Abstract

The neurobehavioral mechanisms of human motor-control and learning evolved in free behaving, real-life settings, yet to date is studied in simplified lab-based settings. We demonstrate the feasibility of real-world neuroscience, using wearables for naturalistic full-body motion-tracking and mobile brain-imaging, to study motor-learning in billiards. We highlight the similarities between motor-learning in-the-wild and classic toy-tasks in well-known features, such as multiple learning rates, and the relationship between task-related variability and motor learning. Studying in-the-wild learning enable looking at global observables of motor learning, as well as relating learning to mechanisms deduced from reductionist models. The analysis of the velocity profiles of all joints enabled in depth understanding of the structure of learning across the body. First, while most of the movement was done by the right arm, the entire body learned the task, as evident by the decrease in both inter- and intra- trial variabilities of various joints across the body over learning. Second, while over learning all subjects decreased their movement variability and the variability in the outcome (ball direction), subjects who were initially more variable were also more variable after learning, supporting the notion that movement variability is an individual trait. Lastly, when exploring the link between variability and learning over joints we found that only the variability in the right elbow supination shows significant correlation to learning. This demonstrates the relation between learning and variability: while learning leads to overall reduction in movement variability, only initial variability in specific task relevant dimensions can facilitate faster learning.

Author Summary

This study addresses a foundational problem in the neuroscience: studying the mechanisms of motor control and learning in free behaving, real-life tasks, where our brains and bodies operate in on a daily basis and which contains the richness of stimuli and responses for what our nervous system evolved. We used the competitive sports of pool billiard to frame an unconstrained real-world skill learning experiment which is amenable to predictive modelling and understanding. Our data-driven approach unfolds the structure and complexity of movement, variability, and motor-learning, highlighting that real-world motor-learning affects the whole body, changing motor-control from head to toe. Crucially, we are enabling novel hypothesis driven experimental approaches to study behavior where it matters most - in real life settings.

Introduction

Motor learning is a key feature of our development and daily lives, from a baby learning to roll, to an adult learning a new sport, or a patient undergoing rehabilitation after a stroke. The process of learning a real-world motor skill is usually long and complex, and difficult to quantify. As a result, real-world motor learning is rarely studied, and most of the motor learning literature focuses on relatively simple tasks, performed in a lab setup or an MRI scanner, such as force-field adaptations (e.g. Diedrichsen et al., 2005; Howard et al., 2015; Shadmehr and Mussa-Ivaldi, 1994; Smith et al., 2006), visuomotor perturbations (e.g. Haar et al., 2015; Krakauer et al., 2000; Mazzoni and Krakauer, 2006; Taylor et al., 2014), and sequence-learning of finger tapping or pinching tasks (e.g. Clerget et al., 2012; Ma et al., 2011; Reis et al., 2009; Yokoi et al., 2018).

These reductionistic tasks enable to isolate specific features of the motor learning and tackle them individually. While this plays an important role in our understanding of sensorimotor control and learning, it addresses a very restricted range of behaviors that do not capture the full complexity of real-world motor control and may overlook fundamental principles of motor control and learning in real-life (Faisal et al., 2010; Ingram and Wolpert, 2011; Wolpert et al., 2011). It is only in natural behavioral settings that neuroscientific mechanisms are subject to evolutionary selection pressures and it is the operation in these contexts for which the nervous system has been designed (Hecht et al., 2014). Over the past decade there were few important efforts in this direction. One line of research devised more complex tasks for skill learning (e.g. Abe and Sternad, 2013; Cohen and Sternad, 2009; Shmuelof et al., 2012), but those were still computer based toy-tasks which try to emulate real-world tasks. The other line used actual real-world tasks such as juggling (e.g. van Beers et al., 2013; Hecht et al., 2014; Ono et al., 2015; Sampaio-Baptista et al., 2014, 2015; Scholz et al., 2009), but these studies analyzed only anatomical and functional MRI changes following learning and did not address behavior or neural activity during the learning process.

Here we are taking a novel data-driven approach to study behavior where it matters most – in natural real-life settings. The paradigm in which we study real-world motor learning is the game of pool table billiards. Billiards is a real-world task ideally suited to neurobehavioral study as motion tracking in terms of movement in space, the natural constraints of game playing, and divisibility into trials captures the style of reductionistic lab-based motor learning tasks. Billiards is also a natural task which is complex and involves many different sub-tasks (precision, alignment, ballistic movements, high-level sequential planning) which requires complex skills. To tackle the complexity of the high dimensional task space of this real-world task, we applied naturalistic approaches and developed a neurobehavioral database of real-world motor learning behavior. This includes the full body movement during the entire learning period, as well as the measurements of task performance (balls movement on the table). This enabled us to quantify the trends of changes

90   in each of them separately during the entire learning process, and to look for correlations between
91   the changes in the body movement and the performance in the task.

92   We structured the results as follows: We ground our results in previous work on
93   reductionistic lab tasks, to show that our unconstrained task and its task goal (directional error of
94   the target ball relative to the pocket it is meant to go in) displays the well-known features of human
95   motor learning. We then characterize full-body movement structure during the task, and how
96   learning changes the kinematics of all joints over trials. Next, we compare across subjects to map
97   their performance, learning rates, and motor variability, and how initial variability and learning
98   rates are linked.

Results

100   30 right-handed volunteers, with little to no previous experience playing billiards,
101   performed 300 repeated trials (6 sets of 50 trials each with short breaks in-between) where the cue
102   ball and target ball were placed in the same locations, and subjects were asked to shoot the target
103   ball towards the far-left corner pocket (Figure 1A). During the entire learning process, we recorded
104   the subjects' full body movements with a 'suit' of inertial measurement units (IMUs; Figure 1B),
105   and the balls on the pool table were tracked with a high-speed camera to assess the outcome of each
106   trial (Figure 1C).

Movement and Learning in a real-world pool task

108   The ball tracking data showed a double exponential learning curve for the decay in the
109   directional error of the target ball (relative to the direction from its origin to the center of the target
110   pocket) over trials (Figure 1D). The direction of the initial trials error was consistent across subjects
111   as they tended to hit the center of the target ball and shot it forward towards the center of the table.
112   For measuring success rates and intertrial variability we divided the trials into blocks of 25 trials
113   (each experimental set of 50 trials was divided to two blocks to increase the resolution in time).
114   The learning curve over blocks (Figure 1E) emphasized the reduction in the inter-subject variability
115   during learning (decreasing error bars). The success rate over blocks (percentage of successful trials
116   in each block; Figure 1F) showed similar learning to the directional error. The learning was also
117   evident in the intertrial variability in the shooting direction which decayed over learning (Figure
118   1G). Since learning also occurred within a block (especially during the first block) and the
119   variability might be driven by the learning gradient, we corrected for it by calculating intertrial
120   variability over the residuals from a regression line fitted to the ball direction in each block (while
121   the learning curve is exponential, within the small blocks of 25 trials it is almost linear). This
122   corrected intertrial variability showed the same pattern (Figure 1H). Overall, the task performance
123   data suggested that subjects reached their peak performance on the fifth experimental set (blocks
124   9-10, trials 200-250) and are doing the same (or even slightly worse) on the last experimental set

4

125   (blocks 11-12, trials 250-300). Thus, we refer to the last two experimental sets (blocks 9-12, trials

126   201-300) as the 'learning plateau'.

Figure 1. *Experimental setup and task performance*. (**A**) 30 right-handed healthy subjects performed 300 repeated trials of billiards shoots of the target (red) ball towards the far-left corner. (**B**) Full body movement was recorded with a 'suit' of 17 wireless IMUs (Xsens MVN Awinda). (**C**) The pool balls were tracked with a high-speed camera. Dashed lines show the trajectories of the cue (white) and target (red) balls over 50 trials of an example subject. (**D**) The trial-by-trial directional error of the target-ball (relative to the direction from its origin to the centre of the target pocket), averaged across all subjects, with a double-exponential fit (red curve). Grey lines mark the range of successful trials. (**E**) The mean absolute directional error of the target-ball. (**F**) The success rates. (**G**) directional variability. and (**H**) directional variability corrected for learning (see text). (**E-H**) presented over blocks of 25 trials, averaged across all subjects, error bars represent SEM.

127

128   The full body movements were analyzed over the velocity profiles of all joints, and not the

129   joint angles profiles, as those are less sensitive to potential drifts in the IMUs and have proven to

130   be more robust and reproducible across subjects in natural behavior (Thomik, 2016). In the current

131   data we can also see this robustness across trials (Figure 2A). The covariance matrix over the

132   velocity profiles of the different joints, averaged across the initial block trials of all subjects, showed

133   that most of the variance in the movement is in the right arm, and specifically in the right shoulder

134   (Figure 2B). This is a signature for the naivety of the subjects, as pool billiards guide books

135   emphasize that the shooting movement should be from the elbow down while the shoulder should

136   be kept still. The covariance of the velocity profiles averaged across the initial block of the learning

137   plateau (trials 201-225) showed similar structure with an overall decrease relative to the initial trials

138   but an increase in the variance of right elbow rotation (Figure 2C).
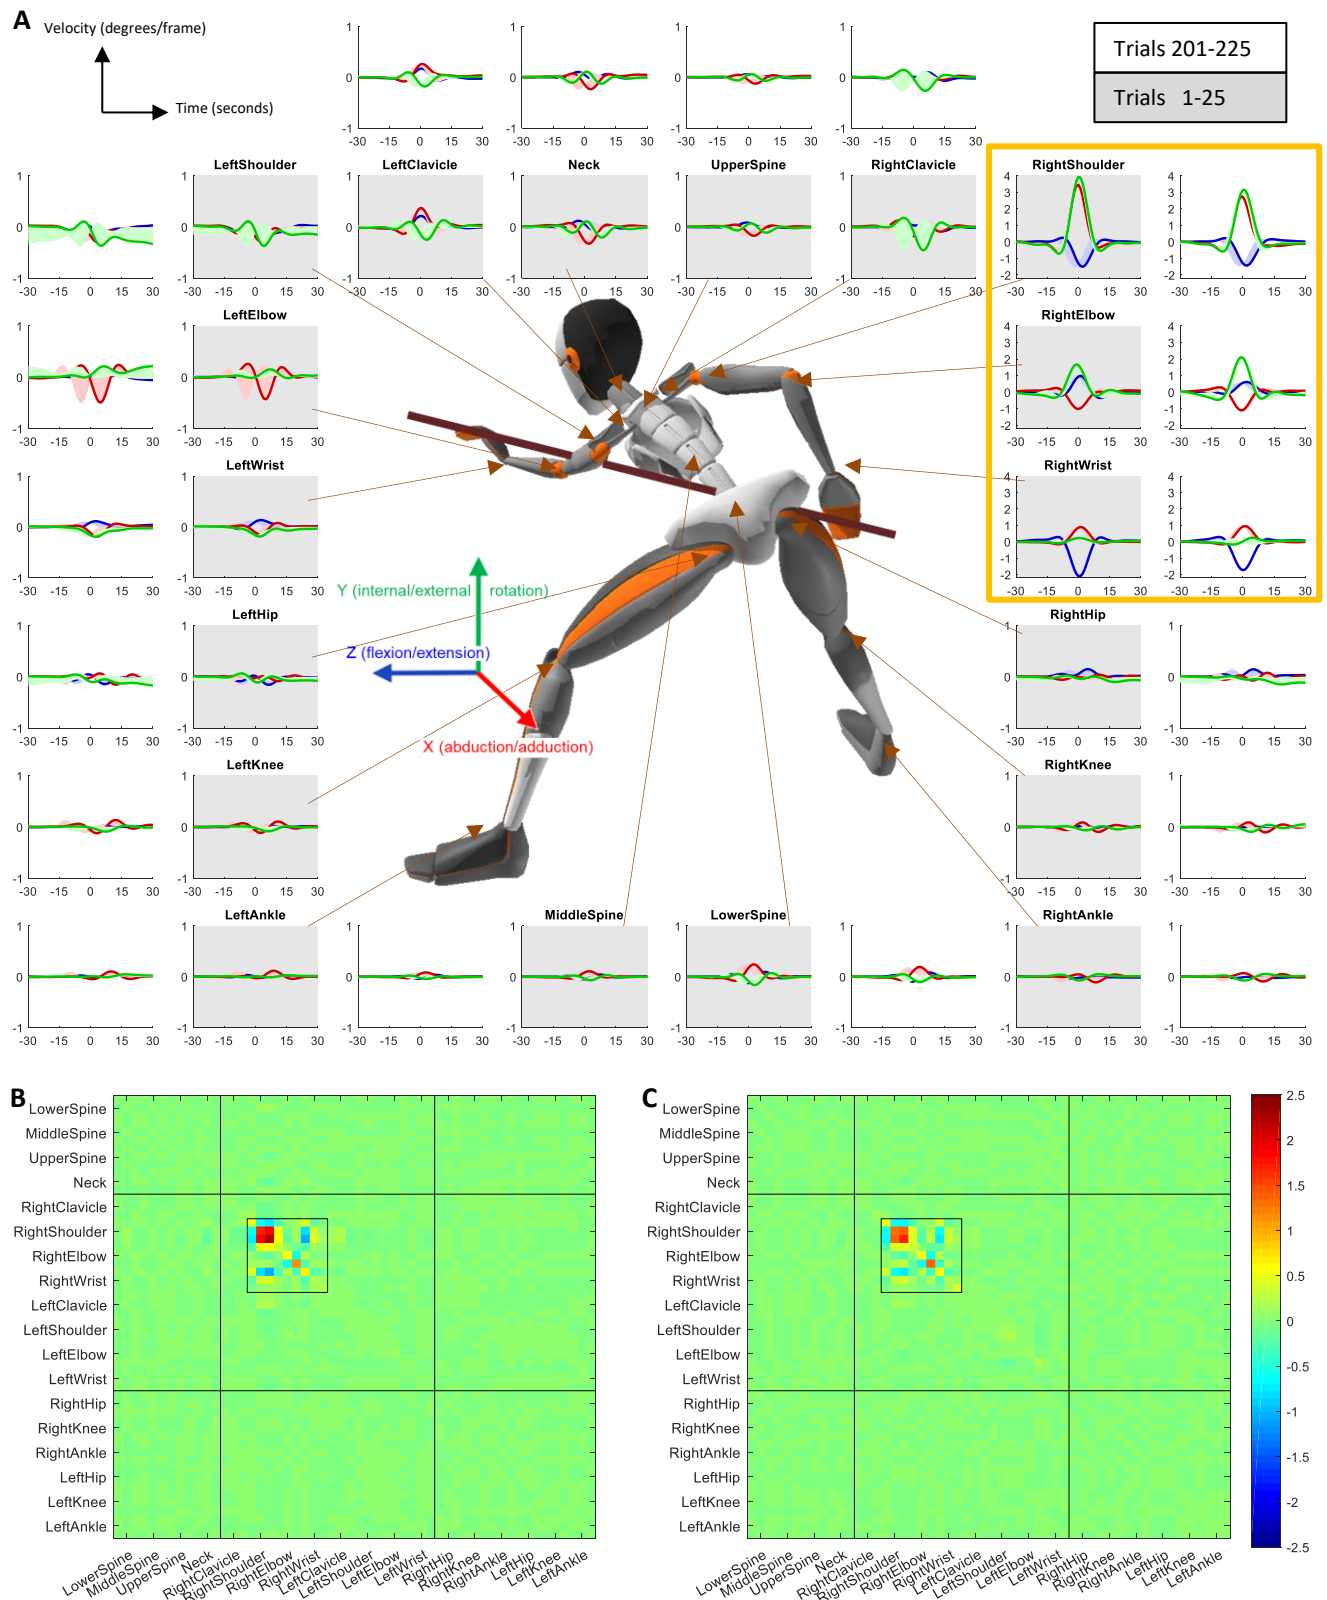

5

Figure 2. *Velocity profiles and covariance*. (**A**) Velocity profiles in 3 degrees of freedom (DoF) for each joint (blue: flexion/extension, red: abduction/adduction; green: internal/external rotation) averaged across subjects and trials over the first block of trials (1-25) in the inner circle (grey background) and the first block after learning plateau (201-225) in the outer circle (white background). The joints of the right arm, which do most of movement in the task, are highlighted in orange box. (**B,C**) The variance covariance matrix of the velocity profiles of all joints averaged across subjects and trials (**B**) over the initial block (1-25) and (**C**) first block after learning plateau (201-225). The order of the DoF for each joint is: flexion/extension, abduction/adduction, internal/external rotation.

139

140   On the group level, the velocity profiles of all joints (including the joints of the right arm
141   that carry most of the movement variance) showed only minor changes following learning. For
142   example, the flexion/extension of the right elbow showed a decrease in velocity from the initial
143   trials to the trials of the learning plateau (Figure 2A).

144   The generalized variance (GV; the determinant of the covariance matrix (Wilks, 1932))
145   over the velocity profiles of all joints increased fast over the first ~30 trials and later decreased
146   slowly (Figure 3A), suggesting active control of the exploration-exploitation trade-off. The
147   covariance over the initial block, the block over the peak GV, and first block after learning plateau
148   (Figure 3B), shows that the changes in the GV were driven by an increase in the variance of all
149   DoFs of the right shoulder, and the negative covariance between the abduction/adduction and
150   internal/external rotation of the right shoulder to the flexion/extension of the right shoulder and
151   wrist. The internal/external rotation of the right elbow showed a continuous increase in its variance,
152   which did not follow the trend of the GV. Principal component analysis (PCA) across joints for the
153   velocity profiles per trial for each subject, showed that while in all trials ~90% of the variance can
154   be explained by the first PC, there is a slow but consistent rise in the number of PCs that explain
155   more than 1% of the variance in the joint velocity profiles (Figure 3C). The manipulative
156   complexity, suggested by Belić and Faisal (2015) as way to quantify complexity for a given number
157   of PCs on a fixed scale ($C = 1$ implies that all PCs contribute equally, and $C = 0$ if one PC explains
158   all data variability), showed cleaner trajectory with the same trend (Figure 3D). This suggests that
159   over trials subjects use more degrees of freedom in their movement.

Figure 3. *Variance and Complexity*. (**A**) The trial-by-trial generalized variance (GV), with a double-exponential fit (red curve). (**B**) The variance covariance matrix of the right arm joints velocity profiles averaged across subjects and trials over the initial block (trials 1-25), the second block (trials 26-50), in which the GV peaks, and first block after learning plateau (block 9, trials 201-225). The order of the DoF for each joint and the colorbar are the same as in Figure 2. (**C**) The number of principal components (PCs) that explain more than 1% of the variance in the velocity profiles of all joints in a single trial, with an exponential fit (red curve). (**D**) The manipulative complexity (Belić and Faisal, 2015), with an exponential fit (red curve). (**A,C,D**) Averaged across all subjects over all trials.

160

7

161 As a measure of task
162 performance in body space,
163 we defined a measure of
164 Velocity Profile Error (VPE)
165 for each joint in each trial
166 (see methods). For all joints,
167 VPE showed a clear pattern
168 of decay over trials in an
169 exponential learning curve
170 (Figure 4A). A proximal-to-
171 distal gradient in the time
172 constant of these learning
173 curves was observed across
174 the right arm, from the
175 shoulder to the elbow and
176 the wrist rotation which
177 showed very slow learning
178 (the other wrist angles had
179 very low VPE from the start,
180 thus did not learn much).
181 Intertrial variability in joint
182 movement was measured
183 over the VPEs in each block.
184 Learning was also evident in
185 the decay over learning of
186 the VPE intertrial variability
187 over most joints across the
188 body (Figure 4B).

189 **Inter-subject differences**
190 **in variability and learning**
191 We found
192 substantial differences
193 between subjects in their
194 initial errors, final errors,
195 intertrial variability, and
196 learning, which are

Figure 4. *Learning over Joints*. (**A**) Velocity Profile Error (VPE) reduction across all joints. The trial-by-trial VPE for all 3 DoF of all joints, averaged across all subjects, with an exponential fit. The time constants of the fits are reported under the title. The color code of the DoF is the same as in figure 2 (blue: flexion/extension; red: abduction/adduction; green: internal/external rotation). (**B**) Velocity Profile Error (VPE) intertrial variability over blocks of 25 trials, averaged across all subjects.

197 overlooked in the group average results. One subject, who had low initial errors, showed no

198 learning, i.e. did not reduce her error over trials from the first block (trials 1-25) to the learning
199 plateau (trials 201-300). For all other subjects the final errors were smaller than the initial errors
200 (Figure 5A). There was a significant correlation between the initial and the final errors, meaning
201 subjects with higher initial errors tended to have higher final errors as well.

Figure 5. *Variability and learning across subjects*. (**A**) Correlation between subjects' mean absolute directional error over the first block (trials 1-25) and the learning plateau (trials 201-300). (**B**) Correlation between subjects' directional variability over first block (corrected for learning trend, see text) and over the learning plateau (**C**) Correlation between subjects' mean absolute directional error over the learning plateau and their learning (**D**) Correlation between subjects' directional variability over the first block (corrected for learning trend, see text) and their learning (**E**) Correlation between subjects' VPE variability (in logarithmic scale) over the first block and the learning plateau for the right arm joints. (**F**) Correlation between subjects' VPE variability (in logarithmic scale) over the first block and their learning for the right arm joints. (**A-F**) Correlation values are Spearman rank correlation, regression lines are linear fits with 95% confidence intervals.

202

203 While over learning most subjects decreased their intertrial variability in the outcome (ball
204 direction; Figure 1H & 5B) there was some tendency (though non-significant) for subjects who
205 were initially more variable to be also more variable after learning (Figure 5B). The intertrial
206 variability of the joint velocity profiles, which also decreased over learning (Figure 4B), showed a
207 clearer and stronger correlation between the initial and the final intertrial variability (Figure 5E &
208 S1 Fig). While this phenomenon was observed in various joints across the body, and dominant in
209 the abduction across the spine joints, it was most dominant in the right shoulder abduction and

9

210   rotation, the two joint angles that do most of the movement and carry most of its variance (Figure

211   2).

212   Learning was defined as the difference between the initial error (over the first block: trials

213   1-25) and the final error (over the learning plateau: trials 201-300) normalized by the initial error.

214   There was no significant correlation between the learning and the final error (as subjects who started

215   worse could have learn more but still not perform better after learning), but there was a trend that

216   more learning leads to smaller final errors (Figure 5C). We tested if higher levels of initial task-

217   relevant motor variability (variability in the directional error of the target ball) in this complex real-

218   world task could predict faster learning across individual, as found in simple lab experiments (Wu

219   et al., 2014). We indeed found that individuals with higher intertrial variability in the directional

220   error of the target ball over the first block showed more learning (Spearman rank correlation r=0.64,

221   p<0.001; Figure 5D). Importantly, this is the corrected intertrial variability (as in Figure 1I) which

222   is calculated over the residuals from a regression line fitted to the ball direction to correct for the

223   learning that is happening within the block. As a control we also tested for correlation with the

224   initial variability in the target ball velocity, task-irrelevant motor variability, and found no

225   correlation (Spearman rank correlation r=0.06, p=0.77). Next, we tested the link between learning

226   and initial variability over the joint velocity profiles of the right arm (Figure 5F). We found that the

227   only joint angle where the intertrial variability showed significant correlation to learning was the

228   right elbow rotation (Spearman rank correlation r=0.47, p=0.0086), which is the arm supination.

229   We further tested the link over the full body kinematics (S2 Fig) and found no other joint that

230   showed this correlation. Thus, while learning leads to overall reduction in movement variability,

231   only initial variability in specific, task-relevant, dimensions can facilitate/predict learning.

Discussion

233   In this paper we introduce a new paradigm for studying naturalistic motor learning during

234   whole-body movement in a complex real-world motor skill task. Our results present new insights

235   into motor learning in the real-world. While the learning curves in this in-the-wild paradigm are

236   within the same range of those reported in reductionistic motor adaptation tasks (e.g. McDougle

237   et al., 2015; Smith et al., 2006) we find that this learning is taking place not only in the task relevant

238   joints but across the entire body. Also, we found that task relevant initial variability in the ball

239   direction (movement outcome) can predict learning, like in toy tasks (Wu et al., 2014), and so can

240   the initial variability in the right arm supination which is the task relevant joint angle variability.

241   While pushing towards real-world neuroscience, we started here with a relatively

242   constrained version of the real-world task, asking subjects to perform repeated trials of the same

243   pool shot. This was to enable analysis using well developed methods of laboratory studies in toy-

244   tasks. Nonetheless, it is a major step in the direction of a naturalistic study. First, we allow full-

245 body unconstrained movement. Second, we do not use any artificial go cue and allow self-paced
246 movement and as many preparatory movements as the subject needs for each shoot. Third, subjects
247 receive natural somatosensory feedback. And last, we do not perturb the feedback to induce
248 learning.

Fundamentals of real-world motor learning

250 Across all subjects, we found that motor learning is a holistic process - the body is affected
251 as a whole from learning the task. This was evident in the decrease in the VPE and the intertrial
252 variability over learning (Figure 4). This result should not come as a surprise considering decades
253 of research in sport science showing this relationship. For example, baseball pitcher's torso, pelvis,
254 and leg movements are directly associated with ball velocity (Kageyama et al., 2014; Oliver and
255 Keeley, 2010; Stodden et al., 2006). Recently it was also demonstrated with full-body motion
256 capture in a ball throwing task (Maselli et al., 2017). And yet, unlike baseball pitches, basketball
257 throws, or any unconstrained overarm throw, where the whole body is moving, in a pool shot the
258 shooting arm is doing most of the movement and there is very little body movement. Thus, the
259 whole-body learning is not trivial and suggestive that even in arm movement toy-tasks there is a
260 whole-body learning aspect which is overlooked.

261 We also found a proximal-to-distal gradient in the learning rates over the right arm joints
262 (Figure 4A). This is especially interesting in light of the well-known phenomenon of proximal-to-
263 distal sequence in limb movements in sports science (Herring and Chapman, 1992) and in
264 rehabilitation (Twitchell, 1951). While there are records of proximal-to-distal sequence at multiple
265 time scales (Serrien and Baeyens, 2017), our results are the first to suggest that this gradient also
266 occur over repetitions as part of the learning process.

Variability & learning

268 Intertrial variability is a fundamental characteristic of human movements and its underling
269 neural activity (for review see Faisal et al., 2008). It was recently reported that individuals exhibit
270 distinct magnitudes of movement variability, which are consistent across movements and effectors,
271 suggesting an individual traits in movement variability (Haar et al., 2017). Our results show that
272 subjects who were initially more variable tended to be also more variable after learning in many
273 joints across the body (Figure 5E & S1 Fig) and specifically in those of right shoulder that carry
274 most of the variance in the movement. This supports the notion that there is an individual trait in
275 movement variability.

276 Intertrial kinematic variability is also thought to be critical for motor learning (e.g. Braun
277 et al., 2009; Dhawale et al., 2017; Herzfeld and Shadmehr, 2014; Teo et al., 2011; Wilson et al.,
278 2008). It was suggested that individuals with higher levels of task-relevant movement variability
279 exhibit faster motor learning in both skill learning and motor adaptation error-based paradigms (Wu
280 et al., 2014). The failures to reproduce this result in visuomotor adaptation studies (He et al., 2016;

11

281 Singh et al., 2016), led to the idea that experiments with task-relevant feedback (which is common
282 in visuomotor studies) emphasize execution noise over planning noise, whereas measurements
283 made without feedback (as in Wu et al., 2014) may primarily reflect planning noise (Dhawale et
284 al., 2017). This is in-line with a recent modeling work in a visuomotor adaptation study (with task-
285 relevant feedback) in which subjects with higher planning noise showed faster learning, but the
286 overall movement variability was dominated by execution noise that was negatively correlated with
287 learning (van der Vliet et al., 2018). In our task there were no manipulations or perturbations, thus,
288 task-relevant feedback was fully available to the participants. On the other hand, in real-world there
289 is no baseline variability, and the variability was measured during early learning and therefore is
290 probably dominated by planning noise, as subjects explore, regardless of the visual feedback.
291 Indeed, subjects with higher variability in the target ball direction over the first block showed higher
292 learning rates (Figure 5D). Our results straighten the link between variability and learning and are
293 the first to show that it applies to real-world tasks. Moreover, the only joint angle that showed
294 significant correlation between initial variability and learning was the right elbow rotation (Figure
295 5F & S2 Fig). Following the idea that task-relevant variability predicts learning, it would suggest
296 that the right elbow rotation is the task-relevant joint angle to adjust during initial learning of a
297 simple pool shoot. Indeed, guide books for pool and billiards emphasize that while shooting one
298 should keep one's body still and move only the back (right) arm from the elbow down. While the
299 elbow flexion movement gives the power to the shoot, the arm supination (also known as 'screwing'
300 in billiards and measured by the elbow rotation in our IMUs setup) maintains the direction of the
301 cue.

Conclusions

303   In this study we demonstrate the feasibility and importance of studying human
304 neuroscience in-the-wild, and specifically in naturalistic real-world skill tasks. While finding
305 similarities in learning structure between our real-world paradigm and lab-based motor learning
306 studies, we highlight crucial differences, namely, real-world motor learning is a holistic full-body
307 process. Looking at the motor behavior over learning across the entire body enabled us to explore
308 the relationship between variability and learning and define task relevant variability that can
309 facilitate learning.

Methods

Ethics statement. All experimental procedures were approved by Imperial College Research Ethics Committee and performed in accordance with the declaration of Helsinki. All subjects gave informed consent prior participating to the study.

Experimental Setup and Design. 30 right-handed healthy human volunteers with normal or corrected-to-normal visual acuity (12 women and 18 men, aged 24±3) participated in the study. The volunteers, who had little to no previous experience with playing billiards, performed 300 repeated trials where the cue ball (white) and the target ball (red) were placed in the same locations and the subject was asked to shoot the target ball towards the pocket of the far-left corner (Figure 1A). The trials were split into 6 sets of 50 trials with a short break in-between. For the data analysis we further split each set into two blocks of 25 trials each, resulting in 12 blocks. During the entire learning process, we recorded the subjects' full body movements with a motion tracking 'suit' of 17 wireless inertial measurement units (IMUs; Figure 1B). Brain activity was recorded with wireless EEG, neural findings reported elsewhere (Haar and Faisal, 2020). The balls on the pool table were tracked with a high-speed camera (Dalsa Genie Nano) to assess the subjects' success in the game and to analyze the changes throughout learning, not only in the body movement and brain activity but also in its outcome – the ball movement (Figure 1C).

Full-Body Motion Tracking. Kinematic data were recorded at 60 Hz using a wearable motion tracking 'suit' of 17 wireless IMUs (Xsens MVN Awinda, Xsens Technologies BV, Enschede, The Netherlands). Data acquisition was done via a graphical interface (MVN Analyze, Xsens technologies BV, Ensched, The Netherlands). The Xsens joint angles and position data were exported as XML files and analyzed using a custom software written in MATLAB (R2017a, The MathWorks, Inc., MA, USA). The Xsens full body kinematics were extracted in joint angles in 3 degrees of freedom for each joint that followed the International Society of Biomechanics (ISB) recommendations for Euler angle extractions of Z (flexion/extension), X (abduction/adduction) Y (internal/external rotation).

Movement Velocity Profile Analysis. From the joint angles we extracted the velocity profiles of all joints in all trials. We defined the peak of the trial as the peak of the average absolute velocity across the DoFs of the right shoulder and the right elbow. We aligned all trials around the peak of the trial and cropped a window of 1 sec around the peak for the analysis of joint angles and velocity profiles.

Statistical Analysis. Trial by trial learning curves were fitted with a single or a double exponential learning curve using matlab fit function.

343   As a measure of task performance in body space, correlation distances (one minus Pearson

344   correlation coefficient) were calculated between the velocity profile of each joint in each trial to

345   the velocity profiles of that joint in all successful trials. The mean over these correlation distances

346   produced a single measure of Velocity Profile Error (VPE) for each joint in each trial.

347
$$VPE_i = \frac{\sum_{s}^{N_{scs}} corrDist(velProf_i, velProf_s)}{N_{scs}}$$

348   Thus, VPE in trial i was the sum of the correlation distances between the velocity profile

349   in trial i ($velProf_i$) and the velocity profiles in successful trials s ($velProf_s$), divided by the

350   number of successful trials (N_{scs}).

351   For measuring success rates and intertrial variability we divided the trials into blocks of 25

352   trials by dividing each experimental set of 50 trials to two blocks. This was done to increase the

353   resolution in time from calculating those on the full sets. To improve robustness and account for

354   outliers, we fitted the errors in each block with a t-distribution and used the location and scale

355   parameters (μ and σ) as the blocks' center and variability measures. Similarly, all correlations

356   between error, variability, and learning are Spearman's rank correlation coefficients. Regression

357   lines are based on linear regression fits (in logarithmic scale for VPE variability) and are presented

358   with 95% confidence intervals.
