29 ABSTRACT

- 30 • Microcystins are toxins produced by cyanobacteria, notorious for negatively
31 affecting a wide range of living organisms, among which several plant
32 species. Although microtubules are a well-established target of microcystin
33 toxicity, its effect on filamentous actin (F-actin) in plant cells has not been
34 studied yet.
- 35 • The effects of microcystin-LR (MC-LR) and the extract of a microcystin-
36 producing freshwater cyanobacterial strain (*Microcystis flos-aquae* TAU-MAC
37 1510) on the cytoskeleton (F-actin and microtubules) of *Oryza sativa* (rice)
38 root cells, were studied by light, confocal, and transmission electron
39 microscopy. Considering the role of F-actin in endomembrane system
40 distribution, the endoplasmic reticulum and the Golgi apparatus in extract-
41 treated cells were also examined.
- 42 • F-actin in both MC-LR- and extract-treated meristematic and differentiating
43 root cells exhibited time-dependent alterations, ranging from disorientation
44 and bundling to the formation of ring-like structures, eventually resulting to a
45 collapse of the F-actin network at longer treatments. Disorganization and
46 eventual depolymerization of microtubules, as well as abnormal chromatin
47 condensation were observed following treatment with the extract, effects
48 which could be attributed to microcystins and other bioactive compounds.
49 Moreover, cell cycle progression was inhibited in extract-treated roots,
50 specifically affecting the mitotic events. As a consequence of F-actin network
51 disorganization, endoplasmic reticulum elements appeared stacked and
52 diminished, while Golgi dictyosomes appeared aggregated.
- 53 • These results support that F-actin is a prominent target of MC-LR, both in
54 pure form and as an extract ingredient. Endomembrane system alterations

55 can also be attributed to the effects of cyanobacterial bioactive compounds
56 (including microcystins) on F-actin cytoskeleton.

57

58 INTRODUCTION

59 Cyanobacteria are photosynthetic, oxygenic prokaryotes, inhabiting a variety of
60 aquatic and terrestrial environments, surviving even extreme conditions (such as high
61 temperature or salinity etc.; Codd et al., 2017). A wide range of species are known to
62 produce cyanotoxins, a group of chemically diverse secondary metabolites (as
63 reviewed by Pantelić et al., 2013), proven to be harmful to higher eukaryotes,
64 including humans (Buratti et al., 2017) and various plant species (Máthé et al., 2013;
65 Mitrovic et al., 2004). The most common cyanotoxins found in freshwater bodies are
66 microcystins (MCs), water-soluble monocyclic heptapeptides, exhibiting two variable
67 amino acids (Catherine et al., 2017). The toxicity of MCs is due to their ability to
68 inhibit the activity of protein phosphatases 1 (PP1) and 2A (PP2A) (MacKintosh et al.,
69 1990), which are involved in the cell cycle progression (Brautigan and Shenolikar,
70 2018).

71 MCs are released into the surrounding water during cyanobacterial cell lysis (Sivonen
72 and Jones, 1999), thus becoming eventually accessible to consumers either directly
73 (through water supply) or indirectly, affecting crops (through irrigation water) destined
74 for consumption. When present in irrigation water (due to naturally occurring
75 cyanobacteria in freshwaters), MCs have been shown to bioaccumulate in cultivated
76 plant species (Corbel et al., 2016; Drobac et al., 2017), raising serious concerns over
77 food safety and the impacts on consumers' health (Cao et al., 2018a).

78 Rice (*Oryza sativa* L.) is a crop of great commercial value worldwide (FAO, 2018).
79 Since its cultivation is closely related to the aquatic environment, it is prone to all the
80 dangers imposed by the presence of cyanobacteria in the surrounding water.
81 Although many studies have focused on the accumulation and toxicity of MCs in rice
82 (Azevedo et al., 2014; Chen et al., 2012; Liang et al., 2016), their effects on the

183 physiology of rice cells remain unclear. A recent study has underlined the negative
 184 effects of MC-contaminated water on rice root growth (Cao et al., 2018b), as a result
 185 of mitotic disruption in dividing root cells.

186 Previous studies on plant cells have shown that MCs disrupt microtubule
 187 organization, leading to mitotic abnormalities, and induce chromatin
 188 hypercondensation, due to histone H3 hyperphosphorylation, while alterations in cell
 189 cycle progression have also been reported (for a review on the effects of MCs, see
 190 Máthé et al., 2013). Even though chromatin and microtubules are well-known
 191 “targets” of MCs in plant cells, the other component of the plant cytoskeleton, F-actin,
 192 has not been studied in MC-treated cells of any plant species so far. However, F-
 193 actin is important for plant growth, regulating the intracellular distribution of several
 194 organelles (Volkman and Baluška, 1999) and driving cytoplasmic streaming, a
 195 function pivotal for plant cell viability (Shimmen and Yokota, 2004). All reports about
 196 the adverse effects of MCs on plant cytoskeleton have been based on applying
 197 purified MCs (e.g. Garda et al., 2016; Máthé et al., 2013), as purified toxins offer high
 198 precision in determining the exact concentrations. On the other hand, crude extracts
 199 of MC-producing cyanobacterial strains, known to negatively affect plant growth, are
 200 helpful in simulating the natural exposure of plants to MCs during lab experiments
 201 (Pflugmacher et al., 2007; Prieto et al., 2011). In accordance, in the present study,
 202 the effects of both purified microcystin-LR (MC-LR) and a toxic cyanobacterial extract
 203 (containing MCs) on F-actin of rice root cells were investigated. In order to further
 204 highlight the significance of any disruption of F-actin due to the toxic extract,
 205 endoplasmic reticulum and Golgi apparatus distribution, related to F-actin (Boevink et
 206 al., 1998), as well as cytoplasmic streaming (Shimmen and Yokota, 2004; Volkman
 207 and Baluška, 1999) were examined.

208

209 **MATERIALS AND METHODS**

210 **Cyanobacterial strains, growth media and culture conditions**

111 A strain of the TAU-MAC culture collection (Gkelis and Panou, 2016), *Microcystis*
112 *flos-aquae* TAU-MAC 1510, isolated from Lake Pamvotis, Greece (Gkelis et al.,
113 2015a), was used for experimental purposes. *Microcystis flos-aquae* TAU-MAC 1510
114 has been found to be toxic (Gkelis et al., 2015a), producing a range of microcystins,
115 including MC-YR, MC-LR, [D-Asp³] MC-LR and MC-HiLR (Gkelis et al., 2019). The
116 strain was cultured in BG-11 medium, containing NaNO₃ (Rippka, 1988), in a 500 mL
117 glass Erlenmeyer flask (250 mL of medium were inoculated with a 4-5 mL inoculum,
118 from an exponentially growing pre-culture, under aseptic conditions). The culture was
119 grown at 24±1°C for about 30 days in a 12 h:12 h light:dark cycle at a photosynthetic
120 photon flux density of 10 µmol m⁻² s⁻¹ using cool white fluorescent lamps.

121

122 **Biomass collection and extraction**

123 The culture was centrifuged at 3,500 rpm for 10 min. The supernatant was discarded
124 and the precipitate (biomass) was stored at -70°C overnight. Frozen biomass was
125 lyophilized with an ALPHA 1-4 freeze dryer (Martin Christ, Gefriertrocknungsanlagen,
126 Osterode am Harz, Germany), at temperature ranging from -48°C to -54°C and
127 pressure between 0.05 and 0.02 mbar, until dry. Dry biomass was weighed (150 mg)
128 and extracted thrice in 21 mL of 75% (v/v) methanol in glass tubes. The sample was
129 sonicated during the first extraction step for 10 min with a Vibra-Cell VC-300 High
130 Intensity Ultrasonic Processor (Sonics and Materials Inc., Newtown, CT, USA) and
131 stirred for 45 min at each extraction step at room temperature. The extract was left to
132 evaporate under aseptic conditions and the pellet was resuspended in 5 mL of
133 double-distilled water. The aqueous extract was filtered through Whatman Polydisc
134 TF filters (Whatman plc, Little Chalfont, UK) with a pore size of 0.2 µm.

135

136 **Plant material and exposure to MC-LR and the crude extract**

137 Rice (*Oryza sativa* cv Axios, kindly provided by the National Cereal Institute,
138 Thessaloniki, Greece) seeds were germinated on filter paper moistened with tap

139 water, in the dark, at 24±1°C. MC-LR purified from *Anabaena* strains (Halinen et al.,
140 2007), generously provided by Prof. Kaarina Sivonen (Department of Microbiology,
141 University of Helsinki), was used for treatments. Four- to five-day-old seedlings were
142 placed with their roots submerged in either cyanobacterial aquatic extract or an
143 aquatic solution of MC-LR inside Eppendorf tubes for various time periods (30 min, 1,
144 2, 3 or 24 h) at the same conditions. Seedlings submerged in tubes with distilled
145 water were used as control. The concentration of the MC-LR aquatic solution was set
146 at 45 µg·mL⁻¹, equal to the total concentration of microcystins contained in the
147 *Microcystis flos-aquae* TAU-MAC 1510 strain (Gkelis et al., 2019), in order to achieve
148 comparable results. Following exposure, root tips 2-3 mm long were cut with steel
149 razor blades and prepared for fluorescence and transmission electron microscopy
150 (TEM). All chemicals and reagents were purchased from Applichem (Darmstadt,
151 Germany), Sigma-Aldrich (Taufkirchen, Germany) and Merck (Darmstadt, Germany)
152 and all experimental procedures described below were performed at room
153 temperature, unless otherwise stated.

154

155 **Endoplasmic reticulum and tubulin immunolabeling**

156 Endoplasmic reticulum and tubulin immunostaining were performed as mentioned by
157 Adamakis et al. (2016), with some modifications. In particular, root tips were fixed in
158 4% (w/v) paraformaldehyde (PFA) solution in PEM buffer (50 mM PIPES, 5mM
159 EGTA, 5 mM MgSO₄, pH 6.8) with the addition of 5% (v/v) dimethyl sulfoxide
160 (DMSO) for 1 h. Fixed specimens were washed with PEM (3 x 10 min) and cell walls
161 were digested with 2% (w/v) Macerozyme R-10 + 2% (w/v) cellulase Onozuka R-10
162 (Duchefa Biochemie, Haarlem, Netherlands) solution in PEM for 1 h. After washing
163 with PEM (3 x 10 min), the root tips were squashed on poly-L-lysine-coated
164 coverslips, left to dry, and the cells were extracted with a 5% (v/v) DMSO + 1% (v/v)
165 Triton X-100 solution in phosphate-buffered saline (PBS, pH 7.2) for 1 h. For
166 endoplasmic reticulum immunolabeling, mouse anti-HDEL antibody (2E7, Santa Cruz

167 Biotechnology, Dallas, TX, USA), diluted 1:50 in PBS, and AlexaFluor488-anti-mouse
168 (Invitrogen, Carlsbad, CA, USA), diluted 1:150 in PBS, were used. For tubulin
169 immunolabeling, rat anti- α -tubulin (YOL 1/34, Serotec, Kidlington, UK) was applied as
170 primary antibody and incubated overnight, then washed with PBS and incubated with
171 FITC-anti-rat at 37°C for 3 h. Both antibodies were diluted 1:40 in PBS. DNA was
172 counterstained with DAPI (0.9 mM stock solution of 4',6-diamidino-2-phenylindole in
173 DMSO and further diluted 1:1000 in PBS) for 5 min. After final wash with PBS, all
174 specimens were mounted with an anti-fade medium [PBS 1: 2 glycerol (v/v) + 0.5 %
175 (w/v) p-phenylenediamine].

176

177 **F-actin labeling with phalloidin**

178 F-actin labeling with fluorescent phalloidin was performed according to Stavropoulou
179 et al. (2018). In short, F-actin in root tips was pre-stabilized in 300 μ M *m*-
180 maleimidobenzoyl-*N*-hydroxysuccinimide ester in PEM, with the addition of 0.1%
181 (v/v) Triton X-100 for 30 min in the dark. Immediately after pre-stabilization, fixation
182 was performed with 4% (w/v) PFA in PEM + 5% (v/v) DMSO + 0.1% (v/v) Triton X-
183 100, while DyLight 554-phalloidin (Cell Signaling Technology, Danvers, MA, USA)
184 1:400 was also added in the fixative for better F-actin preservation. After washing
185 with PEM (3 x 10 min), the specimens were extracted in 5% (v/v) DMSO + 1% (v/v)
186 Triton X-100 in PBS for 1 h and F-actin labeling was performed by incubating with
187 DyLight 554-phalloidin diluted 1:40 in PBS + 0.1% (v/v) Triton X-100 at 37°C for 2 h
188 in the dark. After DNA counterstaining with DAPI (as mentioned above) and washing
189 with PBS, all specimens were mounted with anti-fade medium.

190

191 **Confocal fluorescence microscopy**

192 Fluorescent specimens were observed with a Zeiss Observer.Z1 (Carl Zeiss AG,
193 Munich, Germany) microscope, equipped with the LSM780 confocal laser scanning

(CLSM) module, with the appropriate filters for each fluorophore. Imaging was achieved with ZEN2011 software according to the manufacturer's instructions.

196

197 **Fluorescence intensity measurements**

198 Fluorescence intensity measurements for F-actin were performed in maximum
199 intensity projections of serial CLSM sections of root tips (in the meristematic and
200 differentiation zone), treated with 45 $\mu\text{g}\cdot\text{mL}^{-1}$ MC-LR or the cyanobacterial extract for
201 various time periods (30 min, 1, 2 or 24 h), using ImageJ (<https://imagej.net/Fiji>),
202 according to Adamakis et al. (2014) and Mylona et al. (2020). The corrected total cell
203 fluorescence (CTCF; Gavet and Pines, 2010) was calculated with the formula: CTCF
204 = Integrated Density – (Area of selected cell X Mean fluorescence of background
205 readings). Thirty individual cells from three different roots per treatment were
206 measured for fluorescence intensity. Results were statistically analyzed (ANOVA with
207 Dunnett's test) using SigmaPlot (San Jose, CA, USA), with significance at $P < 0.001$.

208

209 **Cell cycle analysis**

210 To assess the frequency of cells in various cell cycle stages, control and treated
211 specimens prepared for F-actin labeling or tubulin immunostaining and DAPI staining
212 were examined under a Zeiss Axiolmager.Z2 light microscope equipped with
213 epifluorescence or a Zeiss Observer.Z1 (Carl Zeiss AG, Munich, Germany)
214 microscope with CLSM module. Cells at different cell cycle stages (interphase,
215 preprophase/prophase, metaphase/anaphase and cytokinesis) were recognized
216 according to F-actin/microtubule arrangement and/or chromatin state. At least 1000
217 individual cells from three different roots per treatment (a minimum of 300
218 meristematic cells per root) were counted. Statistical analysis of data (chi-squared
219 test, $df = 3$) was performed with SigmaPlot, with significance at $P < 0.001$.

220

221 **Live imaging of cytoplasmic streaming**

For cytoplasmic streaming recording, 4- to 5-day-old rice seedlings were placed on glass slides and their roots were dipped either in water (control) or in the extract, covered with a coverslip and observed with DIC optics under a Zeiss AxioImager.Z2 light microscope (Carl Zeiss AG), equipped with an AxioCam MRc5 camera (Carl Zeiss AG). Time lapse images were captured using AxioVision Rel. 4.8.2 software (Carl Zeiss AG). Specifically, for each recording, 60 images captured every 2 sec, were combined in videos of 12 sec duration. The extract used for treatment was replenished regularly after each image capture.

Transmission Electron Microscopy (TEM)

Control and extract-treated (for 30 min or 1 h) root tips of 4- to 5-day-old rice seedlings were fixed in 3% (v/v) glutaraldehyde (PolySciences, Niles, IL, USA) in 50 mM sodium cacodylate buffer (pH 7) for 4 h, washed and post-fixed with 1% (w/v) osmium tetroxide in the same buffer for 3 h at 4°C in the dark. Dehydration was performed in an acetone series, followed by treatment with propylene oxide (SERVA, Heidelberg, Germany) at 4°C and embedding in Spurr's resin (PolySciences, Niles, IL, USA). The embedded specimens were sectioned with a Reichert-Jung Ultracut E (Reichert-Jung Optical Company, Vienna, Austria) ultramicrotome. Ultrathin sections (70-90 nm) were collected on formvar-coated copper grids and double-stained in the dark with 2% (w/v) uranyl acetate in 70% (v/v) ethanol for 15 min and 1% (w/v) lead citrate for 10 min. The sections were examined with a JEOL JEM 1011 (JEOL Ltd., Tokyo, Japan) TEM, equipped with a Gatan ES500W (Gatan Inc., Pleasanton, CA, USA) digital camera and images were acquired using Digital Micrograph 3.11.2 software. CLSM and TEM images were processed with Adobe Photoshop CS4 with only linear settings.

RESULTS

Effects on F-actin

250 Fine actin filaments were abundant in all untreated meristematic cells (Fig. 1A1). F-
251 actin phragmoplasts were obvious in cytokinetic cells, either control or treated with
252 MC-LR for various times (arrows in Fig. 1). In MC-LR-treated cells, cortical actin
253 filaments appeared disoriented (indicative arrowheads in Fig. 1B2) and bundled
254 (indicative arrowheads in Figs 1C2, D2), from 30 min until 2 h of exposure, compared
255 to the control (Fig. 1A2). Especially after 30 min and 1 h, ring-shaped F-actin
256 conformations (typical examples in Fig. 1C4) could be observed in affected
257 meristematic cells (arrowheads in Figs 1B3, C3, C5). However, after 24 h of
258 treatment, F-actin intensity deteriorated significantly (Fig. 1E1) and cortical actin
259 filaments were barely visible (Fig. 1E2).

260 Meristematic cells treated with the cyanobacterial extract (Fig. 2) also exhibited
261 disoriented cortical actin filaments after 30 min of exposure (Fig. 2A2), as well as
262 bundling effects (indicative arrowheads in Figs 2B1, B2, C1, C2) after 1 and 2 h. After
263 24 h, apart from F-actin bundling (arrowhead in Fig. 2D2), several cells appeared
264 totally devoid of actin filaments (star in Fig. 2D1).

265 In the differentiation zone, F-actin cables could be observed in untreated cells,
266 exhibiting a predominant longitudinal orientation (Fig. 3A). After treatment with MC-
267 LR, disorientation and bundling of F-actin was detectable (arrowheads in Figs 3B-E)
268 between 30 min and 2 h of exposure, eventually leading to disappearance of F-actin
269 in large areas of the tissue after 24 h (Fig. 3E).

270 In roots treated with the extract (Fig. 4), F-actin bundles were disoriented, an effect
271 increasing in a time-dependent manner (arrows in Figs 4A, B, C1, D1). Furthermore,
272 F-actin rings occurred in the affected cells after longer exposure (Figs 4C2, D2, D3).
273 After 24 h, several cells were devoid of F-actin (Fig. 4D1).

274 CTCF measurements (Fig. 5) confirmed the hypothesis that fluorescence intensity
275 gradually diminishes during the treatment with either MC-LR or the extract, in both
276 meristematic and elongation zone the lowest levels being recorded after 24 h of
277 treatment. This decrease appeared to be especially steep in MC-LR treated roots,

278 just after 30 min of treatment. Any temporary increases in fluorescence intensity (e.g.
279 in differentiated root cells after 1 h of treatment with the extract) could be attributed to
280 F-actin bundling effects.

281

282 **Effects on microtubules and chromatin**

283 Untreated meristematic root cells exhibited the typical microtubule arrays, i.e. cortical
284 microtubules in interphase cells (Fig. S1A), the preprophase band and perinuclear
285 microtubules in preprophase/prophase cells (Fig. S1B), the mitotic spindle in
286 metaphase/anaphase cells (Fig. S1C) and the phragmoplast in telophase/cytokinetic
287 cells (Fig. S1D).

288 Rice root cells treated with the toxic cyanobacterial extract for 30 min-24 h exhibited
289 various time-dependent alterations in the organization of microtubules (Fig. S1E-K).
290 After 30 min of exposure, cortical microtubules of interphase cells were significantly
291 fewer (Fig. S1E; *cf.* S1A). In affected preprophase cells, preprophase bands were
292 visible, but perinuclear microtubules were absent (Fig. S1F; *cf.* S1B). In affected cells
293 with condensed chromosomes, as assessed by DAPI staining, typical spindles were
294 not found, as microtubules connected to the chromosomes appeared either
295 abnormally elongated (Fig. S1G) or short and disoriented (Fig. S1H). In the above
296 affected mitotic cells, microtubule fragments and/or fluorescent tubulin structures,
297 apart from chromosome-connected microtubules, could also be observed (Figs S1G,
298 H). In telophase/cytokinetic cells treated as above, phragmoplasts could be
299 observed, the microtubules of which were longer than those of untreated cells (Fig.
300 S1I; *cf.* S1D), their (-) ends sometimes attached on the surface of daughter nuclei.

301 After 1 h of treatment, microtubules were depolymerized (Figs S1J, K) in cells with
302 normal-looking nucleus (Fig. S1J), as well as in cells with abnormal chromatin
303 condensation (Fig. S1K). In some of these cells, fluorescent tubulin spots could be
304 observed (Fig. S1J).

305 Interestingly, MC-LR-treated root cells exhibited control-like microtubule arrays.
306 Occasionally, 30 min- and 1 h-treated interphase cells with typical cortical
307 microtubules (Figs S2C, E; *cf.* S2A) exhibited endoplasmic microtubules, not typically
308 observed in untreated cells (Figs S2D, F; *cf.* S2B), while in affected preprophase
309 cells preprophase bands exhibited gaps (Fig S2G; *cf.* Fig. S2H). MC-LR-affected
310 metaphase cells appeared to have typical mitotic spindles (Figs S2I, J; *cf.* Fig. S1C),
311 while occasionally chromosomes out of the spindle could be observed (arrow in Fig.
312 S2J).

313

314 **Effects on cell cycle progression**

315 The assessment of cell cycle stages in treated root tip cells revealed that each stage
316 frequency was significantly altered after 1 h of treatment with MC-LR, while it was
317 severely disturbed in extract-treated roots even after 30 min (Table 1). In the latter
318 case, the percentage of preprophase/prophase cells was increased after 30 min of
319 treatment, as was the percentage of metaphase/anaphase cells after 1 h, compared
320 to untreated roots. On the contrary, there was a notable decrease in the percentage
321 of cytokinetic cells after 30 min and 1 h of treatment with the extract. Alterations
322 observed (in both MC-LR- and extract-treated roots) were statistically significant (chi-
323 squared test, $df = 3$, $P < 0.001$)

324

325 **Effects on cytoplasmic streaming**

326 Alterations of cytoplasmic streaming in affected root cells were visible after treatment
327 with the extract (see Supplementary Videos). After 1 h, streaming either stopped or
328 appeared to be slower (left and right arrow, respectively, Video S5; *cf.* S4), as
329 opposed to that of root cells in presence of water, in which streaming remained vivid
330 during the exposure time period (Videos S1-3). After 2 h, streaming (where present)
331 was noticeably abnormal and cytoplasmic aggregates could be observed (arrow and
332 arrowhead, respectively, Video S6; *cf.* S4).

333

334 **Effects on the endoplasmic reticulum and Golgi apparatus**

335 The toxic extract also affected the integrity and distribution of the endoplasmic
336 reticulum. In cells exposed to the extract for 30 min and 1 h, fluorescent endoplasmic
337 reticulum aggregates were observed by CLSM, located cortically and/or around the
338 nucleus (Fig. 6B, C), in contrast to the evenly distributed endoplasmic reticulum of
339 untreated cells (Fig. 6A). After 3 h of treatment, these aggregates appeared to fade,
340 while the nucleus exhibited morphological alteration (Fig. 6D).

341 TEM observations of root cells treated with the extract for 30 min revealed that
342 endoplasmic reticulum cisternae were heavily stacked (Fig. 6F), in contrast to the
343 loosely packed cisternae of untreated cells (Fig. 6E). In addition, while in untreated
344 cells Golgi dictyosomes were evenly distributed (Fig. 7A), in cells affected by the
345 extract the dictyosomes appeared clustered, even after 30 min of treatment with
346 vesicles trapped among them (Fig. 7B). After 1 h of exposure, Golgi apparatus
347 clustering and vesicle aggregation were intensified (Fig. 7C).

348

349 **DISCUSSION**

350 In this study, MC-LR disrupted F-actin in rice roots. The detrimental effects were
351 recorded as significant alterations of the network (Figs 1, 3) and as a gradual
352 decrease in F-actin fluorescence intensity (Fig. 5), eventually leading to a collapse in
353 both meristematic and differentiating root cells (Figs 1, 3).

354 Apart from the above similarity, there was a significant difference between the
355 treatment with purified MC-LR and the extract. Exposure to the latter induced severe
356 disruption of microtubule arrays and alterations of the frequency of cells at various
357 cell cycle stages after just 30 min (Table 1). On the contrary, MC-LR affected
358 microtubule organization only slightly, as well as cell cycle distribution only after 1 h
359 of exposure.

360 According to cytological studies on other plant species, MCs affect the integrity and
361 organization of microtubules, causing chromatin hypercondensation in plant cells by
362 inhibiting PP1 and PP2A, which subsequently leads to histone H3
363 hyperphosphorylation (Beyer et al., 2012; Máthé et al., 2009; Ujvárosi et al., 2019).
364 Also, experiments on *Arabidopsis thaliana* indicated the involvement of subfamily II
365 and TON2 subunits of the PP2A holoenzyme in cortical microtubule organization
366 and, probably, in microtubule nucleation through interaction with γ TuRCs (Yoon et
367 al., 2018). Studies on PP2A have highlighted its importance for plant cytoskeleton
368 organization (especially microtubules), affecting preprophase band formation,
369 division plane determination (Spinner et al., 2013), and cell shape (Kirik et al., 2012).
370 Interestingly, in the present study, treatment with purified MC-LR did not result in any
371 of these effects. A possible reason for this could be that the duration of treatments
372 here was far shorter than in the previously mentioned studies. In most of the relevant
373 studies, exposure to MC-LR spanned from 4 h to 20 days (Beyer et al., 2012; Garda
374 et al., 2016; Mathé et al., 2009). However, in the present study microtubules were
375 severely affected only after treatment with the crude toxic extract for a very short time
376 (30 min and 1 h), which indicates the possible involvement of other compounds in the
377 effect mechanism. Except of microcystins, which have been detected in *Microcystis*
378 *flos-aquae* TAU-MAC 1510, it is also likely that these effects may be the result of a
379 synergistic action of various bioactive compounds produced by the strain. For
380 example, anabaenopeptins, which show activity against PP1 (Gkelis et al., 2006), are
381 known to occur in large concentrations in *Microcystis*-dominated blooms (Gkelis et
382 al., 2015b) or microginins, which have been recently reported to be abundant in
383 blooms of Greek freshwater cyanobacteria (Zervou et al., 2020), are also known to
384 be bioactive (Ujvárosi et al., 2020; for a review on the variety of cyanobacterial
385 bioactive compounds, see Dittmann et al., 2015; Elisabeth & Janssen, 2019).
386 The findings of the present study prove that F-actin is indeed a target of
387 cyanobacterial toxicity, specifically of microcystins, in plant cells. To date, information

about the way actin filaments are affected by microcystins derives exclusively from studies on treated animal cells. In rat hepatocytes and fibroblasts, all three cytoskeletal components (microtubules, intermediate filaments and microfilaments) are sensitive to MC-LR treatments in a dose- and time-dependent manner (Wickstrom et al., 1995). Disorganization of intermediate filaments and microtubules was reported to precede alterations in normal disposition of microfilaments in animal cells. These alterations included extensive reorganization of F-actin into “rosette-like structures”, which eventually collapsed, forming aggregates around the cell nucleus (Wickstrom et al. 1995). Similar observations concerning F-actin were also made in rat hepatocytes by Ghosh et al. (1995) and by Batista et al. (2003) in primary human hepatocytes, while Gácsi et al. (2009) reported the formation of circular actin aggregations around the nuclei of MC-LR-treated Chinese hamster ovary (CHO-K1) cells after 24 h of incubation at high concentrations of the cyanotoxin (20 μ M). In particular, actin aggregation at the cell periphery seems to be a common alteration in microcystin-treated animal cells (Eriksson et al., 1989; Falconer and Yeung, 1992; Runnegar and Falconer, 1986; Wickstrom et al., 1995), at least for some time during the cascade of F-actin-collapse events. As expected, alterations in F-actin organization consequently led to animal cell shape deformation.

It could be suggested that F-actin disruption in rice root cells is attributed to protein phosphatase inhibition. In human T lymphocytes, inhibition of PP1 and PP2A has been shown to block dephosphorylation of actin depolymerizing factor (ADF)/cofilin, an actin-binding protein, which is responsible for actin depolymerization when in active, unphosphorylated state (Ambach et al., 2000). Such an effect on PP1 and PP2A could explain the bundling effects observed in the F-actin network of rice root cells affected by microcystin, as F-actin tends to become stabilized. In a more recent study (Wang et al., 2014), MC-LR was found to directly bind to PP2A in SMMC-7721 human liver cancer cells, inhibiting enzyme activity and causing cytoskeletal rearrangements. More specifically, PP2A inhibition led to hyperphosphorylation of

various cytoskeleton-associated proteins (including cofilins) and inactivation (as well as changes in subcellular localization) of Rac1, a small GTPase, which is regulated by PP2A (Nunbhakdi-Craig et al., 2003) and is involved in microtubule and actin dynamics (Wittmann et al., 2003). In plants, the presence of cofilins has been reported in various species (Hussey et al., 2002), while PP2A-2, an isoform of PP2A, is known to directly regulate ADF/cofilin (and, therefore, F-actin rearrangements) in *Arabidopsis thaliana* (Wen et al., 2012). In addition, OsRac1 (a rice homolog of Rac1), along with its activator GEF protein OsSPK1, have been recently suggested to be regulators of actin dynamics in rice (Wang et al., 2018). Importantly, in rice root cells, progression of F-actin disorganization/disorientation appeared to be slower than in animal cells and not as harsh; in fact, even after 24 h of exposure, actin filaments could still be observed, though scarce. The increased resistance of actin filaments to microcystins could be attributed to at least three reasons: (1) Most of the actin filaments, especially in vacuolated cells, are interconnected in thick bundles, which could offer stabilization against adverse factors. (2) Cortical actin filaments are interconnected to cellulose microfibrils of the cell wall by formin1 (Martinière et al., 2011), also regulating F-actin stability and cell shape (Rosero et al. 2013, 2016). (3) F-actin may appear more stabilized following inactivation of ADF/cofilin, due to inhibition of protein phosphatases by microcystins. Whichever the mechanism by which F-actin is affected by microcystins, the effect of a microcystin-rich crude extract indicates that this could occur in environmental conditions, due to cell lysis during cyanobacterial blooms. According to this view, disruption of F-actin may be one more possible reason for cyanobacterial toxicity to plants, apart from the already established effects on microtubules and the cell cycle. In addition, the importance of F-actin disorganization is also reflected on the alterations observed in endoplasmic reticulum and the Golgi apparatus. As reviewed by Volkmann and Baluška (1999), movement and distribution of endoplasmic reticulum and the Golgi apparatus in plant cells are controlled by the F-actin network.

444 Furthermore, cytoplasmic streaming was disturbed (see Supplementary Videos), due
 445 to its dependence on actomyosin integrity and function (for a review, see Shimmen
 446 and Yokota, 2004). Consequently, stacking of endoplasmic reticulum as well as
 447 abnormal aggregation of Golgi dictyosomes could be a direct result of defective F-
 448 actin organization and subsequent intracellular motility defects. Apart from the
 449 involvement of F-actin, alterations of endoplasmic reticulum have been reported in
 450 both plant (Huang et al., 2009) and animal cells, either fish (Li et al., 2001) or
 451 mammalian (Alverca et al., 2009), and attributed to microcystins, after treatment for
 452 various time periods, ranging from hours to days. These results, therefore, suggest
 453 the presence of a mechanism of toxicity, which involves microcystins and affects a
 454 variety of cell systems. Nevertheless, in the present study, endoplasmic reticulum
 455 cisternae seemed to diminish after 1 h of exposure. Interestingly, absence of smooth
 456 endoplasmic reticulum has been also previously observed in rat hepatocytes after
 457 treatment with MC-LR for 20 min (Eriksson et al., 1989).

458 In conclusion, F-actin is a target of MC-LR. In addition, the microcystin-rich extract of
 459 the cyanobacterial strain *Microcystis flos-aquae* TAU-MAC 1510 disrupts cytoskeletal
 460 components, F-actin and microtubules, as well as the endomembrane system and
 461 cell cycle distribution, in root tip cells of *Oryza sativa*. Microcystins present in the
 462 extract could be held responsible for certain of the effects observed, as they have
 463 previously been linked with defects in chromatin condensation, but most probably a
 464 synergistic action of microcystins with other cyanobacterial bioactive compounds may
 465 be hypothesized. To our best knowledge, this is the first report of a microcystin (MC-
 466 LR) affecting the plant F-actin cytoskeleton and the first attempt to feature the potent
 467 effects of cyanobacterial bioactive compounds on F-actin-related cell functions.
 468 Further research is needed in order to elucidate the above in detail.

469

470 **ACKNOWLEDGEMENTS**

471 This research is part of a PhD thesis (Dimitris Pappas) and is co-financed by Greece
472 and the European Union (European Social Fund- ESF) through the Operational
473 Programme «Human Resources Development, Education and Lifelong Learning» in
474 the context of the project “Strengthening Human Resources Research Potential via
475 Doctorate Research” (MIS-5000432), implemented by the State Scholarships
476 Foundation (IKY). Emmanuel Panteris is supported by the AUTH Research
477 Committee (Grant No 91913). The authors would like to deeply thank Prof. Kaarina
478 Sivonen (University of Helsinki, Finland) for generously providing a stock of MC-LR,
479 as well as Assist. Prof. Ioannis-Dimosthenis Adamakis (National and Kapodistrian
480 University of Athens, Greece) and Assoc. Prof. George Komis (Palacký University
481 Olomouc, Czechia) for their advice and critical reading of the manuscript.

696 Tables

697 **Table 1.** Occurrence of various cell cycle stages in *O. sativa* root tips, either control
698 or after treatment with microcystin-LR (MC-LR) or the *Microcystis flos-aquae* TAU-
699 MAC 1510 extract for 30 min and 1 h. Data represent absolute cell counts
700 (percentages in parentheses). Data exhibiting statistically significant difference
701 compared to the control are noted with asterisks (chi-squared test, $df = 3$, $P < 0.001$).

		MC-LR		<i>Microcystis flos-aquae</i> 1510	
	Control (%)	30 min (%)	1 h (%)*	30 min (%)*	1 h (%)*
Interphase	1080 (91.6)	1012 (90.68)	978 (92.44)	895 (89.5)	914 (91.4)
Preprophase/Prophase	44 (3.73)	53 (4.75)	44 (4.16)	79 (7.9)	51 (5.1)
Metaphase/Anaphase	12 (1.02)	8 (0.72)	7 (0.66)	12 (1.2)	31 (3.1)
Cytokinesis	43 (3.65)	43 (3.85)	29 (2.74)	14 (1.4)	4 (0.4)

706 Figure Legends

707 **Figure 1. Maximum intensity projections of serial CLSM sections (A1, B1, C1,**
708 **D1, E1, B3, C3-C5) and single cortical CLSM sections (A2, B2, C2, D2, E2) of *O.***
709 ***sativa* protodermal cells in the root meristematic zone, after F-actin staining.**
710 **treatment with purified MC-LR and/or.** In all images the root tip points towards the
711 bottom of the page. Single cortical sections depict cells from the same root areas as
712 the projections, at higher magnification. Control cells exhibit a well-organized network
713 of abundant fine cortical and endoplasmic actin filaments (**A1**). The dominant
714 orientation of cortical actin filaments is transverse (perpendicular to the root axis,
715 **A2**). Cytokinetic cells with prominent F-actin phragmoplasts are noted by arrows
716 (projections **A1-E1**). After treatment with MC-LR, cortical actin filaments appear
717 disoriented at 30 min (indicative arrowheads in **B2**; cf. **A2**), tending to form bundles
718 after 1 h (indicative arrowheads in **B2, C2, D2**). Ring-shaped F-actin conformations
719 (actin-rings) are visible in affected cells after 30 min and 1 h of treatment
720 (arrowheads in **B3** and **C3-C5**, enlargements of framed areas in **B1** and **C1**,
721 respectively). After 24 h, F-actin fluorescence intensity is noticeably decreased (**E1**)
722 and the cortical F-actin network barely visible (**E2**). Scale bars: 10 µm.

723 **Figure 2. Maximum intensity projections of serial CLSM cortical sections (A1,**
724 **B1, C1, D1) and single cortical CLSM sections (A2, B2, C2, D2) of *O. sativa***
725 **protodermal cells in the root meristematic zone, after treatment with the *M.***
726 ***flos-aquae* TAU-MAC 1510 extract and F-actin staining.** All figures are oriented
727 with the root tip to the bottom of the page. Single cortical sections (**A2-D2**) depict
728 cells from the same root areas as the projections (**A1-D1**), at higher magnification.
729 After 30 min of treatment with the extract (**A1**), cortical actin filaments appear
730 disoriented (**A2**; cf. **Fig. 1A2**), tending to form bundles after 1 h (indicative
731 arrowheads in **B1, B2**). After 2 h, bundling increases (indicative arrowheads in **C1**,
732 **C2**). After 24 h, the F-actin network has collapsed and cells devoid of actin filaments

733 (area marked with star in **D1**) can be observed, along with remnants of bundles
734 (arrowhead in **D2**). Scale bars: 10 μ m.

735 **Figure 3. Maximum intensity projections of serial CLSM sections of *O. sativa***
736 **epidermal cells in the root differentiation zone, after F-actin staining.** All figures
737 are oriented with the root tip to the bottom of the page. In control cells, longitudinal
738 subcortical F-actin bundles can be observed (**A**). Cells treated with MC-LR for 30 min
739 exhibit disoriented subcortical F-actin bundles, converging at several cell sites
740 (indicative arrowheads in **B**; cf. **A**). This effect is also detectable after 1 and 2 h
741 (arrowheads in **C** and **D**, respectively). After 24 h, F-actin bundles have diminished
742 and only remnants of F-actin bundles (arrowheads in **E**) can be observed. Scale
743 bars: 10 μ m.

744 **Figure 4. Maximum intensity projections of serial CLSM sections of *O. sativa***
745 **epidermal cells in the root differentiation zone, after treatment with the *M. flos-***
746 ***aquae* TAU-MAC 1510 extract and F-actin staining.** All figures are oriented with
747 the root tip to the bottom of the page, except for (**C2**, **D2**) with the root tip to the right.
748 After treatment with the extract for 30 min, subcortical F-actin bundles appear to be
749 disoriented (**A**; cf. **Fig. 3A**), tending to form aggregates at 1 h (**B**). After 2 h, actin
750 filaments begin to diminish (**C1**) and F-actin rings can be observed (arrows in **C2**,
751 enlargement of the framed area of **C1**). After 24 h, cells devoid of F-actin can be
752 observed (**D1**), while F-actin rings (arrows in **D2** and **D3**, enlargements of framed
753 areas of **D1**) are abundant in cells that still exhibit actin filaments. Scale bars: 10 μ m.

754 **Figure 5. Fluorescence intensity measurements of F-actin in *O. sativa* root**
755 **cells.** Maximum intensity projections of serial CLSM sections of the meristematic and
756 differentiation zones of roots treated with the *M. flos-aquae* TAU-MAC 1510 extract
757 (maroon) or purified MC-LR (green) for various durations (30 min, 1, 2 and 24 h)
758 were compared to similar images of control roots. Fluorescence intensity decreases

759 drastically in a time-dependent manner, especially after treatment with MC-LR.
760 Temporary increases, where visible, could be attributed to F-actin bundling effects.
761 Error bars indicate the standard error. All data shown exhibit statistically significant
762 difference compared to control (ANOVA with Dunnett's test), $P < 0.001$. $n = 30$.

763 **Figure 6. Endoplasmic reticulum distribution in *O. sativa* root cells.** Various
764 durations of treatment with the *M. flos-aquae* TAU-MAC 1510 extract are indicated
765 on the images. **A-D**. Single CLSM central sections, after endoplasmic reticulum
766 immunolabeling (green) and DNA staining with DAPI (pseudocoloration in red).
767 Untreated cells (**A**) exhibit even endoplasmic reticulum distribution during interphase
768 (cells at middle and right), while during metaphase endoplasmic reticulum encages
769 the spindle (left). Treatment with the extract results in appearance of endoplasmic
770 reticulum aggregates (arrows in **B-D**), even after only 30 min (**B**), the fluorescence
771 intensity of which fades as treatment duration increases (**C**, **D**). Scale bars: 5 μm . **E**,
772 **F**. TEM micrographs depicting normal endoplasmic reticulum distribution in control
773 cells (**E**) and a stack of endoplasmic reticulum cisternae (arrow in **F**) after 30 min of
774 treatment. After longer treatment, endoplasmic reticulum cisternae could not be
775 found by TEM. Scale bars: 0.2 μm .

776 **Figure 7. TEM micrographs of Golgi dictyosome distribution in *O. sativa* root**
777 **cells.** Dictyosomes are normally distributed and distanced in an untreated cell (**A**).
778 After 30 min (**B**) and 1 h (**C**) of treatment with the *M. flos-aquae* TAU-MAC 1510
779 extract, dictyosomes gather in clusters, displaying aggregates of vesicles (asterisks)
780 entrapped between them. Scale bars: 0.2 μm (**A**, **B**) and 0.5 μm (**C**).
