complete canopy defoliation, probably fuelled by old C reserves (D'Andrea *et al.* 2019).

After the second re-sprouting, cambium cell production decreased and became non-productive, although the environmental conditions were potentially still favourable for radial growth, being related to day-length (Rossi *et al.* 2006; Camarero, Olano & Parras 2010). Stem radial growth of beech in Selva Piana was greatly affected by the extreme late spring frost in 2016 because of the premature cessation of cambial cell production and the lower growth rate during the active period, which resulted in 82% narrower annual xylem increments compared to 2015 and 2017. This can be related to a somewhat hypothesised, genetically controlled, form of hierarchy in C allocation (composed by old C reserve and recently fixed photosynthates), which identifies newly developing leaves as the main C sink rather than radial growth. In beech, previously reported growth reduction – as a consequence of late frost – has ranged from 48 to 83% in beech, with the maximum occurring at the northern fringe of

the Alps (Dittmar *et al.* 2006). Radial growth rates had fully recovered in 2017, with no visible long-term effects of the late spring frost event in 2016, showing the high resilience of beech growth to late frost (Dittmar *et al.* 2006; Principe, Struwe, Wilmking & Kreyling 2017). However, as recently shown in D'Andrea *et al.* (2019), beech trees during 2016 were able to compensate the lost C reserve, completely refilling the pool to the same level as before the frost event. Hence, there was no need to prioritize reserve recharge over stem biomass production the subsequent year.

The 2017 summer drought became severe only in August (SPEI > 1.5), when the trees had already completed most of their radial growth, as already seen for other tree species growing in the Mediterranean adjusting the end xylem growth before potential stressful conditions may occur (e.g. Lempereur *et al.*, 2015; Forner *et al.*, 2018). Instead, the importance of spring climatic conditions on beech growth has been reported for the Apennines and the Eastern Alps (Piovesan, Biondi, Di Filippo, Alessandrini & Maugeri 2008; Di Filippo, Biondi, Maugeri, Schirone & Piovesan 2012).

Effluxes from stem are not entirely synchronised to radial growth

Mean annual values of Q_{10} ranged between 2.11 (2016) and 2.71 (2015) and were similar to the values estimated at the same site for co-dominant (2.59) and dominant (2.34) trees (Guidolotti *et al.* 2013). Q_{10nw} and Q_{10w} estimated in this study are closely comparable with the dataset of various coniferous and broadleaf tree species reported in Damesin *et al.* (2002). Similar intra-annual variability of Q_{10} has been observed in many studies on different species with higher Q_{10} during the growing period (Paembonan, Hagihara & Hozumi 1992; Carey, Callaway & DeLucia 1997; Stockfors & Linder 1998; Gruber *et al.* 2009). However, other studies found (or assume) stable Q_{10} throughout the year (Ceschia *et al.* 2002; Damesin *et al.* 2002).

Our results suggests that wood formation affects Q_{10} , indeed Q_{10w} was higher than Q_{10nw} , despite higher temperatures during the wood formation period, exactly contrary to a case of sole control of temperature on the parameters (Atkin & Tjoelker 2003).

As reported in other studies, ES15, stem CO_2 efflux at an air temperature of $15^\circ C$, was sensitive to wood formation processes, showing an increase during the growing period (Ceschia *et al.* 2002; Damesin *et al.* 2002).

Maximum xylem production and maximum ES were not synchronized, while a constant delay, of about a month, was observed, as similarly found in a young beech forest in which peak ES occurred *c.* 27 days after the maximum stem growth rate (Ceschia *et al.* 2002).

Furthermore, our results confirmed that peak ES occurred when xylem cells were still in the phase of wall thickening and lignification, as previously hypothesized (Ceschia *et al.* 2002).

Moreover, when maximum ES was observed, it is very likely that trees were already refilling the stem C reserves pool (Scartazza, Moscatello, Matteucci, Battistelli & Brugnoli 2013).

Only spring frost affects negatively stem C fluxes

The amount of C fixed by stem biomass formation in 2015 and 2017 ranged from 2.58 to 2.70 $Mg\ C\ ha^{-1}\ yr^{-1}$, a bit higher than the values reported for a beech forest in Germany, ranging from 1.69 to 2.41 $Mg\ C\ ha^{-1}\ yr^{-1}$ (Mund *et al.* 2010). In 2016, however, we measured only $0.48 \pm 0.13\ Mg\ C\ ha^{-1}\ yr^{-1}$, i.e., only about 20% of the fixation during the two reference years, emphasizing how exceptionally negative this year was.

Annual stem CO_2 efflux (AES) is known to be highly variable in temperate forests (Yang *et al.* 2016). Our data ranges from 1.58 to 2.24 $Mg\ C\ ha^{-1}\ yr^{-1}$ and thus is similar to the 1.65 to 2.25 $Mg\ C\ ha^{-1}\ yr^{-1}$ reported for a younger beech forest (Damesin *et al.* 2002).

An earlier estimate of AES at the study site was $0.63\ Mg\ C\ ha^{-1}\ yr^{-1}$ (Guidolotti *et al.* 2013) for 2007, year characterized by an extreme summer drought (SPEI > 2). The stem C efflux of the drought year presented in this study (2017, $1.58\ Mg\ C\ ha^{-1}\ yr^{-1}$) was about 150% higher

than in 2007, which could be due to an increase in stem biomass (*c.* 15% lower in 2007 than in 2017, see also Collalti *et al.*, 2019) and to different measurement tools. The contribution of AESg to annual stem effluxes, ranging from 7% to 19%, was lower than that measured in a young beech forest (Ceschia *et al.*, 2002), evidencing the importance of forest developmental stage in determining wood formation and growth respiration. The construction cost we found of 0.23 g C fixed per g C emitted is consistent with the values reported for beech, 0.2 – 0.38 g C fixed per g C emitted (Ceschia *et al.* 2002; Damesin *et al.* 2002).

While the late frost event in 2016 reduced both wood growth and stem CO₂ efflux with respect to those measured in the other two years, the percentage of growth reduction (80%) was much larger than the reduction of ES (25%). Hence, it seems that in mature beech the contribution of growth respiration to total stem CO₂ fluxes is lower than that of maintenance respiration, as reported in Collalti *et al.*(2019). In the year of late frost, the strong reduction of fixed growth C and the contemporary lower reduction of stem CO₂ efflux strongly affected the overall stem carbon balance. In contrast, the summer drought did not have any effect on stem growth, and thus neither on C efflux due to growth respiration.

In conclusion, this study further highlights the sensitivity of beech to leaf damage due to late spring frost. Since leaf development is forecast to start earlier for beeches due to global warming (Augspurger 2013), the likelihood that spring frost may damage leaves will increase. We demonstrated that stem growth was significantly reduced due to the prolonged absence of photosynthesizing leaves after frost, since beech trees tapped their pool of old C reserves. However, the loss in growth was not completely compensated for after re-growth of leaves, but rather the cambium activity ceased shortly thereafter. Consequently, the trees fixed less C in the stem biomass, showing also a reduction of the stem carbon efflux related to growth respiration.

Moreover, the summer drought occurred too late to affect wood formation and stem CO₂ effluxes. However, more investigations are needed to evaluate its effects on other physiological processes. This study also underlines the crucial role of spring weather conditions on the growth and physiology of beech trees.

A better understanding of fine scale C dynamic will help in evaluating a medium- to long-term response to climate change under an increasing frequency of extreme events.

Figure

Fig. 1: 3-month Standardized Precipitation Evapotranspiration Index (SPEI) at the experimental site of Selva Piana- Collelongo.

Fig. 2: Number of cambium cells (N. cells vs. leaf area index (LAI, m^2m^{-2})). Grey points and dashed lines are the MODIS-LAI values and modelled intra-annual dynamic of Selva Piana beech forest, respectively. Green and blue vertical lines represent the green-up and maturity phases of leaf phenology, respectively. The red vertical line represents the late frost of 25th April 2016. Black triangles are the average number of cambial cells of five beech trees. Bars are the standard error.

Fig. 3: Intra-annual dynamics of xylem formation (μm) in 2015 (red dots and solid line), 2016 (green dots and solid line) and 2017 (blue dots and solid line). Gompertz functions were fitted to the total xylem increment comprised of enlarging, wall thickening and mature cells. Each point is the mean of 5 sampled *Fagus sylvatica* trees and bars are standard errors. * p -value < 0.001**

Fig. 4: Critical dates and duration of wood formation phases. Different letters (a, b and c) represent significant differences among the beginning of the enlargement phase (grey dots), the

beginning of the wall thickening phase (black dots), cessation of the enlargement phase (grey triangle) and cessation of the wall thickening phase (black triangle) (p -value < 0.05). Grey and black rectangles represent the duration of the enlargement and wall thickening phases, respectively. The sum of their length is the duration of wood formation. Each shape is the mean of 5 sampled trees per year and the bars error represent standard error.

Fig. 5: Top panel: T_{air} (°C) at the measuring time in 2015 (red), 2016 (green) and 2017 (blue). Bottom panel: Measured stem CO₂ effluxes ($\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$) in 2015 (red), 2016 (green) and 2017 (blue). Each point is the mean of 5 *Fagus sylvatica* trees. Bars are standard errors.

Fig. 6: Relationship between ES ($\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$) and air temperature (T_{air} , $^{\circ}\text{C}$). Annual, considering the whole measurements for each year, each point is the mean of five sampled trees. Each point represents the mean of those trees, during non-wood and wood formation phases, at a given sampling date. Bars are the standard error. * p -value < 0.001, ** p -value < 0.01, * p -value < 0.05.**

Fig. 7: Relationships between ring widths (mm) and the mean annual ES (μmol CO₂ m⁻² s⁻¹) measured in 2015 (green), 2016 (blue), and 2017 (red). Each point represents a sampled *Fagus sylvatica* tree per year. Bars are the standard error. * p -value < 0.001.**

Fig. 8: Daily increment and stem Carbon effluxes of *Fagus sylvatica*. The black line is the daily increment during 2015, 2016 and 2017, respectively. The red line represents ES, the daily C effluxes. The lower panel, ESb/ES shows the contribution of maintenance respiration to daily stem C efflux.

809 Tables

810 **Table 1: List of terms used in the text**

Terms	Definition	Spatial Scale
ES	stem CO ₂ efflux per surface area ($\mu\text{mol m}^{-2} \text{s}^{-1}$)	Local
ES _{15w}	specific CO ₂ efflux at an air temperature of 15°C during the wood formation period ($\mu\text{mol m}^{-2} \text{s}^{-1}$)	Local
ES _{15nw}	specific CO ₂ efflux at an air temperature of 15°C during the non-wood formation period ($\mu\text{mol m}^{-2} \text{s}^{-1}$)	Local
Q _{10w}	ES temperature sensitivity for a 10 °C increase during the wood formation period	Local
Q _{10nw}	ES temperature sensitivity for a 10 °C increase during the non-wood formation period	Local
ES _w	stem CO ₂ efflux per surface area ($\mu\text{mol m}^{-2} \text{s}^{-1}$) during wood formation	Local
ES _b	stem CO ₂ efflux per surface area ($\mu\text{mol m}^{-2} \text{s}^{-1}$) due to maintenance respiration	Local
ES _g	stem CO ₂ efflux per surface area ($\mu\text{mol m}^{-2} \text{s}^{-1}$)	Local

s^{-1}) due to growth respiration

TES	annual stem C efflux ($g\ C\ yr^{-1}$)	Tree
TESb	annual stem C efflux due to maintenance respiration ($g\ C\ yr^{-1}$)	Tree
TESg	annual stem C efflux due to growth respiration ($g\ C\ yr^{-1}$)	Tree
AES	annual stem C efflux ($Mg\ C\ ha^{-1}\ yr^{-1}$)	Stand
AESb	annual stem C efflux due to maintenance respiration ($Mg\ C\ ha^{-1}\ yr^{-1}$)	Stand
AESg	annual stem C efflux due to growth respiration ($Mg\ C\ ha^{-1}\ yr^{-1}$)	Stand
SG	annual C fixed in stem biomass ($Mg\ C\ ha^{-1}\ yr^{-1}$)	Stand

Table 2: Parameters describing the intra annual radial growth derived from the Gompertz function for the total xylem increment comprised of enlarging, wall thickening and mature cells. α is the upper asymptote, representing the final ring width at the end of the growing season; tx is the DOY at which the daily increment is maximum (Gompertz curve inflection point); rx is the maximum daily increment ($\mu\text{m day}^{-1}$). Different letters represent significant differences among the monitored years.

Total xylem increment				
Parameter	Year	Mean ($\pm$ S.E.)	F	p-value
α	2015	1312.17 ($\pm$ 196.15) a		
α	2016	230.12 ($\pm$ 31.54) b	13.722	< 0.01
α	2017	1234.80 ($\pm$ 269.32) a		
rx	2015	25.77 ($\pm$ 2.95) a		
rx	2016	6.09 ($\pm$ 2.00) b	8.469	0.014
rx	2017	22.71 ($\pm$ 3.51) a		
tx	2015	174 ($\pm$ 2.19) a		
tx	2016	157 ($\pm$ 5.65) b	22.667	< 0.001
tx	2017	174.80 ($\pm$ 1.24) a
