20 **Abstract**

21 Phytoplankton populations are intrinsically large and genetically variable, and interactions
22 between species in these populations shape their physiological and evolutionary responses.
23 Yet, evolutionary responses of microbial organisms in novel environments are investigated
24 almost exclusively through the lens of species colonising new environments on their own,
25 and invasion studies are often of short duration. Although exceptions exist, neither type of
26 study usually measures ecologically relevant traits beyond growth rates. Here, we
27 experimentally evolved populations of fresh- and seawater phytoplankton as monocultures
28 (the green algae *Chlamydomonas moewusii* and *Ostreococcus tauri,* each colonising a novel,
29 unoccupied salinity) and co-cultures (invading a novel salinity occupied by a resident
30 species) for 200 generations. Colonisers and invaders differed in extinction risks, phenotypes
31 (e.g. size, primary production rates) and strength of local adaptation: invaders had
32 systematically lower extinction rates and broader salinity and temperature preferences than
33 colonisers – regardless of the environment that the invader originated from. We emphasise
34 that the presence of a locally adapted species has the potential to alter the invading species'
35 eco-evolutionary trajectories in a replicable way across environments of differing quality, and
36 that the evolution of small cell size and high ROS tolerance may explain high invader fitness.
37 To predict phytoplankton responses in a changing world, such interspecific relationships need
38 to be accounted for.

40 **Introduction**
41

42 Ecology and evolution affect invader success and native species' responses, and in a
43 warming, changing world, invasion scenarios are likely to become more frequent [1-3]. Eco-
44 evolutionary studies on biological invasions for microbial populations are arduous to carry
45 out - especially when encompassing an element of tracking evolutionary responses in real
46 time for species less cultivable than bacteria (e.g. [4]), and are accordingly rare (but see e.g.
47 [5,6])
48

49 When the survival of an organism – including invaders, colonisers, and resident species -
50 hinges largely on physiological short-term responses, they can cope with a changed or
51 changing environment through phenotypic plasticity. There, a given genotype produces a
52 different phenotype in response to changes in the abiotic or biotic environment [7]. In
53 asexually dividing microbes, these plastic responses occur within a single or a few
54 generations and unless the new environment is lethal to most individuals in a sufficiently
55 diverse population, it is unlikely that selection acts through sorting on such short time-scales.
56 In clonal populations – the standard scenario in many laboratory experiments - evolution
57 through *de novo* mutations is similarly rare on such short time-scales [8,9].
58

59 In the long term, the speed at which genetic sorting can affect the mean population trait in a
60 diverse population depends on the amount of standing genetic variation, the strength of
61 selection, and the size of the population [10,11]. Both plasticity and changes in allele
62 frequency contribute to the magnitude and direction of an organism's response to a novel
63 environment. In aquatic microbes, short- and long-term responses to environmental change
64 have been extensively studied in single isolate experiments (e.g. e.g. [12-15]). Far fewer
65 studies consider ecologically complex environments [16-19]. Studies that have tested how

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.19.103978; this version posted May 21, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

66 species interactions evolve are traditionally carried out in environments that are of low
67 quality for the focal species (traditionally low-nutrient or toxic environments), i.e. in
68 environments that lead to slower growth and a drastic and near-fatal decline in population
69 size of the focal species [8,20].
70
71 Under circumstances where resources are scarce, competition is often the main type of
72 interaction [21-23]. Whether competition can then help or hinder evolution is highly context-
73 dependent: Competition can explain changes in lineage or species frequencies as a function
74 of the environment (e.g. light, nutrients, temperature) [24], but interactions between microbes
75 need not be solely competitive and can range from competition to facilitation to mutualism
76 to interdependence and combinations thereof [25-27], especially when environmental change
77 is not leading to a decrease, but an increase in growth rate [28]. While the breadth of
78 interactions is well understood in ecology [29-31], today's models, when considering how
79 microbes behave in a changing world, largely assume that interactions be competitive in
80 nature [32]. Finally, these models are increasingly incorporating traits (and changes therein)
81 other than growth rates, such as cell size and carbon fixation. Those traits are not routinely
82 monitored in most selection experiments, where the focus tends to be on growth rates.
83
84 Here, we used an experimental evolution approach to conceptually investigate if coloniser or
85 invader status changes an organism's chances of survival in a new salinity and whether these
86 dynamics differ between short- term (a few generations) and long-term (~200 generations)
87 responses under otherwise non-limiting conditions. We define colonisers as a species moving
88 into a novel environment that is unoccupied (an ecologically rather unlikely scenario, but
89 standard in most selection experiments), and invaders as species moving into a novel
90 environment where local species are present. We used two green algae, the freshwater

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.19.103978; this version posted May 21, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

91 phytoplankton *Chlamydomonas moewusii* and the marine picoplankton *Ostreococcus tauri*.
92 Both genera of green algae are cosmopolitan in natural systems and established model
93 organisms for long-term studies in experimental evolution [33-35] . We evolved all
94 populations for *ca* 200 generations either alone or in co-culture, in freshwater and marine
95 conditions (Figure 1). To test whether differences between colonisers and invaders are
96 general and repeatable in environments favouring faster growth, we superimposed a full-
97 factorial temperature treatment, where all invaders and all colonisers were grown at 22ºC (the
98 culture 'control' temperature) , 26ºC (mild warming, and constituting a 'better' , favourable
99 environment where growth is faster and stress is lower), 32ºC (extreme warming, constituting
100 a 'worse', unfavourable environment, where growth is reduced and stress is higher), and a
101 fluctuating temperature treatment, where temperature cycles between 22ºC and 32ºC every 3-
102 5 generations (constituting a 'better' , 'favourable' environment). The temperatures were
103 chosen based on pilot studies examining the temperature tolerance curves of each species (see
104 supporting information). We show that across all environments, freshwater and marine
105 invaders fare better than colonisers, that samples selected under the invasion scenario evolve
106 more generalist tendencies than samples selected as colonisers in the same environment, and
107 that organisms in the invasion scenario evolve significantly different phenotypes compared to
108 those in the coloniser scenario.

110 **Results**

111 **Extinction risk is lower for invaders than for colonisers**

112 Rapid changes in salinity can reduce the probability of phytoplankton survival and may limit
113 population sizes to a point at which evolutionary adaptation becomes increasingly unlikely
114 [36,37]. In our case, populations of all surviving cultures remained large enough to supply
115 mutations and avoid drift at *ca* 10^5 cells mL-1, which ensures a large enough supply of
116 mutations for an evolutionary response, and makes differences between colonisers' and
117 invaders' or different species' responses in the long-term likely to be independent of
118 population size.
119
120 Extinction rates in a new salinity were lower in invading than colonising phytoplankton (in a
121 novel salinity, invading *Chlamydomonas* were two thirds less likely to go extinct than
122 colonising *Chlamydomonas*, and for invading *Ostreococcus*, the likelihood of extinction was
123 halved compared to colonising *Ostreococcus*, survival analysis: $z = -2.90$, $P = 0.0037$
124 Supporting Tables 1 and 2). Extinction events occurred early on in the experiments (within
125 the first 70 generations, $z = -4.13$, $P = 3.6 \times 10^{-5}$; Fig. 2; Supporting Table 1 and 2,
126 Supporting Figure 1), with no further extinctions after 100 generations. After the first ~ 70
127 generations, population sizes in all surviving invader cultures stabilised and were no longer
128 statistically different from colonisers ($F_{1,2} = 1.72$, $p = 0.32$; more details in Supporting
129 Tables 3 to 4).
130
131 70 -100 generations is a time-frame corresponding roughly to a single growing season of fast-
132 growing green algae, and is comparable to other marine microbial experiments where
133 evolution occurred on the scale of just below 100 to a few 100 generations [13,15,38], though
134 as few as two generations have been reported to suffice for an evolutionary response [39].

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.19.103978; this version posted May 21, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

135 Theory predicts that evolutionary potential should be high in good quality environments
136 leading to an increased or unchanged fitness, and that extinction risk should be low in
137 environments that fluctuate predictably (e.g. [40]). We found that extinctions were indeed
138 overall lowest in the ameliorated environments, i.e. under mild warming at 26ºC, and in the
139 fluctuating environment (survival analysis: z = -1.22, P = 0.043; Supporting Figure 1,
140 Supporting Table 2). *Ostreococcus* colonisers had a small but significant (see Supporting
141 Table 2) advantage over *Chlamydomonas* colonisers, with higher survivability over all. While
142 we cannot determine the mechanism by which co-culture favours survival, or whether
143 *Ostreococcus* are per se better colonisers than *Chlamydomonas* (Fig. 2 and Supporting Table
144 2), we can begin to quantify the effects of abiotic environment and species interactions on
145 evolutionary and short-term responses.
146
147 **Invaders and colonisers differ in salinity and temperature tolerances**
148 Survival is insufficient: Once extinction is no longer one of the main mechanisms driving
149 responses, we need to know the performance of the population across environments, and the
150 phenotypes they might display. To integrate plastic and evolutionary responses into
151 ecosystem [41] and individual-based models [42], and to better understand the dynamics in
152 laboratory experiments [43] knowledge of phenotypic traits and organismal biology is
153 needed. Here, colonisers differed from invaders in the magnitude of their evolutionary
154 response, their ability to grow in their ancestral environments, and in the phenotypes they
155 evolved.
156
157 When colonisers were transferred back into their ancestral salinity, their growth rates were
158 the same as or lower than they had been in that same salinity before evolution in a novel-
159 salinity environment (e.g. average growth rate per day of the coloniser in the novel salinity

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.19.103978; this version posted May 21, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

160 after evolution in novel salinity: 1.13 ± 0.02 SEM, and after transfer back into the ancestral
161 salinity: 0.79 ± 0.02 SEM , Fig. 3, Supporting Tables 5 and 6 for more details). Growth rates
162 of invaders were overall higher, and did not decrease significantly upon being transplanted
163 back into their ancestral salinity (average growth rate of the invader in the novel salinity after
164 evolution in novel salinity: 1.31 ± 0.01 SEM, and after transfer back into the original
165 salinity:1.29 ± 0.01 SEM). Invaders and colonisers also differed with regards to their
166 responses to warming (supporting Tables 7 and 8 for details), where invaders again
167 outperformed colonisers. This pattern was exacerbated under mild warming in 26ºC where
168 invader growth rates were on average 1.3 times higher than coloniser growth rates (tukey post
169 hoc, P<0.001), and under the fluctuating treatment, with an average fold increase of invaders
170 *vs* colonisers of 1.2 (tukey post hoc, P<0.001). The most pronounced advantage of invaders
171 over colonisers was at the selection temperature (Fig. 4 A, Supporting Tables 7 and 8).
172 Growth rates were diminished under environmental deterioration at 32º C, and this decrease
173 in growth was the least pronounced in invading species (Fig. 4A). We find support that in the
174 unfavourable environments (high temperature, changed salinity), intracellular reactive
175 oxygen species (ROS) production is higher, and ROS tolerance impeded, but that this effect
176 is more pronounced in colonisers than invaders (Supporting Figures 2 and 3).
177

178 **Phenotypic traits of colonisers and invaders**

179 Cell size overall declined with selection temperature regardless of selection regime or
180 species. *Ostreococcus* was more reactive to temperature than *Chlamydomonas* overall
181 (Supporting Figure 4, Supporting Tables 9 and 10), and whether the species was invading or
182 colonising also had an impact on the focal species' cell size (Supporting Tables 9 and 10,
183 Supporting Figure 4), with smaller invaders than colonisers. Cell size of *Chlamydomonas*
184 was more likely to change in response to a resident species than cell size of *Ostreococcus,*

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.19.103978; this version posted May 21, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

185 with *Chlamydomonas* cells up to 1.43 fold smaller after evolution invading the marine
186 species in saltwater than after colonising saltwater on their own (also Figure 4B).
187
188 While we cannot disentangle the relative contributions of the individual species to Net
189 Photosynthesis rates in the co-cultures (NP, i.e. rates of photosynthesis after respiration has
190 been accounted for), net-photosynthesis per gram carbon of evolved co-cultured samples was
191 on average 13% higher than expected from the NP of the same two species at the same
192 salinity in monoculture in line with over-yielding observed in other species [44] (Supporting
193 Figure 5, and Supporting Tables 11 -14). The same pattern emerged when we assayed the
194 same species at the same salinity after decomposition of the co-cultures into monocultures
195 (e.g. physically separating a former mixed culture of *Chlamydomonas* residents and
196 *Ostreococcus* invaders into monocultures (Supporting Tables 11 -14)).
197
198 **Experimental community decomposition**
199 Experimentally separating ('decomposing') the evolved co-culture samples into
200 monocultures yielded insights into how strongly the invaders had adapted to the presence of
201 the resident species, and what effect the invader had on the growth of the resident species
202 (see methods for details). In samples that had only lived in co-culture for two transfers (<20
203 generations), growth after decomposition was indistinguishable from growth in mono-
204 cultures at the same salinity and temperature (Supporting Table 15, Supporting Figure 6). In
205 contrast, in samples that had lived in co-culture for ~200 generations, growth of the invading
206 species when assayed alone in the selection salinity was reduced by up to 30% compared to
207 when assayed in co-culture (Supporting Figure 7), and compared to the same species evolved
208 in mono-culture at the same salinity/temperature regime. Of the resident species,
209 *Ostreococcus* selected in co-culture with *Chlamydomonas* showed evidence of a marked

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.19.103978; this version posted May 21, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

210 decrease in growth when the invading *Chlamydomonas* was removed. Resident
211 *Chlamydomonas* grew faster when the invading *Ostreococcus* population was removed, with
212 no significant effect of temperature on this pattern.
213
214 In the decomposed samples, patterns in net primary production of former invaders mirrored
215 the patterns found in growth rates: invaders always photosynthesised less after decomposition
216 than the same species evolved in monoculture in the same selection salinity. High
217 photosynthesis rates in formerly invaded *Chlamydomonas* were in line with higher growth
218 rates in formerly decomposed *Chlamydomonas* (Supporting Tables 11-14, Supporting Figure
219 7). The resident species *Ostreococcus* photosynthesised more after decomposition than when
220 evolved in monoculture - but grew more slowly. The higher NP rates were, at least for the
221 duration of the assay (two weeks), not directly channelled into growth, indicating that the
222 presence of other species may explain hitherto often observed but poorly explained variations
223 in growth rates in more complex systems (but see [16,45]). We found that samples with the
224 highest surplus NP (or least increase in growth) had a tendency to have higher Nile Red
225 fluorescence, indicating higher lipid storage (Supporting Figure 8). Similar responses
226 including high rates of NP but suppressed growth can be achieved by merely spiking
227 *Ostreococcus* and *Chlamydomonas* cultures with water conditioned by the other species
228 (Supporting Figure 9).
229

230 **Discussion and Conclusions**

231 Rapid adaptation to a novel salinity or the evolution of salinity tolerance are major driving
232 forces in determining the distribution and phenotypic characteristics of phytoplankton
233 communities [46-50]. Changes in salinity (IPCC, 2014), particularly in combination with
234 elevated temperatures, have the potential to impact the phenotypic characteristics of

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.19.103978; this version posted May 21, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

235 phytoplankton species, the communities they populate, and the role of phytoplankton species
236 on aquatic food webs and global nutrient cycles [48,50,51]. Here, we found that species
237 *colonising* a new salinity were prone to extinctions, but that survivors rapidly became locally
238 adapted to their novel salinity. Rapid evolution to a novel salinity has been proven before
239 [34,52], but evolution as a single species might not be a common ecological scenario, as
240 species are likely to not arrive in a new environment and find it unoccupied. Species *invading*
241 a new salinity were less likely to go extinct and evolved high tolerance to both fresh and
242 saltwater, especially under environmental amelioration, such as mildly elevated or rapidly
243 fluctuating temperatures. Invaders had higher survival and growth rates, and were also
244 characterised by overall smaller cell size, lower reactive oxygen species (ROS) production,
245 higher ROS tolerance, and a tendency to store lipids. ROS are a natural by-product of cellular
246 metabolism, but can damage the cell at high quantities [53]. Therefore, higher tolerance
247 toward or lower quantities of ROS may infer a fitness benefit [54]. Taking into account
248 growth rates across all temperature treatments, the invader became more of a generalist, with
249 better performance across multiple environments. Successful invading species often have
250 traits associated with generalists (see e.g. [55,56]), but whether generalist traits enable
251 successful invasions or whether organisms evolve to have more generalist traits as a
252 consequence of invasions remains an open question.
253
254 Our results suggest that under warming and increased climate variability, invasions through
255 small, warm-adapted taxa with intrinsically elevated metabolic and growth rates may become
256 more frequent ('tropicalisations', see [57,58]), with nigh-unpredictable consequences on
257 aquatic ecosystems as a whole. As changes in fitness, cell size and metabolic activity are
258 often linked [59,60], it stands to reason that one possible mechanisms for higher invader
259 fitness in our invader samples lies in their ability to rapidly down-regulate cell size [61-63],

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.19.103978; this version posted May 21, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

260 which in turn might be what is giving rise to their ability to better handle reactive oxygen
261 species [54,62] (Figure 4B and Supporting Figure 10 – the smallest cells had highest fitness
262 and were better able to detoxify ROS). The dynamics and mechanisms of increasing fitness
263 under constant directional selection are well understood [64,65], and experimental evolution
264 lends itself well to linking environmental cause to evolutionary effect, but it is limited in
265 accurately deciphering the mechanisms that underlie trait evolution. Strategies that increase
266 fitness can vary over time [9] and when there are multiple genotypes in a population,
267 evolutionary trajectories, as well as the traits evolved will depend on the environment as well
268 as the genotype [39]. Due to the complex nature of fluctuating selection regimes, barring
269 further analyses, for example on the level of the transcriptome, we cannot with certainty
270 elucidate the exact mechanism that allows for the evolution of these strikingly different
271 phenotypes in invasion *vs.* colonisation scenarios. Still, *Ostreococcus* selected in co-culture
272 with *Chlamydomonas* showed evidence of a marked decrease in growth when the invading
273 *Chlamydomonas* was removed, suggesting that interactions were mutualistic or facilitating in
274 nature. *Chlamydomonas*, when *Ostreococcus* were removed, did *not* show a marked decrease
275 in growth, making it seem likely that the fact of being an invader had direct phenotypic and
276 fitness consequences regardless of the nature of the interaction.
277
278 Understanding the impacts of environmental change over evolutionary timescales will require
279 that we experimentally investigate the mechanisms underlying the differences between
280 colonisers and invaders, the direct effects of rising temperatures on species interactions, and
281 the indirect reciprocal feedbacks between ecological and evolutionary dynamics
282 [29,30,66-68]**.**

320 temperature regimes over time (where one cycle or transfer corresponds to one week), with 1.0 as 100% of
321 populations surviving, and shaded areas denoting 95% confidence intervals. All treatment combinations
322 started with N = 8. The proportion of populations and replicates surviving decreased rapidly at the
323 beginning of the experiment but levelled off after about 10 transfers as extinctions stopped. The number of
324 surviving biological replicates at the end of the experiment is shown in Table S1. Invader trajectories in
325 red, coloniser trajectories in yellow.

357

358 Methods

359 **Should the methods exceed the allowed number of pages, we will provide a methods**

360 **summary here, and the detailed methods, in the supporting information.**

361

362 **Algae strains**

363 The marine picoplankton *Ostreococcus tauri* (clone of the original OTH95) and the

364 freshwater alga *Chlamydomonas moewusii* (CCAP 11/5B) were sourced as non-axenic stock

365 cultures from the Roscoff culture collection and the CCAP (Culture Collection of Algae and

366 Protozoa) respectively. The fact that these two species do not usually co-occur in nature is

367 not problematic here because species invasion is the result of a new species being introduced

368 into a new environment with resident species it has not interacted with before.

369 Pilot studies revealed that long-term growth was impoverished upon removal of the

370 associated bacterial component or after antibiotic treatment, and thus no further attempts at

371 using axenic cultures were made for the purpose of this study. The total amount of bacterial

372 co-inhabitants was tracked and did not change throughout the experiment. Samples were

373 maintained in semi-continuous batch culture (i.e. a fixed volume of exponentially growing

374 cells was transferred into fresh medium at regular intervals) at 22ºC, 100µmol quanta*s^{-1}*m^{-2}

375 under a 12:12 hour light:dark cycle in INFORS ™ multitron incubators with integrated

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.19.103978; this version posted May 21, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

376 shakers until use. *Ostreococcus* was grown at a salinity of 32 (PSU, roughly 30g NaCl*l^{-1};
377 referred to from now on as saltwater or SW) in f/2 media [69], *Chlamydomonas* in modified
378 Bold's media (roughly 0.025g NaCl*l^{-1}; referred to from now on as freshwater or FW).
379 Concentrations of major nitrogen and phosphorus sources were the same in the fresh- and
380 saltwater media.
381
382 **Selection experiment**
383 We set up our experiment using two salinity regimes (saltwater and freshwater, where we
384 refer to the salinity that the species originated from as the 'ancestral' salinity) and three biotic
385 regimes (two monoculture, and one co-culture scenario; Figure 1A). Residents are species
386 evolved in their ancestral salinity (i.e. *Chlamydomonas* in freshwater, *Ostreococcus* in
387 saltwater) either in mono-culture or in co-culture with an invading species. Invaders are
388 species evolved in a novel salinity where the resident species is present (i.e. *Chlamydomonas*
389 invading *Ostreococcus* in saltwater, *Ostreococcus* invading *Chlamydomonas* in freshwater).
390 Finally, colonisers are species evolved in a novel salinity as a mono-colture (i.e. *Ostroeoccus*
391 in freshwater, and *Chlamydomonas* in saltwater).

392 In pilot studies, we characterised temperature reaction curves for each species at each
393 salinity. Temperature/salinity combinations that lead to a significant decrease in growth rate
394 in the short-term compared to the coloniser in its ancestral salinity at 22ºC were called 'low'
395 quality or 'unfavourable environments. Thermal environments where growth rate increased
396 were called 'high' quality or 'favourable' environments (here, these are the 26ºC and
397 fluctuating environment – this is also reflected in samples' abilities to deal with reactive
398 oxygen species). Based on these pilot studies, the long-term experiment was replicated across
399 four different temperature regimes, for a total of 24 unique treatments (x 8 biological
400 replicates = 192 cultures, Figure 1A). The temperature regimes consisted of a fluctuating

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.19.103978; this version posted May 21, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

401 temperature treatment and three stable temperatures, encompassing a stable ambient 22ºC
402 treatment (control), a stable 32ºC treatment (severe warming), and a stable 26ºC treatment
403 (mild warming). In the fluctuating temperature treatment, temperature was switched between
404 22ºC and 32ºC .ca every 3-5 generations.
405
406 We expect the first adaptive step to occur more rapidly in genetically diverse starting
407 populations than in clonal populations, and have leveraged this in our study by starting with
408 genetically diverse rather than clonal populations. [70]
409
410 All cultures started out as mono-cultures before invading species were added. Cultures were
411 grown on 48-well plates with sterile, breathable membranes (Aeraseal ™, Sigma-Aldrich) to
412 minimise uneven evaporation and air exchange across plates. Monocultures were initially
413 inoculated with 100 cells of *Chlamydomonas* or 1000 cells of *Ostreococcus* to account for the
414 difference in cell size. In co-cultures, the resident species were inoculated at 100 fold the
415 biomass of the invading species, for an 'invading from rare' scenario at the beginning of the
416 experiment. The invasion event occurred only once at the beginning of the experiment, after
417 which we tracked the fate of the invaders throughout the experiment. The 48-well plates were
418 positioned randomly in the incubator, and their position was changed every other day to
419 minimise location effects. Cultures were maintained in semi-continuous batch culture, where
420 well-mixed samples of 200µl were serially transferred into 1200µl of new media every 7-10
421 generations ('transfers'). At each transfer, cell count was determined using an Accuri c6 (BD
422 Scientific) flow cytometer at high flow rate. Cells from the two species grown in co-culture
423 could be distinguished based on the SSC (side scatter for granularity), FSC (forward scatter
424 for cell size), and FL3 (red fluorescence for chlorophyll content) channels (Supporting Figure
425 11), allowing for species growth curves to be tracked separately. To analyse differences in

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.19.103978; this version posted May 21, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

426 cell sizes between treatments and species, we calibrated the flow cytometer with beads of
427 known size.
428 Cell counts at the beginning and end of each transfer cycle were used to calculate the rate of
429 increase in cell numbers and approximate generation times. Rates of increase in cell number
430 were determined assuming logistic growth (based on pilot experiments), using the formula
431 $$\mu = (\ln(N_1)-\ln(N_0))/dt \qquad (1)$$
432 Where N_1 is the cell count at the end, and N_0 at the start of the transfer, and dt is the length of
433 the transfer cycle (seven days).
434 The experiment was carried out for approximately 200 generations.
435

436 **Reciprocal assays**

437 After 27 transfers in their respective selection environments, all samples were subjected to a
438 full reciprocal transplant assay in all salinity and temperature regimes to test whether the
439 surviving colonisers and invaders had adapted to the novel salinity in each temperature
440 regime (Figure 1 B and C), and to calculate the magnitude of the short term and evolutionary
441 responses (Figure 1B and C). A well-mixed sample from each surviving population was used
442 to seed the assays. Assays were performed using the same inoculum size and duration of
443 transfer cycle as during the selection experiment. The assays consisted of two transfers,
444 where the first was used to allow the cultures to acclimate to the environment, and the second
445 was used to measure the rate of increase in cell number as a proxy for fitness. Samples
446 evolved at 22°C in their ancestral salinity in mono-culture were used as 'evolved controls',
447 which take into account any evolution that may have occurred due to laboratory conditions
448 *per se*.
449

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.19.103978; this version posted May 21, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

450 We measured three types of responses: the short term response (occurring largely through
451 rapid sorting and physiological acclimation within the same or a few generations, here, less
452 than 10-14 generations), the long term response (likely largely evolutionary, > 100
453 generations), and the correlated response (growth in environments other than the selection
454 environment, 10-14 generations after termination of the long-term experiment). See e.g. [38]
455 for calculation of the magnitude of short-and long term responses, as well as responses in the
456 reciprocal environments.
457

458 **Experimental decomposition of populations grown and evolved in co-culture into mono-**
459 **cultures**

460 To assess whether invaders evolved in co-culture had adapted to the novel salinity, the
461 presence of the resident species, or both, we passed all co-cultured samples through a 5µm
462 nitrocellulose filter, allowing *Ostreococcus* cells to pass, while *Chlamydomonas* cells
463 remained on the filter, from which they could be rinsed off. Samples were then inspected
464 under the microscope and flow cytometric data was again used as above to ensure a good
465 separation of the two species. Samples were grown for two transfers in both their evolved and
466 their ancestral salinity (Figure 1D). We compared the increase in cell number when they were
467 grown on their own after decomposition to when they were grown in co-culture or had been
468 selected for growth in monoculture. For logistic reasons, samples were only assayed at the
469 temperatures that they had evolved in and not across all temperatures. To measure the short-
470 term acclimation response to encountering another species, we re-created the starting
471 conditions of the invasion experiment using mono-culture evolved samples (colonisers
472 evolved in their ancestral salinity). These samples were inoculated to recreate the invasion
473 from rare scenario as described above. The new co-cultures were maintained for two cycles,

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.19.103978; this version posted May 21, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

474 and then separated again by filtration afterwards. This tested for whether dependence on the
475 species was established within very few generations (Supporting Figure 6).
476
477 **Characterisation of net primary production**
478 To characterise phenotypic changes in the different treatments, we gathered data on cell size
479 and chlorophyll through flow cytometry (Accuri B6), and measured rates of oxygen evolution
480 and consumption using a 24-channel PreSens Sensor Dish Reader. For all phenotypic
481 characterisations, samples were harvested during exponential growth. The reader was placed
482 in the incubator at assay temperature in a manner such that the light gradient across the reader
483 plate was minimal (<5 µE m^{-2} s^{-1}). Glass vials were filled to 1.2 mL with the respective
484 sample, i.e. colonisers, invaders, or decomposed samples, covered with para-film and sealed
485 tight. The samples were then left in the dark for 35 minutes, and gently inverted before
486 measurements of oxygen evolution at the light level in the incubator for 5 minutes, and
487 measurements of oxygen consumption in the dark for another 5 minutes. A vial containing
488 filtered Bold's medium or f/2 medium at the appropriate salinity was used to account for any
489 drift in the oxygen measurements. Cell count was determined using a flow cytometer as
490 described above. The rates of oxygen evolution and consumption were then calculated per
491 unit biomass, assuming spherical cells and carbon conversion factors after [71] (Supporting
492 Figure 12 and Supporting Tables 16 and 17 for effects of selection regimes on biomass).
493
494 **Nile Red stain**
495 A Nile Red stain was used as a proxy to determine relative quantities of intracellular polar
496 and neutral lipids [72]. It works well for Ostreococcus [73] and while stains of the BODIPY
497 class are preferred for quantification of lipids in Chlamydomonas, Nile Red can serve well to
498 establish relative differences[74]. The dye was added to each 200 µL sample on a 9-well plate

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.19.103978; this version posted May 21, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

499 for a final concentration 15 m and left to incubate in the dark for 30 min, as pilot trials had
500 shown that after this, fluorescence levels were stable long enough for the time taken
501 to measure one 96 well plate. As Nile Red excites in the same wavelength as chlorophyll
502 (FL3) and chlorophyll derivatives (FL2), samples were measured before and after adding the
503 dye, and the chlorophyll fluorescence subtracted from the fluorescence obtained after staining
504 the sample (Supporting Figure 9).
505
506 **ROS assay**
507 We tested how capable samples were of detoxifying harmful reactive oxygen species (ROS)
508 and also estimated the intra-cellular ROS levels in order to gain an estimate on whether
509 samples under unfavourable conditions experience more stress, and are therefore producing
510 more/ being less able to detoxify ROS. We used the protocols established by [54,62].
511 Samples from 'unfavourable environments' had higher intra-cellular ROS content, were less
512 well able to detoxify harmful ROS (Supporting Figures 2,3, 11).
513
514 **Statistical analyses**

515 All data were analysed in R versions 3.3.1 and 3.3.3 [75].

516 **Survival analysis**
517 We first analysed the extinction dynamics by performing a survival analysis using a Cox
518 proportional hazards regression model with the R package 'survival'(Supporting Table 1 and
519 2). The model included biotic regime, temperature regime, and species as fixed effects.
520 Biological replicate strains (per species) were treated as random effects. We also included a
521 censor variable for populations that had not gone extinct by the end of the experiment. Note
522 that an extinction event here was defined as cell numbers of a population declining below the

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.19.103978; this version posted May 21, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

523 detection limit of the flow cytometer. We treat extinction as an event occurring on the
524 replicate level in each individual treatment.

525 **Analysis of short-and long-term responses to changes in salinity, in stable and**
526 **fluctuating temperatures**

527 We analysed the growth of the surviving replicates as assayed at the end of the experiment in
528 the reciprocal transplants using analyses of variance within a mixed effects model (package
529 nlme, version 3.1-131). Growth relative to growth of the evolved control at 22ºC in
530 monoculture was the response variable. This normalisation by growth under standard
531 laboratory conditions allows us to correct for evolution occurring merely due to selection for
532 laboratory conditions and further creates a baseline for easy comparison of the selection
533 temperatures in relation to each other. We fitted the following fixed factors in the global
534 model: species (*Chlamydomonas* or *Ostreococcus*), biotic regime (invading or colonising),
535 selection temperature (22ºC,26ºC,32ºC, or fluctuating), and response type ('short' for growth
536 rates in the novel salinity after two weeks of culturing in the novel salinity, 'long' for growth
537 rates in the novel salinity after evolution in the novel salinity, 'back' for growth rates in the
538 ancestral salinity after evolution in the novel salinity). The ancestral and selection salinities
539 can be inferred from the species and biotic regime factors, and therefore selection salinity
540 was not added as an explicit factor. Replicates (Supporting Table 1 for number of surviving
541 replicates in each unique treatment) nested within 'unique treatment' were used as random
542 factors. The nesting was necessary as all replicates originally came from the same starting
543 culture, i.e. replicate 1 of any given treatment was not more or less related to replicate 1 in
544 another treatment than it was to, e.g., replicate 5. We ran the model only on samples where
545 the assay temperature was identical to the selection temperature. We started the model with
546 the fixed factors in full interaction, and searched for the model with the lowest AICc scores
547 through the 'dredge' function within the MuMIn package (version 1.40.4). The model with

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.19.103978; this version posted May 21, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

548 the lowest AICc was consequently used. In all cases of model selection by AICc, we used a
549 delta value of > 2 to confirm the best model (Supporting Tables 5 and 6).
550
551 **Analysis of local adaptation to temperature**
552 To specifically test whether samples had locally adapted to their selection temperature
553 without risking over parameterising the mixed model, we built a separate mixed effects
554 model using data where the assay salinity was the same as the selection salinity, thus
555 focusing on the temperature dependence of growth rates in the samples' selection salinity.
556 We used growth rates relative to the evolved control in mono-culture at 22ºC as the response
557 variable, and species (*Chlamydomonas* or *Ostreococcus*), biotic regime (invading or
558 colonising), selection temperature (22ºC,26ºC,32ºC, or fluctuating), and assay temperature
559 (22ºC,26ºC,32ºC, or fluctuating) as fixed factors. The random factors and model fitting were
560 as described above (Supporting Tables 7 and 8).
561
562 **Analysis of growth rates in decomposed samples**
563 To analyse whether invaders and residents developed a dependence on each other in the
564 short-term, we compared growth rates of the decomposed samples (decomposition after two
565 weeks of co-culture) to growth rates of the same species at the same temperature and salinity
566 in mono-culture *via* a t-test (Supporting Table 15). For the long term-responses, we analysed
567 the decomposed samples (measured at selection temperature) by fitting a mixed model, using
568 the ratio between growth rates of either species after decomposition and growth rates of the
569 species in co-culture as the response variable. We fitted species (*Chlamydomonas* or
570 *Ostreococcus)*, biotic interaction during selection(resident or invader) and selection
571 temperature as the fixed effects. Random effects and model fitting were as described above
572 (Supporting Tables 11 and 12).

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.19.103978; this version posted May 21, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

573

574 **Phenotypic characterisation**

575 In order to estimate the effect of the selection regimes (biotic scenarios, temperature, and
576 salinity) on cell size and total biomass we fitted a mixed model with the full interaction of the
577 parameters species (*Chlamydomonas* or *Ostreococcus*), assay salinity ('home' for the assay
578 salinity being equal to the focal species' *selection* salinity, and 'away' for assay salinity being
579 different from the focal species' selection salinity), biotic regime (invading or colonising) and
580 selection temperature (22ºC, 26ºC, 32ºC, fluctuating). Model fitting and selection proceeded
581 as described above (Supporting Tables 9 and 10 for size, Supporting Tables 16 and 17 for
582 biomass). For the analysis of rates of net primary production in the evolved and decomposed
583 samples specifically, a mixed model was fitted using species (*Chlamydomonas* or
584 *Ostreococcus*), 'previous interaction' (invader or resident), assay salinity (including a unique
585 identifier for each salinity in interaction with whether the sample had been decomposed and
586 at which point in time – after 2 weeks, or at the end of the experiment – it had been
587 decomposed, Fig. 1D for an example), selection temperature (22ºC, 26ºC, 32ºC, fluctuating),
588 'biotic selection regime' (colonisers or invaders) as the fixed effects. Model fitting and
589 selection then proceeded as described above (Supporting Tables 13 and 14).
