ABSTRACT

Phagocytosis by glial cells is essential to regulate brain function during development and disease. Given recent interest in using amyloid β ($A\beta$)-targeted antibodies as a therapy for patients with Alzheimer's disease, removal of $A\beta$ by phagocytosis is likely protective early in Alzheimer's disease, but remains poorly understood. Impaired phagocytic function of glial cells surrounding $A\beta$ plaques during later stages in Alzheimer's disease likely contributes to worsened disease outcomes, but the underlying mechanisms of how this occurs remain unknown. We have developed a human $A\beta_{1-42}$ analogue ($A\beta^{pH}$) that exhibits green fluorescence upon internalization into the acidic phagosomes of cells but is non-fluorescent at physiological pH. This allowed us to image, for the first time, glial uptake of $A\beta^{pH}$ in real time in live animals. Microglia phagocytose more $A\beta^{pH}$ than astrocytes in culture, in brain slices and *in vivo*. $A\beta^{pH}$ can be used to investigate the phagocytic mechanisms removing $A\beta$ from the extracellular space, and thus could become a useful tool to study $A\beta$ clearance at different stages of Alzheimer's disease.

Keywords: Amyloid beta, real-time phagocytosis, microglia, astrocytes, live animals, pH reporter, phagosomes, lysosomes, live cell imaging, confocal microscopy, two-photon microscopy

INTRODUCTION

Glial cells make up more than half of the cells of the central nervous system (CNS) and are vital to the regulation of brain function¹. Microglia are specialized CNS-resident macrophages that respond to pathogens and injury by clearing cell debris, misfolded protein aggregates and damaged neurons by the process of phagocytosis². Mature microglia in the adult brain exhibit a ramified morphology and constantly survey their surroundings for “eat me” signals³ present on or released from apoptotic cells, microbes, protein deposits, dysfunctional synapses and other target substrates. After CNS injury or during neurodegenerative diseases like Alzheimer’s disease (AD) microglia become “reactive”, and change morphology, becoming rod-like or amoeboid⁴, and actively engage with their environment by secreting inflammatory cytokines like TNF- α and IL-1 α . These cytokines cause functional changes in astrocytes, microglia themselves and other cells^{5,6}.

During phagocytosis, proteins on the microglial cell surface, such as the Toll-Like Receptors (TLRs), Fc receptors, and scavenger receptors including CD36 and the receptor for advanced glycation end products (RAGE) among others, recognize the “eat-me” signals and engulf the target substrates into intracellular compartments called phagosomes^{7–10}. The phagosomes mature by fusing with lysosomes to form highly acidic phagolysosomes and mobilize the phagocytosed material for enzymatic degradation. The pH of phagosomal organelles during this maturation process is progressively reduced¹¹ from 6.0 to 4.5-4.0. Although microglia are the “professional phagocytes” of the CNS, astrocytes also competent phagocytic cells with important roles both during health, and in response to injury or in disease^{12–15}. Recent evidence has demonstrated the phagocytic abilities of reactive astrocytes towards cellular debris in CNS injury¹⁶. Together, reactive microglia and astrocytes play a crucial role in clearing extracellular debris and cellular components and aid in remodeling the tissue environment during disease.

AD is characterized by the generation of soluble oligomers of amyloid β (A β) that have numerous downstream actions, including reducing cerebral blood flow¹⁷, inhibiting glutamate uptake that may cause hyperexcitability of neurons¹⁸, and inducing hyperphosphorylation of the cytoskeletal protein tau^{19,20} that leads to synaptic dysfunction and cognitive decline. Ultimately A β oligomers are deposited as extracellular plaques in the brain, a hallmark of AD, which contribute to neuroinflammation and neuronal death²¹. The main A β species generated excessively in AD is A β ₁₋₄₂, which is a small ~4.5 kDa peptide produced by the cleavage of

amyloid precursor protein on neuronal membranes by β - and γ -secretases^{22,23}. Removal of A β from the extracellular space by phagocytosis into microglia and astrocytes, as well as by clearance across endothelial cells into the blood or lymph vessels, is thought to limit the build-up of extracellular A β concentration. However, AD occurs when A β generation outweighs its removal²⁰. Thus, to understand the onset of plaque deposition during AD (and perhaps how to prevent it) it is essential to understand glial phagocytosis and degradation of A β . A method that can monitor this process, especially in real time *in vivo*, will facilitate identification of the receptors that bind to A β and initiate its phagocytic clearance. This will allow investigation of why glia that surround A β plaques in AD show impaired phagocytic function^{24–26}, and why in inflammatory conditions microglia may increase their phagocytic capacity depending on their state of activation^{27,28}.

Current methods to study glial phagocytosis involve the use of fluorescent latex beads²⁹ or particles of zymosan³⁰ or *E. coli*³¹ conjugated to non-pH based fluorophores like fluorescein and rhodamine³². A non-pH based particle makes it hard to determine whether the particle is inside the phagosomes or outside the cell during live-cell monitoring (**Figure S1a**). Some bioparticles can be labeled with pH-sensitive dyes such as pHrodo™, however, currently available pH-sensitive dyes are not suitable for labeling disease-specific pathogenic molecules like A β for *in vivo* use. While non-pH sensitive fluorophore conjugates of A β have been used to evaluate A β phagocytosis^{29,33}, they have several disadvantages for live-cell imaging and cannot be used for selective identification and isolation of phagocytic cells *in vivo*. First, pH-insensitive fluorophore conjugated A β peptides exhibit sustained fluorescence in the extracellular space (at physiological pH) thus contributing a noisy background that hinders the clear visualization of the live phagocytic cells (**Figure S1b**). Second, in live-cell imaging and in fluorescence-activated cell sorting (FACS) of live cells, it is difficult to differentiate between A β molecules that are internalized by the cells versus A β molecules that are stuck to the cell surface.

To address these issues, we have developed a pH-dependent fluorescent conjugate of human A β_{1-42} , which we call A β^{pH} , and characterized it using mass spectrometry, atomic force microscopy and imaging of its uptake into cells *in vitro* and *in vivo*. We show the functionality of the A β^{pH} probe for identifying phagocytic microglia and astrocytes in several different biological model systems such as cell lines, primary cell cultures, brain tissue slices, and *in vivo* in brain and retina. A β^{pH} retains an aggregation phenotype similar to that of synthetic A β *in vitro* and exhibits increased green fluorescence within the acidic pH range of 2.0 to 4.5 and not at the extracellular and cytoplasmic physiological pH values of 7.4 and 7.1, respectively. A β^{pH} can be

used to visualize phagocytosis in live cells in real time without the use of any A β -specific antibody. It is internalized by glial cells (both astrocytes and microglia) in live rat hippocampal tissue sections *in situ*. Stereotaxic injection of A β^{pH} into the mouse somatosensory cortex leads to its uptake by astrocytes and microglia, following which microglia retain the A β^{pH} within the cells up to 3 days *in vivo* unlike astrocytes. Similarly, fast astrocyte clearance was observed in retinal tissue, using immunohistochemical staining of tissue sections. Finally, we show, for the first time, real-time phagocytosis of A β into microglia and astrocytes in mouse cortex *in vivo* by two-photon excitation microscopy.

RESULTS

Properties of a novel pH-dependent fluorescent conjugate of human A β_{1-42}

We synthesized a new pH-sensitive fluorescent dye-labelled phagocytic A β probe for imaging both *in vitro* and *in vivo*, and cell sorting that allows for downstream analysis of functional subtypes of cells. We used a facile bioconjugation strategy to make our new probe safe for use with live cells *in vitro* and with live animals *in vivo*. The A β^{pH} conjugate was synthesized at the microgram scale by linking the synthetic human A β_{1-42} peptide to the amine-reactive Protonex Green 500, SE (PTXG) fluorophore (**Figure 1a**). We selected PTXG based on its ability to emit intense fluorescence at the low pH of 4.5-5.0 found within lysosomes. Conjugation of the fluorophore was performed at the side chain amine groups of the lysine residues within, and at the N-terminal of, human A β_{1-42} peptide. The conjugation was confirmed with matrix-assisted laser desorption/ionization-mass spectrometry (MALDI-MS) (**Figures S2, S3**) that indicates the conjugation of PTXG with the A β_{1-42} peptide (molecular weight >4.5K) by removal of succinimidyl ester (SE) as a leaving group. Additionally, proton nuclear magnetic resonance ($^1\text{H-NMR}$) analysis of A β^{pH} also demonstrated the presence of PTXG as well as A β_{1-42} peptide (**Figures S4-S6**). The spectrum of A β_{1-42} peptide obtained from attenuated total reflection Fourier transform infrared spectroscopy (ATR-FTIR) also shows a strong absorption peak at 1625 cm^{-1} confirming amine functional group (**Figure S7**) and the spectrum of PTXG shows the presence of amide and ester group with absorption peaks at 1668 and 1727 cm^{-1} , respectively (**Figure S8**). The conjugated product A β^{pH} shows a distinct peak at 1674 cm^{-1} confirming the amide bond formation between the A β_{1-42} peptide and PTXG dye, as expected (**Figure S9**). Collectively, these experiments confirm the formation of the peptide-dye conjugate.

We also synthesized another conjugate of A β_{1-42} with the pHrodo-Red, NHS fluorophore (RODO) and confirmed conjugate formation from the MALDI spectrum (**Figure S10**).

The pH-sensitivity of the PTXG and RODO-conjugated A β^{pH} were confirmed by measuring their fluorescence intensities at pH 1.0 to 9.0 in solution. The PTXG-conjugated A β^{pH} show a sharp maximum of fluorescence between pH 5.0 and 2.0 at concentrations of 0.5, 1.0, 2.0, and 5.0 μM (**Figure 1b**) with excitation/emission wavelengths of 443/505 nm. At these concentrations, the PTXG-A β^{pH} showed maximum fluorescence intensities between 500 and 510 nm in the 4.5-2.0 pH range (**Figure S11**). The PTXG-A β^{pH} conjugate exhibits low fluorescence intensity at pH values more alkaline than 5.0 including at the physiological extracellular pH of 7.4. In contrast, the RODO-conjugated A β^{pH} displayed increased fluorescence within a wider pH range of 1.0-7.0 for the same concentrations (**Figure S12**). Due to the broad range of fluorescence exhibited by the RODO-A β^{pH} conjugates, and long-term sustained fluorescence intensity of PTXG and PTXG-A β^{pH} (**Figure S13**), the PTXG-A β^{pH} conjugate was chosen for all further experiments (termed A β^{pH} henceforth). Lastly, we wanted to determine whether A β^{pH} exhibits aggregation properties similar to the aggregation of synthetic, non-conjugated A β . The A β_{1-42} and A β^{pH} oligomers were prepared³⁴ from hexafluoroisopropanol (HFIP) treated peptide films in PBS pH 7.4 buffer at 4°C. Atomic force microscopy (AFM) revealed that the ability of A β^{pH} to aggregate is similar to that of the non-conjugated A β (**Figure 1c**) suggesting that A β^{pH} is suitable for biological use^{35,36}.

A β^{pH} uptake into human and mouse microglial cell lines

To visualize phagocytosis of A β^{pH} in real-time in live microglial cells, immortalized human microglial clone 3 (HMC3) cells and mouse BV2 and N9 microglial cells were treated with 1, 2 and 5.0 μM concentrations of A β^{pH} and live-cell images were acquired every 30 minutes for 24 hours (**Figure 1d**). We observed internalization and increased fluorescence of A β^{pH} (implying phagocytosis) by HMC3 cells. The fluorescence was quantified as a *Phagocytic Score*, i.e. relative fluorescence compared to initial time (t=0) normalized over the 24-hour period (see **Methods**). For HMC3 cells there was an initial rapid phase of fluorescence (score) increase followed either by a slower increase in fluorescence at 5 μM A β^{pH} concentration or a slow decrease of fluorescence from its peak value at 1 μM and 2 μM A β^{pH} concentration (**Figures 1e, S14**). This suggests rapid initial uptake of A β^{pH} , followed by intracellular degradation of A β^{pH} which occurs either more rapidly than the influx (giving a slow decline) or less rapidly than the

influx (giving a slowed increase) (**Figure S14**). Cells that did not phagocytose A β^{pH} did not display any green fluorescence thereby differentiating A β^{pH} -specific phagocytic and non-phagocytic microglial cells in real time. Rodent microglial cell lines (BV2 and N9) showed a peak of *Phagocytic Score* at 12-16 hours for N9 and 16-20 hours for BV2 at 5 μM A β^{pH} treatment, compared to the HMC3 human microglial cell line that showed a gradual increase in phagocytosis over the 24-hour treatment period for the same concentration. Interestingly, for the lower A β^{pH} doses of 1 μM and 2 μM , the peak value of *Phagocytic Score* for HMC3 cells was within the initial 4 hours compared to the gradual increase for the rodent cell lines over the 24 hour period (**Figure S14**). Using live-cell imaging, we also observed interesting morphological differences over time between phagocytic and non-phagocytic microglial cells. During the initial 2 hours, many cells displayed an elongated, branched morphology followed by an amoeboid morphology during subsequent time points with increased fluorescence (**Movies S1-3**). Thus, the A β^{pH} reporter can be used to visualize A β -specific phagocytosis in real-time and can be used in experiments to evaluate the enhancement or inhibition of microglial phagocytosis for *in vitro* screening of drug candidates for AD.

Flow cytometry of A β^{pH} phagocytic cells and staining of fixed A β^{pH} after phagocytosis by primary cultured microglia and astrocytes

We next determined whether A β^{pH} can be used to purify phagocytosing cells using fluorescent activated cell sorting (FACS). By adding A β^{pH} to BV2 cells *in vitro*, we show that live microglial cells that phagocytose A β^{pH} can be easily analyzed with flow cytometry without the need for traditional dyes or antibodies to detect A β (**Figure 1f**). Phagocytic uptake of A β^{pH} by BV2 microglia was evident with a green fluorescence peak within live cells when the cells were treated with 0.5 μM and 5.0 μM A β^{pH} for 1 hour in culture (**Figures 1f, S15**), with unstained and live/dead stained cells as controls. There was a slight increase in A β^{pH} fluorescence at 1 hour for a 10-fold increase in A β^{pH} concentration for BV2 cells. The green fluorescence signal indicates internalization of A β^{pH} into the cellular acidic organelles thereby avoiding detection of peptide sticking to the cell surface. Thus, A β^{pH} fluorescence after phagocytosis is sufficiently bright to enable FACS experiments, enabling single cell analysis of A $\beta^{\text{pH}+}$ phagocytic and A $\beta^{\text{pH}-}$ non-phagocytic microglia and other glial cells.

Fixing cells that have internalized A β^{pH} , and using specific antibodies and dyes to study specific molecular processes, can help identify molecular mechanisms involved during A β

phagocytosis. To determine whether A β^{pH} can maintain its fluorescence in fixed cells, we used primary mouse CD11b⁺ microglial cells isolated from 3-5 month old mice and cultured in reduced-serum TIC medium³⁷ as well as BV2, N9, and HMC3 microglia. After A β^{pH} (5.0 μ M) treatment for 2 hours, the cells were fixed in 4% paraformaldehyde followed by addition of red phalloidin dye (a podosome core marker for F-actin) to visualize actin filaments and the cell body with confocal microscopy (**Figure S17, S18**). Confocal imaging of the fixed A β^{pH} -treated microglia showed green fluorescence within the red actin filaments thereby confirming the uptake of A β^{pH} peptides by the cells. Further, LysoTracker DND-99 was used to confirm localization of A β^{pH} within acidic organelles such as phagosomes or phagolysosomes. The co-localization of green fluorescent A β^{pH} along with the red signal from the LysoTracker dye confirmed the presence of A β^{pH} within acidic phagolysosomes after 2 hours in HMC3, N9, and BV2 microglia cell lines (**Figures 2a, S19**). Similarly, uptake of A β^{pH} into intracellular acidic organelles was also confirmed in CD11b⁺ primary microglia that were isolated from adult mice and cultured in low serum containing defined media (**Figure 2b**). Finally, we also detected the green fluorescence signal within CD11b⁺ primary microglia (A β^{pH+} cells) at 0.5, 1.0, and 2.0 μ M A β^{pH} concentrations via flow cytometry (**Figures 2c, S16**) after 1 hour of treatment, and found an increase in fluorescence with A β^{pH} concentration. The unstained and live/dead stained cells were used as controls. Microglia recognize and phagocytose A β peptides through scavenger receptors such as^{38–40} Toll-Like Receptor 2 (TLR2) Cluster of Differentiation 14 (CD14) and Triggering Receptors Expressed on Myeloid Cells 2 (TREM2). Thus, the A β^{pH} reporter that we have developed could serve as a valuable chemical tool to delineate the role of receptor proteins involved in A β uptake by glial cells, using specific antibodies or CRISPR-Cas9 genetic screens.

In addition to microglia, astrocytes have been shown to exhibit phagocytic characteristics after ischemic injury¹⁶ and can phagocytose²⁹ extracellular A β . Therefore, we tested whether primary immunopanned cultured mouse astrocytes phagocytosed A β^{pH} . Indeed, this was the case, with retention of the phagocytic A β^{pH} signal after methanol-fixation and staining of cells with GFAP antibody (**Figure 2d**). A β^{pH} phagocytosis could also be detected with live cell imaging (**Figure 2e**). Quantification of A β^{pH} uptake at different concentrations showed internalization increasing for approximately 1 hour, followed by a sustained fluorescence within the cells which may reflect a balance between phagocytosis and degradation of the probe (**Figure 2f**). Thus, A β^{pH} may be a viable candidate for concentration and time-dependent studies of glial cell phagocytosis *in vitro*. The sustained fluorescence of A β^{pH} seen for up to 6

hours inside cultured microglia and astrocytes suggests it is chemically stable under physiological conditions – allowing for long-term use *in vivo*.

A β^{pH} uptake by microglia and astrocytes in hippocampus, cortex, and retina

To assess phagocytic uptake of A β^{pH} in the hippocampus, a brain area that is crucial for learning and memory, we applied 5 μM A β^{pH} for 1.5 hours at 37°C to live hippocampal slices from postnatal day (P)12 rat. The tissue slices were then fixed and stained with glial cell specific antibodies (**Figure 3a**). Microglia phagocytosed A β^{pH} as seen by the localization of A β^{pH} within the IBA1⁺ myeloid cells in these tissues (**Figure 3b**). Our experiments revealed green fluorescent signal both within IBA1⁺ microglial cells as well as outside the IBA1⁺ cells (**Figure S20**), presumably reflecting phagocytic uptake of A β^{pH} by cells other than microglia, such as astrocytes. Indeed, staining with GFAP antibody demonstrated internalization of A β^{pH} within GFAP⁺ astrocytes (**Figure 3c**). Summing over cells, approximately 60% of the taken up A β^{pH} was phagocytosed by microglia and 40% by astrocytes (**Figure 3d**). Interestingly, in astrocytes the phagocytosed A β^{pH} was distributed more homogeneously throughout the GFAP area than the phagocytosed A β^{pH} in IBA1 stained microglia. This is expected since in microglia the acidic compartments (where A β^{pH} is present) are mostly juxtanuclear whereas IBA1 is known to be enriched in podosomes and podonuts⁴¹. In contrast, in astrocytes the acidic compartments occur all over the cell body⁴².

We next tested the A β^{pH} probe in different *in vivo* settings. After intracranial injection of A β^{pH} into the somatosensory cortex of wild-type P7 C57BL/6J mice (**Figure 4a**), phagocytosis of the A β^{pH} by IBA1⁺ microglia and GFAP⁺ astrocytes was assessed by fixing the corresponding tissue sections at 24 and 72 h after injection. At 24 h, A β^{pH} was observed in the injected area and appeared to be enclosed within cell bodies. There was less astrocyte uptake of A β^{pH} compared to microglia, which may be a result of a reactive response by astrocytes which has been shown to downregulate phagocytic pathways in some states⁵ (**Figure 4b, d**). At 72 hours after the A β^{pH} injection there was also A β^{pH} visible in the pial surface and in the periventricular white matter. With increased magnification, we observed cell bodies containing A β^{pH} that were positive for the microglial (IBA1) marker (**Figure 4c**) but astrocytes (GFAP⁺) localized at the injection site showed very little A β^{pH} signal (**Figure 4d**). Thus, microglia engulf the majority of the A β^{pH} under these conditions *in vivo* with astrocytes contributing also at early times.

Next, we injected A β^{pH} into the vitreous of the eye in postnatal rats to eliminate possible complications due to glial scarring resulting from cortical injection, and low penetration through the blood-brain barrier as a result of peripheral delivery (**Figure 4e**). We injected 1 μl of A β^{pH} intravitreally and left the animals for 3, 24, or 72 hours. At the end of the experiment, retinæ were removed, fixed in 4% paraformaldehyde, and whole mount retinal preparations were made. Astrocytes and microglia in the retinal ganglion cell layer were labelled with antibodies to GFAP and IBA1 respectively, and co-localization with the fluorescent signal from the injected A β^{pH} probe was determined. We observed that IBA1+ microglia contained A β^{pH} at all time points, but did not detect any A β^{pH} signal in GFAP+ astrocytes (**Figure 4f-g**). The A β^{pH} positive microglia were less in the retina compared to other brain regions, suggesting that clearance from the eye was more rapid than clearance from the brain parenchyma in other experiments (above).

The *in vivo* investigation of A β phagocytosis described above consists of imaging fixed tissue sections with confocal microscopy. To date, phagocytosis of A β has not been observed in live animals in real time. Using A β^{pH} , we observed phagocytic uptake in live rodents in real time using two-photon microscopy (**Movies S5, S6**). Here, 5.0 μM A β^{pH} was applied onto the cortical surface of live mice through a cranial window for 10 minutes during two-photon imaging in the barrel cortex (**Figure 5a**). This showed an increase in green fluorescence in the cell somata after A β^{pH} application, indicating phagocytic uptake of A β^{pH} (**Figure 5b**). Quantification of the fluorescence within the cell somata showed rapid A β^{pH} uptake after the peptide was added to the cranial window followed by stabilization of the signal at around 20 minutes (**Figure 5c**). The brains were later fixed by cardiac paraformaldehyde perfusion and stained with antibodies to identify the cell types mediating the A β^{pH} uptake. Phagocytosed green A β^{pH} was present in microglia labeled for IBA1 and colocalized with the microglia/macrophage lysosomal protein CD68, and A β^{pH} was also seen in GFAP+ astrocytes (**Figure 5d**). Integrating the fluorescence over the different classes of labeled cells showed that about 70% of the phagocytosed A β^{pH} was taken up by microglia and about 25% by astrocytes (**Figure 5e**). These percentages are approximately similar to those seen in the brain slice experiments of Fig. 3d. Thus, microglial uptake of A β^{pH} dominates over astrocyte uptake.

DISCUSSION

The phagocytic capacity of glial cells has been measured using traditional dyes and fluorophore-labeled particles such as fluorescein or rhodamine-coated *E. coli* and beads,

however, these experiments entail some major drawbacks: (1) difficulty in differentiating between adherent versus internalized particles, (2) use of additional reagents (like trypan blue or ethidium bromide) and additional experimental steps required to quench the extracellular fluorescence prior to analysis by flow cytometry and imaging⁴³, (3) quenching of the fluorescence within the acidic environment of the phagosomes, and (4) lack of specificity of the neuronal target substrate (beads, *E. coli*, zymosan, etc.)⁴⁴. Here, we have synthesized a pH-sensitive fluorogenic A β reporter, A β^{pH} , at a microgram scale and characterized the reporter in detail (**Figures 1a-c, S2-13**). We demonstrated the functionality of A β^{pH} in mouse and human microglial cell lines, in *in vitro* cultures of primary microglia and astrocytes, in acute hippocampal slices from mouse brains, in mice *in vivo* using stereotaxic injections followed by fixation, and in live mice *in vivo*. The A β^{pH} reporter is a useful tool for answering questions related to mechanisms of A β phagocytosis and cellular inflammatory responses, and for developing therapeutic strategies to promote A β clearance.

We observed phagocytic uptake of A β^{pH} in three different microglial cell lines and primary glial cell cultures in real-time (**Figures 1d-e, 2e-f**) and using confocal imaging (**Figure 2a-b, d**). We show the utility of A β^{pH} to be used without the need for any antibodies to identify or detect A β using flow cytometry (**Figures 1f, 2c**) which will greatly benefit experimental design and outcome by reducing the number of steps required in assays. While microglia cultured *in vitro* and *ex vivo* do not completely recapitulate the transcriptomes of microglia *in vivo*⁴⁵, microglial cell culture models provide a convenient system for screening chemical and biological molecules in a rapid and high-throughput manner. We also demonstrate the utility of A β^{pH} in functional assays to evaluate cellular phagocytosis. Further, we demonstrated the phagocytic uptake of A β^{pH} in live tissue hippocampal slices that preserve the 3-dimensional nature of the cell microenvironment and can serve as an additional useful model to study A β -related biology in a tissue environment. Microglia were more efficient in internalizing A β^{pH} than astrocytes (**Figures 3a-d**). During the period of this assay it is unlikely that astrocytes would have become “reactive” so it appears that A β clearance is not just a property of reactive astrocytes^{46–48}, and astrocytes that are most closely associated with neurodegeneration appear to be of a reactive phenotype that downregulates phagocytic pathways⁵, suggesting that the engulfment of A β^{pH} by astrocytes is a normal physiological function of these cells, though this may change with disease progression.

Most importantly, we demonstrated the utility of using of A β^{pH} in various *in vivo* models. Stereotaxic injection of A β^{pH} into the mouse somatosensory cortex was followed by uptake by

microglia and astrocytes (**Figure 4a-d**), injecting A β^{pH} into the vitreous of the eye was followed by uptake by retinal microglia (**Figure 4e-g**), and the real-time uptake of A β by microglia and astrocytes was demonstrated *in vivo* in live mice using two-photon microscopy (**Figures 5a-c**). We confirmed the identity of the cells observed with two-photon excitation by using IBA1 to label microglia, CD68 (a phagocytosis-specific marker) to label microglia and macrophages, and GFAP to label astrocytes (**Figures 5d-e**). The time course of uptake *in vivo* was rapid, with phagocytosed A β^{pH} fluorescence reaching a peak level within 20 mins (this may reflect a balance between continued phagocytosis and intracellular degradation). Approximately two thirds of the A β^{pH} was phagocytosed by microglia and one third by astrocytes, again on a time scale too rapid for astrocytes to have become reactive.

The development of A β^{pH} , in particular the ease with which it can be produced in the lab, will facilitate the characterization of different populations of cells that remove (or do not remove) A β by phagocytosis in various conditions, including AD, trauma-induced amyloidopathy and Down's syndrome. Combining this tracer with transgenic labeling of microglia or other cell types (e.g. *Tmem119*-tdTomato mice⁴⁹ that exhibit red fluorescence in microglia) will allow the transcriptome and proteome of different subpopulations of heterogeneous phagocytic cells to be defined (including young and old cells⁵⁰⁻⁵², and male and female cells⁵³), facilitating the discovery of new mechanisms, targets and functional biomarkers. Understanding the clearance of A β is fundamental to understanding the onset of AD^{54,55}, and having a quantitative technique to assess A β phagocytosis should contribute significantly to this. We expect that A β^{pH} will become a useful tool to facilitate the study of similarities and differences between phagocytic and non-phagocytic cell mechanisms *in vivo* during health and disease.

METHODS

Animal Ethics

Animal maintenance and isolation of primary microglia were performed according to Purdue Animal Care and Use Committee guidelines and approval (protocol number 1812001834). Injection of A β^{pH} into the retina of rats were completed in accordance with the National Institute of Health Stanford University's Administrative Panel on Laboratory Animal Care. Purification of rat primary astrocyte was completed in accordance with NYU Langone School of Medicine's Institutional Animal Care and Use Committee (IACUC) guidelines and approval. All rats were housed with *ad libitum* food and water in a 12 hour light/dark cycle. Standard Sprague Dawley rats (Charles River, #400) were used in all retinal experiments. Animal maintenance and experimental procedure for the intracranial stereotaxic injections of A β^{pH} in mice were performed according to the guidelines established by the IACUC at Harvard Medical School (protocol number IS00001269). Experiments on brain slices and *in vivo* 2-photon imaged mice were carried out under a UK government licence (PPL 70/8976, awarded after local ethical review and UK Home Office assessment) to David Attwell, in accordance with all relevant animal legislation in the UK.

Synthesis of pH-sensitive fluorescent human A β conjugate with Protonex Green™ (A β^{pH})

Human amyloid-beta (A β_{1-42}) was purchased from AnaSpec., Inc (Cat. #AS-20276), Protonex™ Green 500 SE was from AAT Bioquest, Inc. (Cat. #21215), and pHrodo-Red SE was from Thermo Fisher Scientific (Cat. #P36600). To 200 μl aliquot of A β_{1-42} (1 mg/ml in 1M NaHCO₃, pH ~8.5) was added 10 equivalents of Protonex-Green 500 (PTXG), SE dye (88 μl from 5 mM anhydrous stock in DMSO) and incubated at room temperature for 3 hours in the dark (vial wrapped in aluminum foil: note: add 100 μl ultrapure water if the solution becomes viscous). The additional 5 equivalents of PTXG, SE dye (44 μl from 5 mM DMSO stock) was added and incubated under the same conditions for 3 hours. The crude reaction mixture was diluted with 1 ml ultrapure water and the conjugated product was dialyzed by Pierce Protein Concentrators [PES, 3K Molecular Weight Cut-Off (MWCO); Thermo Fisher Scientific, Cat # PI88514] at 4500 *g* for 30-45 minutes in a swinging bucket centrifuge to remove the small molecular weight fragments. The concentrated solution was diluted with 0.5 ml ultrapure water and dialyzed again for 30 minutes as done previously. Finally, MALDI-MS spectrum was recorded to confirm the conjugation of PTXG with A β_{1-42} .

Synthesis of pH-sensitive fluorescent human A β ₁₋₄₂ conjugate with pHrodo (RODO-A β ^{pH})

A solution containing A β ₁₋₄₂ (570 μ g, 12.63 nmol) was prepared in 1M NaHCO₃ (pH 8.5, 570 μ l) and the pHrodo Red-NHS (1 mg) stock solution was prepared in anhydrous DMSO (150 μ l) (~10.2 mM). Next, the A β solution (570 μ l) and pHrodo stock solution (0.6314 μ mol, 61.5 μ l of stock solution) were mixed and incubated at room temperature for 6 hours while wrapped with aluminum foil. This crude reaction mixture was then diluted with ultrapure water (1 ml) and the conjugated product was dialyzed by Pierce Protein Concentrators (PES, 3K MWCO) at 4500 g for 30-45 minutes in a swinging bucket centrifuge to remove the small molecular weight fragments. The concentrated solution was diluted with ultrapure water (0.5 ml) and dialyzed again for 30 minutes as before. Finally, the MALDI-MS spectrum was recorded to confirm the conjugation of pHrodo-Red fluorophore to the A β peptide.

Preparation of HFIP-treated A β and A β ^{pH} stocks

A β and A β ^{pH} was dissolved in HFIP and prepared as previously described³⁴. Briefly, 1 mM A β solution was prepared by adding HFIP directly to the vial (0.5 mg A β or A β ^{pH} in 93.35 μ l HFIP). The peptide should be completely dissolved. The solution was incubated at room temperature for at least 30 min. HFIP was allowed to evaporate in the open tubes overnight in the fume hood and then dry down under high vacuum for 1 hour without heating to remove any remaining traces of HFIP and moisture. The resulting peptide thin clear film formed at the bottom of the tubes. The tubes containing dried peptides were stored at -20°C until further use. To make oligomers, 5 mM A β DMSO stock was prepared by adding 20 μ l fresh dry DMSO to 0.45 mg. To ensure complete resuspension of peptide film, this was pipetted thoroughly, scraping down the sides of the tube near the bottom. This was vortexed well (~30 s) and pulsed in a microcentrifuge to collect the solution at the bottom of the tube and the 5 mM A β DMSO solution was sonicated for 10 min. This preparation was used as the starting material for preparing the aggregated A β .

Atomic Force Microscopy for analysis of A β and A β ^{pH}

We followed the previously published detailed protocols for analyzing A β and A β ^{pH} by Atomic Force Microscopy (AFM)^{34,56}. Oligomers were prepared by incubating the samples at 4 °C for 24 hours. Briefly, sample preparation was performed with sterile techniques using sterile media and MilliQ- water. A 10 ml syringe with ultrapure water equipped with a 0.22 μ m filter was

filled and the initial 1–2 ml was discarded through syringe filter output. 1M HCl and 1x PBS buffer were also filtered through 0.22 μm filter. The samples were prepared for spotting on mica by diluting to final concentrations of 10–30 μM in water. Immediately before sample delivery, top few layers of mica were cleaved away using an adhesive tape to reveal a clean, flat, featureless surface. The fresh surface was pretreated with $\sim 5\text{--}8\ \mu\text{l}$ of filtered 1M HCl for 30 seconds and rinsed with two drops of water (note: the mica was held at a 45° angle and washed with water to allow the water coming out of the syringe filter to roll over the mica). If necessary, the remaining water was absorbed with fiber-free tissue paper/wipes by keeping paper on the edge of the mica. Immediately, the sample was spotted onto mica and incubated for 3 minutes followed by rinsing with three drops of water and blow drying with several gentle pulses of compressed air. Samples were then kept in a dust-free box and incubated on benchtop for a few minutes to hours at room temperature until analysis. AFM imaging was performed with Veeco Multimode with NanoScope V controller with NanoScope Software using the Silicon AFM probes, TAP300 Aluminum reflex coating (Ted Pella, Inc. Cat# TAP300AL-G-10) at $\sim 300\ \text{kHz}$ resonant frequency and $\sim 40\ \text{N/m}$ force constant in the tapping mode.

pH-dependent emission spectra of A β conjugated with Protonex Green® and A β conjugated with pHrodo at various concentrations

The cell culture medium was treated with dilute HCl and NaOH solutions to obtain different solutions of pH ranging from 1.0 to 9.0 for the assay. Lyophilized powder of A β conjugated with pHrodo (RODO-A β^{pH}) and A β conjugated with Protonex Green® (PTXG-A β^{pH}) was dissolved in cell culture medium to make stock solutions and kept at 37°C for 24 hours to pre-aggregate the peptide conjugates. From the stock solutions, different dilutions for each pH condition was prepared at concentrations of 0.5, 1.0, 2.0, and 5.0 μM in a 96-well plate (100 μl /well). Fluorescence intensity of each well containing A β^{pH} was obtained on a Cytation™ 5 imaging multi-mode reader (BioTek Instruments) at 443/505 nm excitation/emission wavelengths. The fluorescence intensity of each pH-solution and A β^{pH} -concentration in relative fluorescence units (RFU) was plotted using GraphPad Prism software.

Concentration-dependent response of Protonex Green and A β^{pH} at acidic pH over time

The solutions of Protonex Green (PTXG) and A β conjugated with PTXG (A β^{pH}) were prepared in the cell culture medium at concentrations of 0, 0.1, 0.5, 1.0, 2.0, 5.0 μM and 50 μl of

each concentration were taken in duplicates in the wells of a 96-well plate. To measure the fluorescence of PTXG and A β^{pH} solutions in acidic conditions at different concentrations, 7.5 μl of pH 1.0 solution (hydrochloric acid in media) was added to each well to obtain a final pH of 3.0. Fluorescence intensities of the acidic solutions were measured at an excitation/emission of 443/505 nm on A Cytation 5 multimode plate reader (BioTek, Inc). Next, to initiate aggregation of A β^{pH} , the plate was incubated at 37°C, 5% CO₂ and fluorescence was measured at 2, 6, 12, and 24-hour time points. The change in fluorescence intensities of the PTXG and A β^{pH} aggregates was analyzed over time using GraphPad Prism software.

Cell lines – culture and maintenance

BV2 and N9 mouse microglial cell lines were generously gifted by Dr. Linda J. Van Eldik (University of Kentucky, USA). The BV-2 cell line was developed in the lab of Dr. Elisabetta Blasi at the University of Perugia, Italy. Cells were maintained at 37°C and 5% CO₂ in DMEM (Dulbecco's Modified Eagle's Medium)/Hams F-12 50/50 Mix (Corning #10-090-CV) supplemented with 10% FBS (Atlanta Biologicals), 1% L-Glutamine (Corning #25-005-CI), and 1% Penicillin/Streptomycin (Invitrogen). HMC3 human microglial cell line was a gift from Dr. Jianming Li (Purdue University, USA) who originally obtained the cells from ATCC. These cells were maintained at 37°C and 5% CO₂ in DMEM supplemented with 10% FBS and 1% penicillin/streptomycin.

Phagocytosis assay with live microglia

Cells were seeded at 5000 cells per well (200 μl per well) in a 96-well flat bottom plate (Falcon) for approximately 16 hours (overnight). For all cell assays, the lyophilized A β^{pH} conjugate was dissolved in the culture medium to prepare a stock solution and was pre-aggregated by placing the stock solution at 37°C for 24 hours. Further dilution for cell treatment was performed in culture media and the diluted solution was filtered using 0.22 μm syringe filter prior to cell treatment. The adherent cells (BV2, N9, HMC3) were treated with a final concentration of A β^{pH} at 0, 0.1, 0.5, 1.0, 2.0, and 5.0 μM by replacing one-half of the culture medium (100 μl) with 2x concentration. Two technical replicates were used for each treatment concentration. The plates were immediately placed in an IncuCyte S3 Live-Cell Analysis System (Essen BioScience) and four images per well were captured at 30-minute time intervals for 24

hours. The fluorescence intensity, cell confluence, and the integrated fluorescence intensity data was obtained and analyzed using the GraphPad Prism software.

The A β ^{PH} uptake was measured as the *Phagocytic Score* metric, defined as a normalized value relative to the initial fluorescent intensity at t=0 and calculated as:

$$\text{Phagocytic Score} = \frac{\text{Relative Total integrated intensity}(t)}{\text{Maximum Relative Total Integrated Intensity}}$$

where, *Relative Total Integrated Intensity* is defined as *Total Integrated Intensity* (t) – *Total Integrated Intensity* (t=0) for each concentration and cell type.

The *Total integrated intensity* is defined as the total sum of A β ^{PH} fluorescent intensity in the entire image and given by the expression $(\frac{CU \times \mu m^2}{Image})$ as defined by Incucyte. We captured 4 images per well with multiple replicates for each A β ^{PH} concentration and for each cell type. These images were used to calculate the value of *Total integrated intensity*, $(\frac{CU \times \mu m^2}{Image})$. The individual units are defined as: CU = Average mean intensity (the average of A β ^{PH}'s mean fluorescent intensity in each cell in an image), μm^2 = Average area (the average area of the A β ^{PH}'s in each cell in an image).

The *Maximum Relative Total Integrated Intensity* is the maximum value of *Relative Total Integrated Intensity* over the 24-hour period. Such a normalization gives *Phagocytic Score* values between 0 and 1 to compare different concentrations across different cell types. The maximum peak indicates the time when the degradation is equal to the uptake for each concentration and cell type. All other values show an interplay between uptake or degradation compared to time, t=0, shown by either increase or decrease in fluorescence that is also observed visually. The corresponding videos (**Movies 1-3**) during live cell imaging were taken on IncuCyte S3 Live-Cell Analysis System (Essen BioScience) and stabilized using the Blender version 2.82a software (www.blender.org).

Isolation and culture of primary mouse microglia

CD11b⁺ primary microglia were isolated from adult mice aged around 7 months (male and female) and cultured as follows. Mice were euthanized with CO₂ following the Purdue University Animal Care and Use Committee guidelines and brains were transcardially perfused with ice-cold PBS. The perfused brains were dissected and cut into small 1 mm³ pieces before homogenizing them in DPBS⁺⁺ containing 0.4% DnaseI on the tissue dissociator (Miltenyi Biotec) at 37 °C for 35 mins. The cell suspension was filterered through a 70 μm filter and

myelin was removed two times, first using Percoll PLUS reagent followed by myelin removal beads using LS columns (Miltenyi Biotec). After complete myelin removal, CD11b⁺ cells were selected from the single cell suspension using the CD11b beads (Miltenyi Biotec) as per the manufacturer's instructions. The CD11b⁺ cells were finally resuspended in microglia growth media made in DMEM/F12 (Corning Cat. #MT15090CV), further diluted in TIC (TGF- β , IL-34, and cholesterol) media³⁷ with 2% FBS before seeding 0.1x10⁶ cells per 500 μ L in a well of a 24-well plate (Corning Cat. #353847). The cells were maintained in TIC media at 37 °C and 10% CO₂ with media change every other day until the day (around 10-14 div) of the phagocytosis assay.

Flow cytometry analysis of BV2 and primary microglia phagocytosis

BV2 microglial cells were seeded at a density of 250k cells/well in a 6-well plate for around 14 hours overnight. The next morning, the cells were treated with 0.5 μ M and 5 μ M A β ^{PH} and placed in a 37°C incubator for 1 hour, after which the plate was brought to the hood, placed on ice to stop phagocytosis, and cell culture medium containing A β ^{PH} was aspirated. The cells were washed once with cold PBS. Next, the cells were treated with ice cold PBS containing 2 mM EDTA for 2 mins on ice to detach the cells from the wells. The cells were then centrifuged at 1400 rpm for 3 mins. The supernatant was aspirated, and the cell pellets were re-suspended in FACS buffer (PBS, 25 mM HEPES, 2mM EDTA, and 2% FBS). Five minutes before analysis of each sample, propidium iodide (PI; Thermo Fisher Scientific, Cat. #P1304MP) was added to the sample (40 ng/ml cell suspension) for staining of dead cells.

Phagocytosis of A β ^{PH} by primary cells was performed on div 10-14 in a similar manner. Cells were treated with A β ^{PH} for 1 hour and detached from the plate using cold PBS and 2 mM EDTA. After centrifuging the cell suspension, the cell pellet was resuspended in 0.1 mL PBA for live/dead staining. Here, Zombie Violet, ZV, (BioLegend, #423113) was used to evaluate cell viability (1:100 per 10⁶ cells in 0.1 mL) for 15 mins followed by PBS wash. Finally, the cells were resuspended in FACS buffer and taken for analysis. Cells exhibiting green fluorescence were captured on the FITC channel upon gating for live cells (PI⁻ negative or ZV⁻ cells are taken as live cells) on Attune NxT flow cytometer (Invitrogen). The files were then analyzed on FlowJo V10 software. Briefly, at least 90% of the total cells were first gated on SSC-A vs FSC-A plot and the single cells within this gate were selected on the FSC-H vs FSC-A plot. From the single cells, the live and dead cells were identified from the viability dye. PI⁻ and ZV⁻ cells were

considered as live cells and PI⁺ and ZV⁺ cells were taken as dead cells on the histogram plots. Finally, Aβ^{pH+} or Aβ^{pH-} cells were identified within the live cell population in the Aβ^{pH} histogram plot on the FITC channel.

Confocal imaging of actin filaments and nuclei in the paraformaldehyde-fixed phagocytic microglial cells

For labeling the cells with phalloidin and DAPI, 20,000 cells/250 μl were plated in 14 mm microwells of 35 mm glass bottom dishes (MatTek #P35G-1.5-14-C) and kept overnight. The cells were treated with 5.0 μM Aβ^{pH} for 2 hours on the next day. Then the medium was aspirated, and cells were fixed with 4% paraformaldehyde for 20 mins, and then gently washed once with PBS. Phalloidin-iFluor 594 reagent (Abcam, Cat. #ab176757) was diluted at a concentration of 1 μl/ml in PBS and added to the fixed cells for 10 minutes for staining the actin filaments. To label the nuclei, DAPI was diluted at a concentration of 1 μl/ml. The cells were washed again with PBS followed by a 10-minute incubation with the diluted DAPI solution. Finally, the DAPI solution (Invitrogen, Cat. #D3571) was aspirated and the fixed cells treated with 2-3 drops of ProLong Gold Antifade Mountant (Invitrogen #P36930) before imaging. Fluorescence images of phagocytic microglial cells were captured using 40x and 60x objectives on the Nikon AR-1 MP confocal laser microscope. Images were obtained on the NIS Elements microscope imaging software.

Confocal Imaging of intracellular acidic organelles and nuclei in paraformaldehyde-fixed phagocytic microglial cells

LysoTracker Red DND-99 (Thermo Fisher Scientific, Cat. #L7528) was used for labeling the intracellular organelles of the cells to observe localization of Aβ^{pH} sensors inside the cells after phagocytosis. 20,000 cells/250 μl were plated in 14 mm microwells of 35 mm glass bottom dishes (MatTek #P35G-1.5-14-C) and kept overnight. The cells were treated with 5.0 μM Aβ^{pH} for 2 hours on the next day. Then the Aβ^{pH} containing medium was aspirated and replaced with 200 μl of media containing 100 nM concentration of the LysoTracker dye and the cells were incubated in the 37°C, 5% CO₂ incubator for 30 minutes. Finally, the cells were fixed and treated with DAPI to stain the nuclei followed by 2-3 drops of ProLong Gold Antifade Mountant using the above-mentioned protocol. Fluorescence images of phagocytic microglial cells were captured

using 40x and 60x objectives on the Nikon AR-1 MP confocal laser microscope. Images were obtained on the NIS Elements microscope imaging software.

Intracranial Injection of A β^{pH} , perfusion and immunohistochemistry

Lyophilized A β^{pH} was dissolved in Hank's Balanced Salt Solution (HBSS no calcium, no magnesium, no phenol red, ThermoFisher #14175079) to obtain a 100 μ M stock solution that was then briefly vortexed and sonicated in a bath sonicator for 1 minute and directly used for intracranial injections or stored at -80°C. For intracranial injections, the stock solution was diluted in HBSS to obtain a 10 μ M working solution and kept on ice to prevent aggregation. Postnatal day 7 mice were anesthetized with isoflurane and were mounted on a stereotactic frame. Two lots of 250 nl of A β^{pH} working solution were unilaterally injected in the somatosensory cortex of wild-type C57BL/6J mice using a Nanoliter Injector (anteroposterior - 2.3mm; mediolateral +2.3 mm; dorsoventral -0.5 mm for lower layers and -0.2mm for upper layers, relative to Lambda) at an injection rate of 100 nl/minute followed by 2 additional minutes to allow diffusion. 24 hours or 72 hours after injections, animals were deeply anesthetized with sodium pentobarbital by intraperitoneal injection and then transcardially perfused with PBS 1x followed by 4% paraformaldehyde (PFA) in PBS. Brains were dissected out and post-fixed for two hours at 4°C, cryoprotected in a 30% sucrose-PBS solution overnight at 4°C. Then, tissue was sectioned at 40 μ m on a sliding microtome (Leica). Free-floating brain sections were permeabilized by incubating with 0.3% Triton X-100 in PBS for 1 hour and then blocked for 3 hours (0.3% Triton X-100 and 10% normal donkey serum), followed by incubation with primary antibodies in 0.3% Triton X-100 and 10% normal donkey serum overnight at 4°C. The next day, brains were rinsed in PBS 1x for 1 hour, incubated with the appropriate secondary antibodies for 2 hours at room temperature, rinsed again in PBS, incubated with DAPI and mounted using Fluoromount-G (SouthernBiotech, #0100-01). During perfusion and immunohistochemistry all solutions were maintained at neutral pH. The following primary antibodies were used: mouse anti-GFAP (1:200, Sigma #G3893-100UL) and rabbit anti-IBA1 (1:500, Wako Chemicals, #019-1974). The secondary antibodies used were donkey anti-mouse-IgG1 647 (Invitrogen, #A21241) and donkey anti-rabbit 594 (ThermoFisher, #A-21207). Tissue samples were imaged on a ZEISS Axio Imager and a ZEISS LSM 800 confocal using a 20X objective. A β^{pH} fluorescence signal was quantified using ImageJ. First, cell contour was manually drawn using IBA1 or GFAP signal and mean fluorescence intensity in the A β^{pH} channel was measured. Next, the selection

was moved to a nearby region with no obvious A β^{pH} fluorescence signal and mean fluorescence intensity in the A β^{pH} channel was measured (background). Normalized fluorescence intensity for each cell was calculated as A β^{pH} fluorescence signal minus background. Data were analyzed by one-way ANOVA followed by the Sidak's post hoc analysis for comparisons of multiple samples using GraphPad Prism 7 (GraphPad Software).

Immunopanning and culture of primary astrocytes

Astrocytes were purified by immunopanning from P5 Sprague Dawley rat (Charles River) forebrains and cultured as previously described⁵⁷. In brief, cortices were enzymatically (using papain) then mechanically dissociated to produce a single-cell suspension that was incubated on several negative immunopanning plates to remove microglia, endothelial cells and oligodendrocyte lineage cells. Positive selection for astrocytes was with an ITGB5-coated panning plate. Isolated astrocytes were cultured in a defined, serum-free base medium containing 50% neurobasal, 50% DMEM, 100 U ml⁻¹ penicillin, 100 μ g ml⁻¹ streptomycin, 1 mM sodium pyruvate, 292 μ g/ml L-glutamine, 1 $\times$ SATO and 5 μ g/ml of *N*-acetyl cysteine. This medium was supplemented with the astrocyte-required survival factor HBEGF (Peprotech, 100-47) at 5 ng/ml⁵⁷. Cells were plated at 5,000 cells/well in 12 well plates coated with poly-D-lysine and maintained at 10% CO₂.

Engulfment assay of A β^{pH} by primary astrocytes

Astrocytes were maintained for 1 week in culture, checked for reactivity state using qPCR⁵ before addition of A β^{pH} . The cells were treated with 0.5, 1.0, or 2.0 μ M A β^{pH} and imaged continuously with still images taken every 5 minutes with an IncuCyte S3 System epifluorescence time lapse microscope to analyze engulfed A β^{pH} particles. For image processing analysis, we took 9 images per well using a 20 $\times$ objective lens from random areas of the 12-well plates and calculated the phagocytic index by measuring the area of engulfed synaptosomes/myelin (fluorescent signal) normalized to the area of astrocytes, using ImageJ.

***In vivo* retinal engulfment of A β^{pH}**

P14 Sprague Dawley rats were anaesthetized with 2.5% inhaled isoflurane in 2.0 l O₂ per min. Once non-responsive, animals received a 1 μ l intravitreal injection of A β^{pH} , or PBS. Retinae were collected for immunofluorescent analyses at 3, 24, and 72 hours. At collection, eyeballs were removed, fixed in 4% PFA overnight, washed in PBS and retinae dissected and

whole-mounts placed on silanized glass slides. Retinae were blocked with 10% heat-inactivated normal goat serum for 2 hours at room temperature. Incubation with primary antibodies to GFAP (Dako, A0063, 1:5000) and IBA1 (WAKO, 019-19741, 1:500) diluted in 5% goat serum in PBS was followed by detection with AlexaFluor fluorescent secondary antibodies (Thermo, 1:1000).

Brain slice experiments

Rats at postnatal day 12 (P12) were sacrificed by cervical dislocation followed by decapitation, and 250 μ m sagittal hippocampal slices were prepared on a Leica VT 1200S vibratome at 4°C in oxygenated solution containing (mM): 124 NaCl, 26 NaHCO₃, 2.5 KCl, 1 NaH₂PO₄, 10 glucose, 2 CaCl₂, 1 MgCl₂, 1 kynurenic acid. Acute slices were allowed to recover for 2.5 hours at room temperature before being transferred to 24-well plates and incubated with 5 μ M A β ^{PH} in HEPES-based aCSF (140 mM NaCl, 10 mM HEPES, 2.5 mM KCl, 1 mM NaH₂PO₄, 10 mM glucose, 2 mM CaCl₂, and 1 mM MgCl₂) for 1.5 hours at 37 °C. Following incubation, slices were quickly rinsed in cold phosphate-buffered saline (PBS) and fixed in 4% paraformaldehyde (PFA) for 45 min at room temperature. For immunolabeling, slices were permeabilized and blocked in buffer containing 10% horse serum and 0.02% Triton X 100 in PBS for 2 hours at room temperature, followed by incubation with goat anti-IBA1 (Abcam, ab5076) or chicken anti-GFAP (Abcam, ab4674) primary antibodies diluted 1:500 in blocking buffer for 12 h at 4°C. Following four 10 min washes in PBS, donkey anti-goat IgG 647 (ThermoFisher, A21447) or donkey anti-chicken IgG 649 (Jackson, 703-495-155) secondary antibodies diluted 1:1000 in blocking buffer were applied for 4 h at room temperature. Finally, slices were incubated in DAPI for 30 min, rinsed in PBS and mounted. Imaging was done using a Zeiss LSM700 confocal microscope and a 20X objective, where 10 μ m image stacks at 1 μ m step interval were acquired. For colocalization analysis, the percentage of A β ^{PH} signal within microglial or astroglial cells was calculated by binarizing the microglia or astrocyte channel, creating a mask and multiplying it by the raw A β ^{PH} signal. The fluorescence intensity of A β ^{PH} colocalizing with either cell type mask was then expressed as a percentage of the total A β ^{PH} signal across the field.

***In vivo* two-photon microscopy**

Adult mice bred on a C57BL/6 background aged ~4-6 months (P123 to P203) were anesthetized using urethane (1.55 g/kg given intraperitoneally). Adequate anesthesia was ensured by confirming the absence of a withdrawal response to a paw pinch. Body temperature was maintained at 36.8±0.3°C and eyes were protected from drying by applying polyacrylic acid

eye drops (Dr Winzer Pharma). The trachea was cannulated and mice were mechanically ventilated with medical air supplemented with oxygen using a MiniVent (Model 845). A headplate was attached to the skull using superglue and mice were head fixed to a custom-built stage. A craniotomy of approximately 2 mm diameter was performed over the right primary somatosensory cortex, immediately caudal to the coronal suture and approximately 2 to 4 mm laterally from the midline. The dura was removed and 2% agarose in HEPES-buffered aCSF was used to create a well filled with HEPES-buffered aCSF during imaging.

Two-photon excitation was performed using a Newport-Spectraphysics Ti:sapphire MaiTai laser pulsing at 80 MHz, and a Zeiss LSM710 microscope with a 20× water immersion objective (NA 1.0). Fluorescence was evoked using a wavelength of 920 nm. The mean laser power under the objective did not exceed 25 mW. Image stacks were taken in 2 µm depth increments (50-200 µm from the cortical surface) every 1.5 min for approximately 30 min. Five µM Aβ^{pH} in HEPES-based aCSF was applied to the cortical surface for 10 min and then replaced with HEPES-based aCSF. Animals were transcardially perfused with ice-cold PBS followed by 4% PFA in PBS at 1.5 or 3 h after pH Aβ^{pH} application. Brains were post-fixed in PFA for 12 h at 4°C and 100 µm sagittal sections were prepared using a vibratome. Slices were permeabilized and blocked for 12 h and incubated with rabbit anti-IBA1 (1:500, Synaptic Systems, 234006), rat anti-mouse CD68 (1:500, Bio-Rad, MCA1957) or chicken anti-GFAP (1:500, Abcam, ab4674) primary antibodies for 24 hours at 4°C. Following washes in PBS, donkey anti-rabbit IgG 647 (1:500, ThermoFisher, A31573), goat anti-rat IgG 647 (1:500, ThermoFisher, A21247) or donkey anti-chicken 649 IgG (1:300, Jackson, 703-495-155) were applied for 12 hours at 4°C. Image stacks (23 µm deep) were acquired at 1 µm interval in the cerebral cortex and analysis was done as for *in situ* experiments.

FIGURES

Figure 1. Synthesis and characterization of A β^{pH} . (a) The A β^{pH} is synthesized by conjugating the amine-reactive pH-sensitive ProtonexTM Green dye to the side chain amine groups of the lysine residues and the N-terminal of human A β_{1-42} peptide. (b) The pH-sensitivity of the A β^{pH} probe characterized at different concentrations from 0.1 μM to 5.0 μM . Increased fluorescence is observed within the narrow range of pH 2.0 to 5.0. (c) Atomic Force Microscopy topographic images of A β^{pH} oligomers compared to synthetic A β oligomers. Left-2D topographic image of A β^{pH} and synthetic A β oligomers. Right-3D image (2 $\times$ 2 μm x-y). (d) Live cell imaging of the phagocytic uptake of 1 μM A β^{pH} by BV2 and N9 mouse microglia and by HMC3 human microglia over 24 h. (e) Quantification of A β^{pH} phagocytic score by BV2, N9, and HMC3 microglial cells from the live cell images. (f) The phagocytic uptake of A β^{pH} by BV2 cells is measured and quantified via flow cytometry analysis. Dot plot shows live (PI⁻) and A β^{pH} cells. No green fluorescence is measured in unstained cells (UC) and in dead cells stained with the PI only whereas green fluorescence is measured in cells treated with 0.5 and 5.0 μM A β^{pH} for 1 hour (higher fluorescence is seen in cells exposed to the higher concentration of A β^{pH}). Data shown in terms of % max, by scaling each curve to mode = 100% (y-axis).

Figure 2. Fluorescence of internalized A β^{pH} is retained in fixed cells. (a) Confocal images of fixed HMC3, N9, and BV2 cells showing the uptake of A β^{pH} (green). Cells are stained for acidic intracellular organelles (LysoTracker Red, confirming co-localization of the A β^{pH} within the acidic intracellular organelles) and nuclei (DAPI, blue). No antibody is required to detect A β^{pH} . (b) Primary mouse microglia grown in defined, reduced-serum media phagocytose A β^{pH} *ex vivo*. Cells are fixed and stained for nuclei and show A β^{pH} colocalized in the acidic organelles with LysoTracker Red. (c) The phagocytic uptake of A β^{pH} by primary microglia is measured and quantified via flow cytometry analysis. Dot plot shows live (ZV⁻) and A β^{pH} cells. No green fluorescence is measured in unstained cells (UC) or dead cells stained with the ZV live/dead stain only whereas green fluorescence is measured in cells treated with 0.5, 1.0, and 2.0 μM A β^{pH} for 1 hour. Data shown in terms of % max, by scaling each curve to mode = 100% (y-axis). (d) Primary immunopanned rat astrocytes also phagocytose A β^{pH} in serum-free conditions. Cells are fixed and stained for astrocyte specific GFAP antibody (red) and nuclei. (e) Uptake of A β^{pH} over time by primary immunopanned astrocytes as observed in live cells in real time. (f) Quantification of uptake of 0.5, 1.0, and 2.0 μM A β^{pH} by primary astrocytes.

Figure 3. $A\beta^{pH}$ is phagocytosed by both microglia and astrocytes *in situ* in rat hippocampal tissue sections. (a) Schematic of phagocytosis assay in rat hippocampal tissue slices. (b) Representative 2D maximum projection of a confocal z-stack showing microglia phagocytosing $A\beta^{pH}$. Closeup of the indicated cell (yellow square) is shown on the right. Orthogonal projections at the level of the crosshairs show internalization of $A\beta^{pH}$ within the microglia. (c) Representative 2D maximum projection of a confocal z-stack showing astrocytes phagocytosing $A\beta^{pH}$. Closeup of the indicated cell (yellow square) is shown on the right. Orthogonal projections at the level of the crosshairs show internalization of $A\beta^{pH}$ within the astrocyte. (d) Quantification of $A\beta^{pH}$ colocalized with microglia and astrocytes, as defined by IBA1⁺ and GFAP⁺ staining, respectively. Data shown as mean $\pm$ s.e.m. collected from 20 and 8 slices for microglia and astrocytes respectively (from 3 animals).

Figure 4. $A\beta^{pH}$ is phagocytosed by cortical microglia and astrocytes *in vivo* and by rat retinal astrocytes *in vivo*. (a) Schematic of stereotaxic microinjection of $A\beta^{pH}$ in the somatosensory cortex of P7 mouse followed by staining of fixed tissue section after 24 and 72 hours. (b) Phagocytic uptake of $A\beta^{pH}$ by IBA1⁺ microglia and GFAP⁺ astrocytes in the periventricular white matter at the 24 h timepoint. (c) IBA1⁺ microglia show bright green fluorescence at 72 h in the same region indicating presence of $A\beta^{pH}$ within the cells at this timepoint. GFAP⁺ astrocytes do not show any green fluorescence in this region at this timepoint suggesting either degradation of the peptide or insufficient $A\beta^{pH}$ concentration for detectable phagocytic uptake by these cells. (d) Quantification of $A\beta^{pH}$ fluorescence within microglia and astrocytes located in the pia and white matter regions show more $A\beta^{pH}$ uptake by microglia compared to astrocytes. (e) Schematic of subretinal injection of $A\beta^{pH}$ to evaluate its *in vivo* uptake by retinal microglia and astrocytes. (f) GFAP⁺ rat retinal astrocytes phagocytose $A\beta^{pH}$ *in vivo*. (g) Quantification of $A\beta^{pH}$ uptake into retinal IBA1⁺ microglia and GFAP⁺ astrocytes. No fluorescence was detected in astrocytes at these 3 time points (n.d.). Data shown as mean $\pm$ s.e.m. from 2 animals.

Figure 5. $A\beta^{pH}$ is phagocytosed by microglia and astrocytes *in vivo* in the cerebral cortex. (a) Schematic of how $A\beta^{pH}$ phagocytic uptake is imaged through a cranial window *in vivo* in real time using two-photon excitation microscopy. (b) *In vivo* two-photon imaging of the mouse barrel cortex before and after topical application of $A\beta^{pH}$. The fluorescence increases in cell somata (indicated by red circles) reflecting $A\beta^{pH}$ uptake. (c) Quantification of mean $A\beta^{pH}$ fluorescence in cell somata over time. The data were normalized to the maximum mean $A\beta^{pH}$ fluorescence for

each cell and then averaged. Data shown as mean $\pm$ s.e.m. N=59 somata from 2 animals. **(d)** 1.5 to 3 hours after *in vivo* two-photon imaging of A β^{pH} , animals were perfusion-fixed and cortical slices were stained for microglia, microglia lysosomes/endosomes and astrocytes using IBA1, CD68, and GFAP antibodies, respectively. **(e)** Quantification of A β^{pH} colocalization with IBA1, CD68, and GFAP suggests that most A β^{pH} is taken up by microglia and astrocytes *in vivo*. Data shown as mean $\pm$ s.e.m. N=12 stacks from 3 animals.
