9

10 Abstract

11 Hi-C is a common technique for assessing three-dimensional chromatin conformation. Recent

12 studies have shown that long-range interaction information in Hi-C data can be used to generate

13 chromosome-length genome assemblies and identify large-scale structural variations. Here, we

14 demonstrate the use of Hi-C data in detecting mobile transposable element (TE) insertions

15 genome-wide. Our pipeline HiTea (Hi-C based Transposable element analyzer) capitalizes on

16 clipped Hi-C reads and is aided by a high proportion of discordant read pairs in Hi-C data to

- 17 detect insertions of three major families of active human TEs. Despite the uneven genome
- 18 coverage in Hi-C data, HiTea is competitive with the existing callers based on whole genome
- 19 sequencing (WGS) data and can supplement the WGS-based characterization of the TE insertion
- 20 landscape. We employ the pipeline to identify TE insertions from human cell-line Hi-C samples.
- 21 HiTea is available at <u>https://github.com/parklab/HiTea</u> and as a Docker image.

22 Keywords

23 retrotransposons, structural variants, Hi-C, split read analysis

24 INTRODUCTION

Over half of the human genome is composed of repetitive DNA sequences (de Koning *et al.*, 25 2011). The repeats belong to two major classes: (i) tandem repeats, consisting of DNA 26 sequences from few bases to few hundreds of bases that have expanded in tandem, stretching up 27 28 to millions of bases in the genome; and (ii) transposable elements (TEs), interspersed throughout 29 the genome and accounting for 44% of the human genome(Mills et al., 2007). Unlike tandem 30 repeats, TEs are capable of transposition, in which they move from one genomic location to 31 another. The distinct self- or *trans*- encoded mechanisms used by the TEs for transposition are used to group them into several families(Wicker et al., 2008). Although a vast majority of the 32 33 TEs are inactive, a small fraction (<0.05%) still remains active in the human genome(Mills *et al.*, 34 2007), primarily SINEs (Small Interspersed Nuclear Elements), LINEs (Long Interspersed 35 Nuclear Elements), and SVAs (SINE-VNTR-Alu). The transposition events are a major source of genomic structural variation (SV) and play an 36

important role in a multitude of human genetic diseases(Hancks and Kazazian, 2016). For

example, elevated levels of non-reference L1Hs (LINE) insertions are associated with epithelial

39 carcinomas(Hancks and Kazazian, 2016; Lee *et al.*, 2012; Chenais, 2015); Alu (SINE) insertions

40 are associated with cystic fibrosis and hemophilia(Chen *et al.*, 2008; Vidaud *et al.*, 1993); and a

41 recent case of Batten's disease that led to the development of an individualized antisense

42 oligonucleotide therapy(Kim *et al.*, 2019) was caused by an SVA insertion. The TE sequences

43 may also encode a range of regulatory features such as promoters, enhancers, transcription factor

binding sites, and non-coding regulatory RNA transcripts(Chuong *et al.*, 2017). Thus at the

45 molecular level, transposition can result in altered gene expression, splicing/RNA stability

defects, genome instability, or decreased integrity of centromere and telomeres(Bourque et al.,

47 2018).

48 In particular, TE sequences are a rich source of binding sites for an insulator protein CTCF,

49 which plays a key role in regulating the 3D structure of chromatin. The extended loops of the

50 DNA are maintained by binding of CTCF at the base of the loop; indeed, the Hi-C chromatin

51 maps suggest enrichment of SINE elements at the topologically associated domains (TAD)

52 boundaries(Rao *et al.*, 2014). The TE-derived CTCF binding sites are a fundamental source for

53 mammalian genome evolution at various time scales, with some highly conserved across species

and some species-specific expansions of CTCF sites co-occurring with species-specific

55 TADs(Schmidt *et al.*, 2012; Cournac *et al.*, 2016). Given the important regulatory role of

56 TEs(Ayarpadikannan and Kim, 2014; Garcia-Perez *et al.*, 2016; Ahmed and Liang, 2012),

57 identification of their transposition is important in understanding the disease biology, gene

58 regulation, and 3D chromatin organization.

59 Several computational tools are available for identifying non-reference (either somatic and

60 germline) TE insertions from WGS data(Rishishwar et al., 2017). A key component of such

61 methods is the identification of discordant read pairs (RP), whose genome alignments display

62 unexpected between-pair distance or orientation. A discordant RP with one end mapping to the

63 consensus TE sequence and the other end mapping to the reference genome is indicative of a TE

64 insertion. Discordant RPs are typically accompanied by 'clipped' reads, whose partial alignment

65 can be used to obtain base-pair resolution of the breakpoints. With judicious integration of these

66 criteria and appropriate thresholds, candidate TEs insertions can be predicted across genome.

Besides WGS, another data type that involves a large amount of sequencing is Hi-C, an unbiased
genome-wide extension of the chromosome conformation capture technique. Hi-C

69 experiments(Rao *et al.*, 2014; Schmitt *et al.*, 2016) are conducted primarily to understand the

70 long-distance regulatory relationships in the genome (e.g., which enhancer interacts with which

71 promoter). In this experiment, the cross-linked DNA fragments are first digested with a suitable

restriction endonuclease (RE). Then, random ligation is performed in a condition that favors

73 ligation between cross-linked fragments. The resulting ligation product contains pairs of

fragments that were close in 3D proximity. Sequenced Hi-C reads indeed show that the effective

rs insert sizes—the distance between the mapped mates—range from few hundred to millions of

bases. Consequently, the proportion of discordant RPs, that are <20% in WGS, are in the excess

of 50-70% for Hi-C data. Furthermore, as the sequenced fragments are generated post-ligation

step, the proportion of reads carrying split mapping (due to encompassed RE sites) is higher in

the Hi-C data. These features thus limit the use of WGS-based TE detection tools on Hi-C data.

80 Here, we present a computational pipeline HiTea (Hi-C based Transposable element analyzer),

81 which identifies non-reference TE insertions of the LINE, SINE and SVA families using Hi-C

82 data. Our comparisons show that HiTea (run on Hi-C) performs similarly to a commonly-used

83 WGS-based tool (run on WGS at similar coverage)(Gardner *et al.*, 2017). With increasing

realization of 3D chromosomal structure as a regulatory component of gene regulation, large

scale efforts such as 4D Nucleome(Dekker *et al.*, 2017) are underway to aim to map genome

86 organization across cell-types and disease models. Our results indicate that Hi-C data can be

- used not only to study 3D genome organization but also to characterize the non-reference TE
- 88 insertions.

89 METHODS

90 Informative Hi-C read pairs for non-reference TE detection

91 To understand the methodology underlying HiTea, we first describe the different types of read 92 pair (RP) mappings observed in Hi-C data (Fig.1A). Discordant RPs, defined in paired-end sequencing, are RPs with unexpected distance or orientations between paired mate reads when 93 mapped to the reference genome. Due to the intrinsic design of Hi-C experiments for detecting 94 interactions between two distant genomic loci, a major proportion of RPs (typically 50-70%) in 95 96 Hi-C data are discordant with large (>1kb) mapping distances or atypical orientations of the paired mates. A small proportion (6-30%) of RPs display WGS-like concordant read mapping 97 98 configuration (Fig. 1A, panel i), where both mates map close (< 500bp) to each other in convergent orientation. 99

100 The RPs in Hi-C data can also be classified into two different categories. First, we introduce the 101 terminology *conforming* RPs to refer to those with mapping configuration explained solely by 102 the Hi-C experiment. For instance, conforming RPs with unique mapping of the entire mate 103 reads on two proximal or distant genomic loci are prevalent in Hi-C data (Fig. 1A-i,ii). Here, the 104 between-pair distance can range from WGS-like insert size (*i.e.*, ~500bp) to millions of bases (Fig. 1B). A third type of conforming RPs are those in which the 5' portion of a mate maps 105 106 uniquely to the genome and the 3' portion maps convergent on the genomic locus of the 107 matching mate, and the two portions are connected with the RE ligation motif (Fig.1A-iii). These mappings are referred to as chimeric Hi-C pairs (~10-20%) and are included in the 3D-contact 108 109 matrices. Second, the remaining RPs (~10-30%) do not conform to any expected configuration 110 of read mappings, and thus are discarded in standard analyses. In those *non-conforming* RPs, one 111 or both mates remain unmapped, multi-mapped, or their partial mapping does not produce chimeric Hi-C pairs (Fig. 1A-iv,v,vi). To identify non-reference TE insertions, HiTea uses non-112

113 conforming RPs whose partial (clipped) sequences or one entire mate read map to TE sequence114 assemblies.

- 115 In Fig. 1C, we show the distribution of reads along a small genomic region. In WGS data, the
- 116 genomic coverage is relatively even. In Hi-C data, the coverage is more variable; however, much
- of the region is still covered with at least some reads, thus allowing for the possibility that most
- 118 TE insertions can be captured. The proportion of discordant RPs (non-gray colors) is very high in
- 119 Hi-C data.
- **Identification of TE insertion breakpoints**
- 121 HiTea starts by identifying non-conforming RPs using Pairtools
- 122 (https://github.com/mirnylab/pairtools). In the discovery step, the clipped reads without
- legitimate RE-ligation motif are then mapped (using BWA-MEM(Li and Durbin, 2010) with '-a
- -k 13 -T 20') to family-wise TE consensus assemblies published earlier(Gardner et al., 2017) for

125 Alu (SINE), L1Hs (LINE) and SVA (https://melt.igs.umaryland.edu/downloads.php).

- 126 Additionally, it uses a separate 200 base long PolyA sequence to improve detection sensitivity of
- 127 TEs, especially those with long PolyA tails. For the alignment, we note that many polymorphic
- 128 insertions may have sequences distinct from the family-based consensus. To accommodate such
- 129 cases, HiTea offers an option to remap clipped reads that initially fail to map to a TE family
- 130 consensus, to a user-provided set of polymorphic sequences for a TE-family or sequences of the
- 131 members of its subfamily (e.g., from Repbase(Bao *et al.*, 2015)). HiTea, in principle, can also
- 132 detect insertions of other template-based transposons such as an active human endogenous
- 133 retrovirus (HERV-K), as long as adequate TE-consensus sequences are provided.

134 The clipped sequences are derived from non-conforming Hi-C RPs, where minimum clip length

135 (default: -s 20) can be defined by the users. Using a two base-pair leeway, a breakpoint on the

reference genome is determined as the location with the maximum number of clipped reads at a

- 137 locus (Supl.Fig.1). HiTea simultaneously records all non-conforming RPs in which a read maps
- to the reference genome and its 'anchor' mate maps to the TE-consensus assembly (using default
- 139 BWA-MEM settings). We refer to these as **R**epeat-Anchored non-conforming Hi-C **M**ates
- 140 (RAMs) pairs (Fig. 1D), following the terminology introduced earlier (Lee *et al.*, 2012). All
- breakpoints supported by at least two clipped reads with partial mapping to a TE-consensus are
- 142 further interrogated for enrichment of available TE supporting clipped reads and RAMs using a

negative binomial model (Supl.Fig.1). The candidate sites where the numbers of clipped reads
and RAMs are less than 5% and 2.5%, respectively, of the total Hi-C coverage at the locus are
omitted as unreliable.

146 Unlike WGS, where the RAM pairs are clustered around the sites of TE-insertion, Hi-C data

147 exhibits wider mapping area. Though, both WGS and Hi-C data are biased by GC-content or

148 overall mappability, the coverage in Hi-C is additionally clearly biased by the density of RE sites

149 at the locus. Hence, HiTea uses a negative binomial model to assess the enrichment of TE-

insertion supporting reads (i.e., RAM pairs and clipped-reads) at the locus. To model the biases,

151 HiTea uses randomly selected loci in the genome that have similar coverage of the non-

152 conforming RPs as the site under investigation. Then, the count of TE-supporting reads at a locus

is assessed against negative binomial model built from the random set.

154 Filtering and annotation of non-reference TE insertions

A substantial fraction of clipped reads in Hi-C data display chimeric mapping (Fig. 1A, panel iii) 155 carrying a ligation motif at the clip position. To avoid calling such canonical Hi-C interactions as 156 TE insertions, HiTea filters out insertion candidates whose predicted breakpoints on either the 157 reference genome or TE-consensus are within 3-bases (user-defined) of the ligation motif 158 159 (Fig.1D, clip reads at RE site; Supl.Fig.1 for detailed filtering steps). It also filters out candidates when multiple breakpoints are predicted around a putative breakpoint, as it is likely to be a 160 161 complex variant other than a TE insertion. At the sites of insertion, clipped mapping positions of the reads indicate a breakpoint where reads mapping to the reference genome cluster (Fig. 1D). 162 163 HiTea expects that the genuine breakpoint should also show reciprocal cluster of the clipped 164 sequences when mapped to the TE-consensus. Insertions defying this expectation are removed as 165 invalid. Furthermore, insertions where clipped reads mapping only to the PolyA sequences are 166 omitted as potential simple repeat expansions. The genuine breakpoints are expected to have 167 clip-sequences mapping to PolyA sequence or presence of a degenerate polyA sequence (here we look for a stretch of 7 As or Ts in the proximal 10 bases at the breakpoint on clipped sequences). 168 169 Subfamily annotation of the insertion is done by mapping the longest clipped sequence to the subfamily consensus sequence derived from Repbase(Bao et al., 2015). HiTea further detects 170 171 target site duplication, strand information, and estimates the size of insertion from the observed mapping of the clipped sequences on the TE-consensus. HiTea is written in PERL and R. It uses 172

173 GNU-parallel(Tange, 2011) for parallelization over available cores. The insertions are reported

- in bed format, with following status. Status-3 insertions are supported by right- and left-hand
- side mapping of the clipped reads (Fig. 1D), whereas status-2 insertions represent a subset of
- status-3 cases that overlap the reference copy of the same TE family. If the insertion is supported
- by clipped reads at one side but have unmapped reads on the other site with polyA stretches (as
- defined earlier), such instances are flagged with status-1.

179 **RESULTS**

180 HiTea shows performance comparable to that of a WGS-based method

181 To assess the performance of HiTea, we utilized Hi-C data generated from the HapMap cell line

- 182 GM12878(Rao *et al.*, 2014). This cell line has been extensively characterized using a wide range
- 183 of technologies and sequencing platforms. To generate the gold standard for comparison, we
- used an improved version of our algorithm Tea(Lee *et al.*, 2012) on PacBio HiFi long
- reads(Zook *et al.*, 2016) with extensive manual curation (hereafter referred to as the PacBio
- reference). For WGS, we employed Mobile Element Locator Tool (MELT)(Gardner *et al.*,
- 187 2017), a popular software package with reportedly superior performance at moderate sequencing
- depth(Rishishwar *et al.*, 2017). The full datasets consisted of ~5B RPs for Hi-C(Rao *et al.*, 2014)
- 189 (MboI-digested dataset; downloaded from 4DN data portal) and ~1.4B RPs for WGS
- 190 (downloaded from the 1000 Genomes project). Sequencing depths have considerable impact on
- 191 the precision and recall(Rishishwar *et al.*, 2017), thus we randomly down-sampled Hi-C data
- to1.4B RPs (~80X coverage) to provide a fair comparison between platforms. At this coverage,
- 193 79% of the genome in WGS and 57% in Hi-C data are covered with at least 60X coverage (Fig.
- 194 2A). The coverage was calculated by counting reads with mapping quality of at least 10 (MAPQ
- 195 ≥10).
- 196 The candidate insertions predicted by HiTea (ran on Hi-C data) and MELT (ran on WGS data)
- 197 were compared against the PacBio reference set (Fig. 2B). We used two sets of insertions
- reported by MELT for GM12878: (*i*) the stringent "PASS" set (1122 insertions, referred as
- 199 MELT-PASS) and (*ii*) a more lenient set that includes the PASS variants and others for which
- 200 genotype could still be inferred (1443 insertions, referred as MELT-GT) in the comparisons. A
- total of 1251 insertion were identified by HiTea while the PacBio reference set consisted of 1747
- 202 insertions.

Overall, HiTea correctly identified 1085 insertions (Fig 2B). The precision (fraction of the true
positives among all identified insertions) was 0.87; recall (fraction of true positives among all
positives) was 0.62 with F1 score of 0.72. MELT-PASS and MELT-GT correctly recovered 925
(precision 0.82, recall 0.53, F1 0.64) and 1115 (precision 0.77, recall 0.64, F1 0.7) insertions,
respectively.

208 (i) Alu. Most of the insertions were Alu, as expected. Among the 1493 Alu insertions from our reference set, HiTea correctly identified 1000 (precision 0.89, recall 0.67, F1 0.76) 209 insertions from the Hi-C data. Whereas, MELT-PASS correctly identified 825 (precision 210 0.87, recall 0.55, F1 0.68) and MELT-GT recovered 986 (precision 0.83, recall 0.66, F1 211 212 0.74) Alu insertions from the WGS data. These results suggest that HiTea (ran on Hi-C) has considerably better performance at detecting Alu compared to MELT (ran on WGS) 213 214 (Fig. 2B). Notably, HiTea can detect Alu insertions with competitive precision and recall from Hi-C samples with lower coverages (Fig. 2C). For instance, at 600M RPs (~40X 215 216 sample; recommended sequencing depth by the 4DN consortium) and 300M RPs (~20X coverage), the precisions are nearly uniform (i.e. 0.89 for 1.4B, 0.89 for 600M and 0.90 217 for 300M) and the recalls decrease only slightly, from 0.67 (1.4B, F1 0.76) to 0.65 (600M, 218 F1 0.75) and 0.59 (300M, F1 0.71) (Fig. 2C). We compared the proportions of the clipped 219 220 reads, which are the starting point of TE insertion identification in HiTea, and RAM reads 221 that map to Alu consensus between Hi-C (identified by HiTea) and WGS (identified by 222 MELT) at the equal sequencing depth of 1.4B. Although the proportions of Alu-mapping 223 clipped reads (44% in Hi-C and 53% in WGS) were higher, we observed that the 224 proportion of RAMs pairs mapping to the Alu consensus is much higher for Hi-C (43% of 225 total RAMs) than WGS (13% of total RAMs). Taken together, better proportions of mapping of clipped and RAM reads in Hi-C is likely associated with better performance 226 227 of HiTea on Alu.

(ii) *L1Hs*. Our PacBio reference set contained 194 high-confidence L1Hs insertions. HiTea
correctly identified 67 (precision 0.64, recall 0.35, F1 0.45), whereas MELT-PASS and
MELT-GT detected 73 (precision 0.61, recall 0.38, F1 0.47) and 91 (precision 0.52, recall
0.47, F1 0.49), respectively (Fig. 2B). With respect to sequencing depths, recall increased
as the depth increased, from 0.11 for 300M (F1 0.19) to 0.4 for 5B RPs (F1 0.48), while
the precision remained in a similar range (0.61 to 0.71) (Fig.2C). Interestingly, the

proportions of both clipped and RAM reads mapping to the L1Hs consensus were 234 substantially higher in the WGS data (39.5% and 84.2% respectively) compared to the Hi-235 236 C data (27.5% and 52.7% respectively). Transposed copies of L1Hs are frequently 237 associated with 5' truncation and/or inversion. Moreover, during target-primed reverse transcription (TPRT), L1 RNA often accommodates sequences from the downstream 238 239 genomic region(Pickeral et al., 2000). These additional features may lower the performance of HiTea for L1Hs compared to Alu. 240 (iii) SVAs. HiTea has relatively poor sensitivity towards SVAs. Of 60 SVAs in the PacBio 241 reference set, HiTea correctly identified 18 (precision 0.75, recall 0.3, F1 0.43), whereas 242 MELT-PASS and MELT-GT respectively detected 27 (precision 0.51, recall 0.45, F1 243 0.48) and 38 (precision 0.48, recall 0.63, F1 0.55) instances. Although the proportions of 244 245 RAMs mapping on the SVA-consensus were comparable (2.7% for Hi-C vs 2.5% for WGS), the proportions of SVA mapping clipped reads were substantially different (4.6% 246 247 in Hi-C vs 7.1% in WGS). SVAs comprise of frequently expanded hexameric repeats at the 5', variable number of tandem repeats (VNTR) in the middle, and Alu-like sequences 248 249 at the 3'. This complex structure may lead to the relatively poor mapping of SVAoriginating reads to the SVA consensus (e.g., some SVA reads map to the Alu consensus 250 251 instead), and thus affect the performance of HiTea for SVAs. Nonetheless, the precision of 252 detecting SVAs was strikingly high for HiTea (0.73 to 0.75) as compared to the MELT 253 calls (<0.51) (Fig. 2B,C). The impact of sequencing depth for SVAs was similar to that for L1Hs. 254

255 Of the 1251 HiTea insertions (at 1.4B), ~13% (166) did not overlap with the PacBio reference

set. Hence, we interrogated them against a collection of 1000 Genome TE insertion set (at a

population allele frequency $\geq 10\%$; results were similar for AF $\geq 0.01\%$ and AF $\geq 0.1\%$),

identified on the low coverage WGS data by MELT(Gardner *et al.*, 2017). Our comparison

suggested that 117/166 (~71%) HiTea-specific insertions overlap with the population-based TE-

insertion set, suggesting that these are true insertions missed by the PacBio reference set. This

also suggests that the precision and recall measures above represent lower bounds.

HiTea missed ~38% (662/1747) of the insertions from the PacBio reference set. Of the 662, 197
insertions overlapped with 1000G set. We assessed the 5' end coverage of RAMs whose mates

or clipped sequences map to the TE consensus in Fig. 2D. This coverage plot(Gu *et al.*, 2018)
shows that the missed events by HiTea do not have a sufficient number of clipped reads (lower
right panels in Fig. 2D; 381/465 and 95/197 have less than two non-Hi-C chimeric clipped reads
mapping to the TE-consensus at the locus.

268 Since the 1.4B-RPs datasets used above are larger than typical datasets, we repeated the above

analysis with down-sampled datasets with ~600M RPs (~35-40X). Our comparison suggests that

270 HiTea (run on Hi-C) shows consistently higher precision in detecting Alu, SVA and L1Hs

compared to MELT (run on WGS data) (Supl.Fig.2A). A total of 1016/1152 HiTea insertions

272 (precision 0.88, recall 0.58, F1 0.70) and 908/1134 MELT-PASS insertions (precision 0.80,

recall 0.52, F1 0.63) overlapped with the PacBio reference set (Supl.Fig.2A). The insertions

missed by HiTea did not seem to show clip-read coverage at the respective loci (Supl.Fig.2B).

275 We tested HiTea on a range of human Hi-C datasets generated using different REs. A 4-cutter

276 RE (MboI, DpnII) is expected to cut the DNA at every 256 bases whereas a 6-cutter (HindIII,

277 NcoI) will digest the DNA at 4096bp on average. The infrequent cuts by a 6-cutter are expected

to provide low spatial resolution of the Hi-C (Supl.Fig.3A), resulting in a smaller number of

clipped reads along the genome. Indeed, when Hi-C datasets generated using different REs for

GM12878 cell line(Rao et al., 2014) were compared, the overall recall dropped from 0.62 (MboI

digested Hi-C, 1.4B RPs, F-score 0.72) to 0.41 (1.8B RPs, HindIII digested Hi-C, F-score 0.56).

For comparison, the overall recalls for WGS sample were 0.53 (MELT-PASS, F-score 0.64) and

283 0.64 (MELT-GT, F-score 0.7) at 1.4B RPs (Supl.Fig.3B). Nonetheless, HiTea showed a high

precision (0.88) compared to MELT-PASS (0.82) and MELT-GT (0.77). Besides 17 unique,

remaining 794 (98%) insertions from the HiTea run either overlapped with PacBio reference set

or the 1000G set, whereas about 79% (811/1032) of the missed insertions displayed poor

coverage of clipped reads (Supl.Fig.3C, D). With the decreasing sequencing cost, many studies

are now using either a 4-cutter or a mix of 4-cutter enzymes, and these high-resolution Hi-C

289 datasets will be suitable for HiTea analysis.

290 Next, we assessed the performance of HiTea on another widely-characterized cell line, K562.

291 We obtained WGS and Hi-C (MboI digested Hi-C) data from Cancer Cell Line Encyclopedia

project(Barretina et al., 2012) and a published study(Rao et al., 2014), respectively. As a PacBio

reference set was not available for this cell line, we resorted to comparing the TE-insertions

called by HiTea (on Hi-C) to those from MELT (on WGS). At comparable sequencing depth of

1.2B RPs between Hi-C and WGS data for K562 cells, a substantial fraction (769/958, ~80%) of

- HiTea insertions overlapped with either MELT-derived (i.e. MELT-GT) insertions or 1000G set.
- 297 In comparison, previously analyzed GM12878 (MboI digested, 1.4B RPs) exhibited similar
- 298 (1101/1251, ~88%) degree of overlap (Supl.Fig.4).

299 HiTea aids in the characterization of the non-reference TE insertions

To assess whether HiTea can correctly identify insertions otherwise missed by MELT, we 300 compared MELT-GT (better recall compared to MELT-PASS) and HiTea insertions (both at 301 1.4B RPs sequencing depth) using the PacBio reference set. Our analysis suggests that a 302 303 substantial number of insertions overlapping with reference-genome copy of the same TE family 304 are missed by MELT (Fig. 3A, B). TE detection along the reference TE copy of the same family can be challenging due to multiple reasons, such as poor mappability of the reads and structural 305 306 variation within the reference-copies of the TE family. Therefore, several WGS-based tools filter out these insertions to limit the number of false positives (Ewing, 2015). However, when 307 308 supporting reads are available and their mappings on both TE-consensus and reference genome 309 provide sufficient confidence for the insertion, HiTea reports these events. Our reference set included 436 TE-insertions overlapping with the reference copies of the same TE-family. HiTea 310 correctly identified 70 insertions reported in the PacBio reference, outperforming MELT (5 and 8 311 by MELT PASS and GT) (Fig. 3B). 312

In total, HiTea identified 160 PacBio reference insertions missed by MELT-GT. Conversely,

MELT-GT identified 180 insertions missed by HiTea from the reference set (Supl.Fig.5A, B).

315 When assessed for the features that led to disqualification of these true-positive insertions by

either MELT or HiTea, we observed that indeed insertions within a reference-genome copy of

the same TE family were preferentially missed by MELT (66/160, ~41%; Supl.Fig.5C). As the

exact features used by MELT are unavailable (the code is not open source), we could not further

investigate the instances missed by MELT. Over half of the insertions (124/180, ~69%) missed

by HiTea were due to poor coverage of clipped reads, proximity to the RE motif, coverage

thresholds, and absence of clipped reads supporting polyA tails (Supl.Fig.5D).

322 Coverage in the Hi-C experiment is significantly higher around the RE sites in the genome.

323 Thus, insertions proximal to the RE sites tend to have higher coverage of supporting reads even

at relatively low overall sequencing depth. In the example shown in Fig.3C, the read coverage at 324 325 an Alu insertion site missed by MELT-GT on chromosome 20 is much higher in Hi-C than in 326 WGS, although the overall sequencing depth is the same (both bam files were subsampled to 327 10% of total reads for better visualization). To assess whether the same phenomenon is observed at many sites, we counted total 5' end coverage in a 1kb window centered at the 925 insertions 328 329 identified by both MELT-GT and HiTea and the 160 insertions identified only by HiTea. As expected, the insertions identified by both methods tend to have similar coverages, whereas those 330 331 missed by MELT-GT tend to have relatively lower coverage overall in WGS compared to Hi-C (Fig.3D). 332

A total of 49/1251 (~4%) insertions detected by HiTea were not explained by either the PacBio

reference set or the 1000G set (Fig.2D, second panel from the top). Of these, 4 and 6 were

reported by MELT-PASS and MELT-GT, respectively. These HiTea-specific insertions exhibit

clear presence of TE-mapping clipped reads from Hi-C data (Fig.2D). Representative examples

of two Alu insertions suggest that the HiTea-unique insertions have the support of both clipped

and discordant reads at the insertion locus in the WGS data (Fig.3E). We suspect that many of

these cases may be true positives that were missed by MELT due to its stringent filtering criteria.

340 Installation and usage

341 HiTea is available at Github (https://github.com/parklab/HiTea) and as a Docker image

342 (4dndcic/hitea:v1on Docker Hub). TE (Alu, L1Hs and SVA) family-wise consensus sequences

and the genomic locations of the TE-family members required for running HiTea are provided

for hg38 and hg19 human genome references, with a description on how to generate them for

other types of TEs on the GitHub page. HiTea dependencies are PERL (\geq v5.24), R (\geq v3.2),

bedtools (\geq v2.26)(Quinlan and Hall, 2010), samtools (\geq v1.7), GNU-parallel(Tange, 2011) and

347 Pairtools (https://github.com/mirnylab/pairtools). Additionally, there are mandatory

348 (GenomicRanges, data.table, MASS) and optional (rmarkdown, knitr, EnrichedHeatmap(Gu et

349 *al.*, 2018), circlize) R packages used for computation and HTML-report generation steps

respectively. Users can start the analysis with a single command by providing a name-sorted bam

351 file, restriction enzyme used for the Hi-C assay and the genome build used to map the Hi-C data.

352 HiTea auto detects if the read class information is present in the bam file (e.g. files obtained from

4DN data portal <u>https://data.4dnucleome.org/</u> carry this information). If not, it automatically

- employs Pairtools to generate read class information. User-defined TE-consensus or
- polymorphic sequences and the genomic locations of the members of TE-sequences can be
- provided using a detailed input option. A HiTea run on a typical Hi-C dataset (~600M RPs) takes
- about 3.5-4 hrs to complete with 8 cores and 20 G memory.

358 **DISCUSSION**

Although used primarily for understanding three dimensional organization of the genome and its regulatory role, the long-range chromatin interaction information in Hi-C data have been used to assemble small scaffolds into chromosome-length assemblies(Dudchenko *et al.*, 2017; Gong *et al.*, 2018) and to identify copy number and translocations(Chakraborty and Ay, 2018; Dixon *et al.*, 2018; Wang *et al.*, 2020). In the present work, we have demonstrated that Hi-C can be used also to identify TE insertions.

The strong performance of HiTea was somewhat unexpected. Given the nature of the

- experiment, the read coverage for Hi-C is highly variable along the genome. We thus expected
- that there would not be enough reads at some TE insertions sites, resulting in degraded
- 368 performance for HiTea compared to a WGS-based method. What makes HiTea competitive with
- a WGS-based method, however, is the use of clipped reads to locate candidate TE insertions at
- the discovery step, in contrast to the discordant RP-based candidate discovery in most WGS-
- based methods. The higher proportion of clipped reads (carrying no RE ligation junction) in Hi-
- C data (1.6%) than in WGS data (1.4%) is further helpful. Moreover, the proportion of RPs
- whose one end remains unmapped or multimapped is higher in the Hi-C data (21%) compared to
- the WGS data (14%) due to wider effective insert sizes, increasing the power of Hi-C data for
- detecting insertions. In particular, the TE insertions in the reference genome copies of the same
- 376 family or those occurring in regions with comparatively lower coverage in WGS data are
- 377 sometimes detected by HiTea but missed by MELT.

378 The availability of PacBio HiFi data (circular consensus sequencing method, with half the reads

>50kb) for GM12878 made it easier to evaluate the performance of different methods. However,

the TE insertion map based on this one sample is obviously incomplete, as seen by the fact that

- many HiTea candidates not present in the PacBio reference set were present in the 1000G data.
- 382 A small fraction (<5%) of HiTea insertions were still not explained by either PacBio reference
- set or 1000G set. Although some of these insertion calls may be false positives, it is interesting to

note that both WGS and Hi-C data show presence of discordant and non-conforming RPs
mapping to the underlying TE consensus, respectively, along most of these loci. Additional longread data or independent experimental validations may prove useful in discerning the nature of

387 HiTea-specific calls.

388 The number of studies mapping chromatin organization in diverse organisms, cell types, and

- disease states as well as the collective efforts to organize such data have gained
- momentum(Dekker *et al.*, 2017). However, it is imperative to mark structural variations in the
- 391 genome before construing the chromatin interactions from Hi-C data as functional interactions,
- as we have demonstrated recently(Wang et al., 2020). HiTea exploits Hi-C data to identify non-
- reference TE insertions, using reads that otherwise would be discarded. Finally, although we
- 394 compared call sets from Hi-C and WGS data in our analysis, the ideal scenario is to have both
- data types for a sample of interest, so that the insertions calls can be cross-validated and
- 396 expanded. Continued development of more comprehensive reference TE insertions maps and
- robust computational methods for TE identification will be important.

474 **Figures and legends:**

475

Figure 1: Properties of Hi-C reads supporting a TE insertion. (A) Hi-C read pairs (RPs) can 476 477 be grouped into two classes that we termed 'conforming' and 'non-conforming'. Conforming RPs comprise of (i) WGS-like pairs with short insert sizes. (ii) pairs with large effective insert sizes. 478 479 and (iii) chimeric RPs where the clip-sequence maps convergent to mapped locus of its paired 480 mate. Non-conforming RPs comprise of mapping configurations where *(iv)* the clipped sequence does not display chimeric mapping or (v-vi) the mate remains unmapped on reference genome. 481 (B) Comparison of the between-pair distances for WGS and Hi-C experiments. (C) A genome 482 483 browser view of a true insertion event, showing both coverage and the discordant RPs (non-grav 484 color) in WGS and Hi-C experiments. Box marks the TE-insertion site. Mapped read pairs in the 485 display are color-coded by the insert sizes using default IGV color scheme. (D) A schematic of 486 Hi-C read configuration at insertion site. Clipped reads supporting TE insertion exhibit partial

487 mapping to TE-family consensus (orange), whereas those that do not, map at distant reference
488 locus (black). RPs with a mate mapping to the TE-family consensus are displayed with orange

489 outline. (RE: restriction endonuclease, TSD: target site duplication)

490

Figure 2: Performance of HiTea. (A) Cumulative distribution of the coverage for different 492 datasets. Gray dotted line marks 60X coverage. (B) Precision and recall for detecting insertions 493 of Alu, L1Hs and SVA families using HiTea (on Hi-C) and MELT (on WGS) at 1.4B sequencing 494 depth. PASS and GT refer to the more and less stringent call sets, respectively, in MELT. (C) 495 Precision and recall comparison at different sequencing depths of Hi-C experiment. (D) 5' end 496 497 coverage for the RAMs whose mates map to the TE consensus (left) or reads whose clippedsequences map to the TE consensus (right). The insertions are grouped according to the criteria 498 499 shown on the right. PacBio is the reference set constructed using PacBio HiFi reads; 1000G set 500 refers to insertions detected in the 1000 Genome data by MELT.

502 Figure 3: Examples of TE insertions detected in Hi-C but missed in WGS.

(A) A browser view of an insertion overlapping the reference-genome copy of a TE-family. This
 insertion is identified by HiTea (on Hi-C) but missed by MELT (on WGS). Reads with concordant
 and discordant mapping configurations are displayed in gray and non-gray colors, respectively.
 The discordant RPs are color-coded according to their insert sizes. Dotted red line with arrowhead

- 507 marks the insertion site. **(B)** Summary of TE insertions detected when the insertion occurs in the
- reference-genome copies of the TE-family. **(C)** Sequencing coverage comparison at an insertion
- 509 correctly called by HiTea but missed by MELT. (D) The boxplot for the Hi-C/WGS read coverage
- ratios shows that Hi-C coverage is higher in cases identified by HiTea but missed by MELT-GT.
- 511 **(E)** More examples of insertions called only by HiTea.
