26 Abstract

The specificity of phosphorylation by protein kinases is essential to the integrity of biological signal transduction. While peptide sequence specificity for individual kinases has been examined previously, here we explore the evolutionary progression that has led to the modern substrate specificity of two non-receptor tyrosine kinases, Abl and Src. To efficiently determine the substrate specificity of modern and reconstructed ancestral kinases, we developed a method using mammalian cell lysate as the substrate pool, thereby representing the naturally occurring substrate proteins. We find that the oldest tyrosine kinase ancestor was a promiscuous enzyme that evolved through a more specific last common ancestor into a specific human Abl. In contrast, the parallel pathway to human Src involved a loss of substrate specificity, leading to general promiscuity. These results add a new facet to our understanding of the evolution of signaling pathways, with both subfunctionalization and neofunctionalization along the evolutionary trajectories.

39

40 Introduction

41 The human genome contains 32 non-receptor tyrosine kinases (NRTKs) that are 42 tightly involved in a multitude of cellular processes including differentiation, apoptosis, 43 and proliferation¹⁻³. The interaction between each NTRK and its substrate comprises a 44 fundamental cellular signal that consequently required the evolution of specificity between 45 signaling pathways. To prevent unwanted signaling 'crosstalk', NRTKs have evolved two main strategies to ensure substrate insulation^{4,5}: kinase localization⁶⁻¹² and active-site 46 47 peptide specificity¹³⁻¹⁸. The localization process is achieved through binding interactions 48 on the NTRKs' SH2/SH3 domains, which complex with either phosphotyrosines or polyprolines, respectively¹⁹⁻²². The differences in the active site of NRTK kinase domains 49 50 results in specificity where only a subset of substrates can bind and thus get 51 phosphorylated.

52 Unlike the serine/threonine family of kinases, NRTKs possess relatively 53 promiscuous active-site peptide specificities with a broad range of potential substrates⁵. 54 high-throughput substrate screens, catalytic domains of NRTK members In 55 phosphorylated hundreds of distinct peptide sequences, highlighting the promiscuity of 56 these kinases. Nevertheless, comparisons within the family show unique sequence 57 preferences and a consequent range of substrate selectivity. For two of the most well-58 studied members, Abl and Src, narrow and broad selectivities are reported, respectively^{13,17}. Because substrates bind at the active site in an elongated fashion, the 59 60 primary peptide sequence largely dictates the description of selectivity⁵. Abl has a clear 61 preference for hydrophobic residues flanking the tyrosine of interest (I/L/V-1, A+1, and P_{+3})^{14,23}. In contrast, little sequence selectivity is observed for Src other than the relatively 62

weaker preferences for a bulky aliphatic residue (I/V/L-1) at the residue preceding the phosphoacceptor, a phenylalanine three residues away from the phosphoacceptor (F_{+3}), and a negatively charged residue on the N-terminal side of the phosphoacceptor (D/E-4, -3, -2)^{17,24,25}.

As Src and Abl are sister clades within the NRTK phylogeny, their distinct 67 68 sequence preferences beget the question: how did peptide selectivity arise throughout 69 evolution? Herein we answer this question using ancestral sequence reconstruction 70 (ASR) for the catalytic domains. ASR uses modern sequences and an evolutionary model to infer the sequences of internal nodes in a phylogenic tree (Figure 1A, Figure 1 — figure 71 supplement 1) ²⁶⁻³¹. Resurrection of ancestral kinases bridging Src and Abl allows the 72 73 evolution of peptide selectivity to be directly traced. The differences in protein sequence 74 between modern kinases and ancestors are spread through the kinase domain and the oldest ancestor only has ~65% similarity with Src (Figure 1B). 75

76 Src and Abl display lower sequence selectivity than other kinases such as Aurora A and B-RAF serine/threonine kinases^{5,24,32}, and, consequently, obtaining an accurate 77 78 description of the primary sequence determinants for each tyrosine kinase is a greater 79 statistical challenge³³. Comparison of ancestral and modern kinases requires a 80 comprehensive library of substrates since ancestral kinases likely refined their sequence 81 preferences over time. To ensure biological relevance, the peptide library should ideally 82 be composed of naturally occurring proteins. To construct such a library, we took 83 advantage of the diversity of sequences present in mammalian whole cell lysate (HEK293) 84 cell line)^{34,35}. After endogenous kinases are covalently inhibited, the proteome of 85 mammalian cells presents a convenient substrate library containing thousands of 86 potential protein substrates. Here we use this comprehensive library to examine the 87 evolution of substrate selectivity in Abl/Src tyrosine kinases. We find that kinase substrate 88 preferences evolved in a complex manner involving two different modes: a promiscuous 89 progenitor specialized into the modern specific Abl, whereas evolution of Src involved 90 relaxing selectivity via a specific ancestral intermediate. We find that kinase substrate 91 preferences evolved in a complex manner involving two different modes: a promiscuous 92 progenitor specialized into the modern specific Abl (subfunctionalization), whereas 93 evolution of Src involved relaxing selectivity via a specific ancestral intermediate

94 (neofunctionalization). Therefore, our results shed light into a critical open question in
 95 signaling, how new protein kinases with novel substrate specificities have evolved.

96

97 **Results**

98 Whole-cell lysate phosphoproteomics-based approach

99 A large and diverse protein library is necessary to readily screen the primary 100 sequence determinants of ancestral and modern NRTKs. An easily accessible, cheap, 101 and biologically relevant pool of substrates was created by inactivating endogenous 102 using the covalent, kinases in HEK293 lysate nonspecific inhibitor 5'-[p-103 (fluorosulfonyl)benzoyl]adenosine (FSBA) (Figure 1C). After dialyzing out unreacted 104 inhibitor, purified kinases were added to the treated lysate and phosphorylation was 105 initiated with the addition of Mg²⁺ and ATP. To assess the required reaction time, total 106 phosphorylation was monitored by western dot blot experiments. Constant 107 phosphorylation levels were found to occur between two to four hours (Figure 1D,E). After 108 protein digestion with trypsin, peptide fragments were enriched for phosphorylation using 109 immobilized metal affinity chromatography (IMAC) and then analyzed by liquid 110 chromatography-mass spectrometry (LC/MS/MS, Figure 1C). Peptides were associated 111 with their full protein sequence based on the known HEK293 proteome, and results were 112 focused on a 15-amino acid sequence window centered on the phosphorylated tyrosine.

To determine a kinase's sequence specificity, each amino acid frequency must be compared between the phosphorylated dataset and the background HEK293 proteome³³. A background dataset was generated by proteomic analysis of lysate that was treated with kinase inhibitor, but where no kinase was added and no phosphorylation enrichment was performed³⁶. From this analysis, the amino acid frequencies of all surrounding tyrosine residues (not only phosphorylated tyrosines) were calculated (Figure 1 — figure supplements 2 and 3).

To determine the extent of endogenously phosphorylated peptides present, we analyzed a lysate sample that was enriched for phosphorylated peptides but lacked exogenous kinase. A total of 26 phosphorylated tyrosines were found in this control and these peptides were excluded from the ancestral/modern NRTK list of substrates in which kinase was added (Figure 1 — figure supplement 4).

125 In the data set where Src was added to the cell lysate, 8208 unique phosphorylated 126 sequences were identified (Figure 2A). These peptides include the characteristic 127 preferences for large aliphatic residues directly preceding the phosphotyrosine (V-1), 128 negatively charged residues in multiple positions N-terminal to the phosphotyrosine (D/E-129 $_{3, -2}$), and a glycine following the phosphorylation site (G₊₁). An inclination for other 130 aliphatic residues preceding the phosphotyrosine (I/P/T-1) is also seen (Figure 2B). 131 Notably, a preference for proline at the -1 position identified in our data was not observed 132 previously. For Abl, specificity for large aliphatic residues preceding the phosphotyrosine 133 is found (I/V-1), as well as the canonical proline at the +3 position (Figure 2B). Additionally, 134 Abl exhibits a high preference for proline at the -2 position, which had not been identified 135 previously.

136 We can compare the results obtained here with the substrate specificity that is observed when only natural substrates are considered. PhosphoSitePlus is a database 137 138 which annotates all known phosphorylation sites in vivo and in vitro that a given kinase phosphorylates²⁴. Overall, our results confirm the previously found descriptions for both 139 140 Src and Abl's substrate specificities based on substrates in the PhosphoSitePlus 141 database, but additionally identify a few new preferences (Figure 2B, C). Our HEK293 142 lysate has a much larger number of phosphorylated substrates than the PhosphoSitePlus 143 database, which allows us to ascertain the residues dictating phosphorylation specificity 144 with greater accuracy and statistical significance than is possible with the 145 PhosphoSitePlus data (Figure 2B,C). Some of the differences may be due to the larger 146 number of substrates in our whole cell lysate. However, many of the observed 147 discrepancies likely result from differences in experimental design. PhosphoSitePlus is 148 based on in vivo substrates for the full-length kinase, whereas we are interested in the 149 intrinsic specificity of the kinase domain. In our experiments, we do not have the full-150 length kinases and, therefore, we only find substrates that are selected by the kinase 151 domain itself. In contrast, phosphorylation within the cellular framework, as reported by 152 PhosphoSitePlus, is strongly determined by regulation and co-localization events, and 153 intrinsic kinase domain specificity plays a relatively smaller role. Indeed, Shah et al. 154 studied the specificity of NRTK kinase domains with a high-throughput, cell-surface based

experiment and found similar discrepancies between PhosphoSitePlus based logos and
 their experimentally determined sequence determinants¹⁷.

157 Evolution of specificity between Src and Abl

158 Having established now the accuracy and statistics of our methodology on the 159 modern kinases, we next chose to determine the sequence specificity of three resurrected 160 ancestral kinases (Figure 1A). Anc-AS and Anc-S1 were previously resurrected for 161 investigating the mechanism of Abl selectivity for Gleevec²⁹, while the newly resurrected 162 Anc-AST (Figure 1 — figure supplement 1) is the oldest common ancestor of the Abl/Src 163 branch and the Tec family. Using our whole cell lysate phosphoproteomics-based 164 method, we identified a total of 12.056 unique sequences phosphorylated by the ancestral 165 and modern proteins (Figure 3A, Figure 3 – figure supplement 2). The common ancestor 166 of Src and Abl, Anc-AS, phosphorylated the least number of substrates (2495), which was 167 comparable to Abl (3073). The relative dearth of substrates for Anc-AS hinted that this 168 ancestor might be more specific than the promiscuous Src, which phosphorylated a total 169 of 8208 substrates. In contrast, the ancestors preceding (Anc-AST) and following (Anc-170 S1) the common ancestor of Src and Abl each phosphorylated a significantly greater 171 number of substrates (8189 and 7242, respectively), indicating these ancestors were 172 likely more promiscuous.

173 General kinase specificity was then quantified by calculating the substrate 174 sequence entropy for each position in the 15-residue window (Figure 3B)³⁷. Lower 175 entropy, with fewer potential amino acid possibilities, indicates higher specificity. As 176 expected from the sequence logos (Figure 2B), Abl possesses the lowest entropy at 177 residues close to the phosphorylated tyrosine (-3, -2, -1, +1, -1, -1), with the most 178 specificity occurring at the signature proline position (+3). In contrast, the promiscuity of 179 Src manifests itself as increased entropy across almost all positions and a more limited 180 region of high specificity (-2, -1, and +1). The ancestral proteins give entropy plots that 181 agree with what was suggested by the observed substrate counts: The common ancestor 182 (Anc-AS) possessed entropy akin to Abl, albeit with a higher entropy at +3 and lower 183 entropy at positions -2 and +5. The two additional ancestors, Anc-AST and Anc-S1, both 184 exhibited 'hybrid' specificity with higher entropy than Abl, but less than Src. Notably, only 185 Src lacks specificity at the +3 position.

186 To analyze each enzyme's positional specificity in more detail, specificity heat 187 maps were created to illustrate the relative specificity for each amino acid at every position 188 in the 15-residue window (shown as a 20x15 matrix of positional normalized amino acid 189 log probabilities, Figure 3C)^{17,38}. Qualitatively, Abl's specificity is apparent from the high-190 intensity signals for both preferred residues (red, P+3 and I-1) and unfavorable residues 191 (blue, S_{-1} , P_{+1} , and D/E_{+3}), while Src has more white space and overall less intense signal. 192 We note that under substrate saturating conditions the enzyme would phosphorylate even 193 the less favorable substrates, which could result in an apparent low specificity. To ensure 194 that the observed promiscuity is not due to substrate saturation, experiments with Src 195 were repeated with a much shorter incubation period of the cell extract and the kinase 196 (10 minutes versus 4 hours). In this control, less phosphorylation was observed (Figure 197 1 C,D); however, the same primary sequence determinants were found (Figure 3 — figure 198 supplements 1 and 2), validating our findings.

199 Tracing individual amino acid preferences at specific positions provides a clear 200 picture of how specificity evolved for Abl (Figure 4A). Focusing on residues which are 201 preferred in Abl, but disfavored in Src (P₊₃, A/V₊₂, A₊₁, and P₋₂), we see that moderate 202 preference is already observed in ancestral kinases. The evolutionary path from the 203 oldest ancestor (Anc-AST) to Abl involves further increasing specificity either at the Anc-204 AS node (P-2 and A/V-1) or in the final transition to Abl (A+1 and P+3). In contrast, the 205 pathway from the more specific Anc-AS to Src involves a corresponding loss of specificity 206 for each of these residues, with Anc-S1 possessing intermediary preferences (Figure 4A).

The evolution of the few positions favored by Src followed a different trend. The preference for P₋₁ appears late, only in Src. Such recent evolution is in agreement with the lack of preference for proline at position -1 of its close homolog Lck¹⁷. Other Src sequence preferences were already present in the oldest ancestor, then lost in Anc-AS and regained in Anc-S1 and Src (Figure 4B).

The increased promiscuity of Src is revealed in overall lower log probability values than that of Abl's specific residues. Despite these differences in substrate specificity, there are multiple positions where all modern and ancestral kinases prefer the same residues, most of which are well-known features of NRTKs (e.g., I-1, D/E-3, and S+2) (Figure 4C). As these characteristics are observed in all ancestral and modern proteins in our study and are common among most NRTKs, they likely represent the oldest features of substratespecificity for the NRTK family.

Validation of evolutionary trends of primary sequence determinants via enzymekinetics

Having determined the primary sequence determinants for the ancestral and modern kinases, *in vitro* peptide enzyme turnover experiments were performed to relate these bulk specificity experiments to quantitative enzymatic parameters. Compressing thousands of substrates into residue-by-residue descriptions is compelling (i.e., preference for P₊₃), but how these preferences relate to enzymatic properties remains unclear. We therefore measured the Michaelis-Menten kinetics of four distinct peptide substrates with each of the five ancestral and modern kinases.

228 Previous microarray specificity experiments had determined optimized substrates for Src and Abl, known as Srctide and Abltide, respectively^{13,18,25}. While both substrates 229 230 are ideal for their respective modern kinases, each also has residues favored by the 231 opposite kinase, which allow it to be phosphorylated to a certain degree by each kinase. 232 Therefore, we designed modified versions of Srctide and Abltide, called Srctide2 and 233 Abltide2, to test our evolutionary trends (Figure 5A,B). Srctide2 was intended to be 234 favored by both Src and Anc-S1, with changes made to Srctide to include residues that 235 occurred more frequently in substrates for these two kinases (D-2, A+2, and I+3). Abltide2 236 was designed to be preferred by both Abl and Anc-AS by mutating the alanine at position 237 -2 into a proline. P-2 is favored by all the kinases, except for Src (Figure 5A, B).

238 As substrates in signaling cascades are generally present at low concentrations in 239 vivo, the k_{cat}/K_{M} likely represents a more fundamentally important parameter than k_{cat} for 240 substrate specificity. As can be seen from the measured Michaelis-Menten curves (Figure 241 5C), the measured differences in the kinetics corroborate the evolutionary trends found 242 before but suggest additional features for substrate specificities. Starting with a 243 promiscuous Anc-AST, Anc-AS becomes more selective, particularly for substrates with 244 P-2, Ablitide2 (which was identified as a highly preferred residue for Anc-AS and Abl from 245 our phosphoproteomics data, Figure 5B). Moving to Abl, the specificity for Abltide and 246 Abltide2 further increases as seen with high increases in $k_{\text{cat}}/K_{\text{M}}$. This is primarily due to 247 the strong preference for P_{+3} (Figure 5B), which are both present in Abltide and Abltide2.

248 At higher concentrations of these two well-optimized peptides we observe partial 249 inhibition, due to the negative cooperativity of ATP and peptide substrate found for Abl³⁹. 250 Following the evolutionary branch towards Src, Anc-S1 becomes more 251 promiscuous, mainly due to its ability to catalyze Src-preferred substrates in addition to 252 the Abltide substrates. Furthermore, the strong preference of I+3 observed in the 253 proteomics data (Figure 5B) can be directly recapitulated by the preference for Srctide2 254 (Figure 5C). The strong preference of Srctide and Srctide2 over the Abltide substrates 255 only appears in Src, primarily due to a complete loss of preference for P₊₃ leading to poor 256 activity for the Abltide substrates, combined with a subtle preference for F₊₃.

257 Discussion

258 There are multiple methods described in the literature for assessing substrate 259 including non-receptor tyrosine kinases specificity of protein kinases, and 260 serine/threonine kinases. Several studies look only at known natural substrates, such as 261 in PhosphoSitePlus, to determine which residues occur more frequently in known phosphorylation sites^{24,40}. Other studies, including the one presented here, use the whole 262 cell lysate as a pool of substrates to test the specificity of kinases^{34,35}. The HAKA-MS 263 264 method reported by Muller et al. used a similar whole cell lysate, yet only found a P+3 preference from 104 Abl substrates (Figure 2 – figure supplement 2)³⁵. In contrast, our 265 266 study found ~30-fold more substrates and several residues that are preferred or 267 disfavored at multiple positions. The large difference in detected phosphorylated 268 substrates could be due to different methods to enrich for phosphorylated peptides: Muller 269 et al. use multiple phosphotyrosine binding antibodies, whereas we use IMAC. We also 270 tried using phosphotyrosine binding antibodies for enrichment, but we found peptide bias 271 and artifacts using this method. Lastly, one of the most popular methods uses peptide libraries to determine the preference of kinases^{13,14,16-18,38}. 272

Our experimental method, which exploits the substrate-rich, kinase-inactive whole cell lysate and has improved statistical significance, discovered new determinants of Abl and Src specificity in addition to those previously reported¹⁷: Src shows significant favorability for proline or threonine at the -1 position and a serine at the -2 location, while Abl shows a preference for proline at the -2 position and a serine at the -2 position. These new features were subsequently verified by *in vitro* enzyme kinetic experiments. The most important advantage of the increased sensitivity of our assay has been the ability toexplore how Src and Abl kinases evolved their sequence preferences.

281 How these kinases have differing specificities can be partially rationalized based on 282 the details of kinase sequence and structure. Y569 in Abl has previously been determined 283 to be required for its preference for proline in the +3 position of substrates⁴¹. Leucine at 284 the homologous position (L475) in Src was previously shown to disfavor proline⁴¹. A437 285 has been proposed to be responsible for Src's preference for phenylalanine at position 286 +3, along with L475¹⁷. All ancestors contain an isoleucine at position 475 and show 287 intermediate specificity towards P₊₃. Moreover, Anc-S1 differs from Src in both positions, 288 1475 and L437 (Figure 5 – figure supplement 1), identical to another Src family kinase 289 member, Lck (I412 and I450 in Lck). Interestingly, when comparing the Anc-S1 substrate 290 preference to that of Lck, as investigated by Shah et al.¹⁷, we see a high similarity in the 291 +3 position preferences. Both Anc-S1 and Lck show a strong preference for L_{+3} and P_{+3} , 292 suggesting that Anc-S1 is more Lck-like, and that the substitution to the less bulky A437 293 in Src causes its preference for F_{+3} (Figure 5 – figure supplement 1). These structural 294 differences between Src and the ancestors explain why the Srctide is less effective at 295 being phosphorylated by other kinases. Anc-S1 was unable to effectively phosphorylate 296 Srctide potentially due to F₊₃, wherein its substitution to the less bulky isoleucine in 297 Srctide2 is favored by Anc-S1. We elect to steer clear from additional structural 298 explanations for other detected specificities, as these are just coarse models of 299 kinase/substrate complexes, and more collective, long-range effects often underlie such 300 specificity changes. For example, in an appealing study of the evolution of CMGC 301 kinases, Howard et al. identified a key residue for imparting specificity at the +1 position²⁸. 302 Tests of their hypothesis via mutations in the corresponding modern kinases resulted in 303 partial changes in specificities. Since the authors were unable to achieve a full swap in 304 specificity, they concluded that there must be additional residues in play that are not 305 readily apparent by looking at the differences in active-site residues.

The different trajectories we find in the evolution of Src and Abl substrate specificity add a new facet to our understanding of the evolution of signaling pathways. It has been postulated that much of biological diversity, including metazoan complexity, has been driven by the evolution of new regulatory networks and signaling pathways, such as those 310 controlled by the post-translational modification of kinase phosphorylation^{42,43}. A key 311 evolutionary challenge in creating a new signaling pathway is ensuring kinase specificity 312 to minimize crosstalk with other pathways, many of which are vital to cellular fitness. One 313 critical open question is how new protein kinases with novel substrate specificities have 314 evolved.

315 Gene duplication has been the major force driving the evolutionary diversity of 316 signaling pathways and kinase specificity⁴²⁻⁴⁴. There are two main ways that gene 317 with duplication can evolve enzymes new and different functions: (1)318 "subfunctionalization", the specialization of previously existing functions, and (2) 319 "neofunctionalization", the creation of a novel function through the accumulation of 320 beneficial, gain-of-function mutations^{45,46}. The evolution of sequence specificity does not 321 cleanly fall in either of these categories, because specificity is not an "all-or-nothing" gain 322 or loss of a function. Nevertheless, for kinases, subfunctionalization most closely aligns 323 with evolution from a non-specific ancestor (which can bind and use many different 324 substrates) to descendants with differing, specialized specificities (which can bind and 325 use only a subset of the ancestral substrates), whereas neofunctionalization involves 326 evolution from a specific ancestor to a descendant with a broad, promiscuous specificity 327 or with a different specificity. Though neofunctionalization is the older of the two 328 hypotheses^{47,48}, it is now widely viewed as relatively improbable and hence less frequent in evolution than subfunctionalization mechanisms⁴⁹⁻⁵³. For instance, in the evolution of 329 330 specificity in CMGC protein kinases, the ancestral kinase was a promiscuous bispecific enzyme in respect to the +1 position, unlike the modern kinases which are specific for a 331 single amino acid²⁸. Currently, the evolutionary mechanisms by which gene duplications 332 333 evolve new functions are controversial, and there are relatively few examples of classic 334 neofunctionalization 54-56.

Intriguingly, we see both mechanisms of gene duplication in the evolution of Abl and Src. With Abl, subfunctionalization converted a promiscuous, non-specific ancestor (ANC-AST) into specific descendants (ANC-AS and modern Abl); with Src, neofunctionalization transformed a surprisingly specific ancestor (ANC-AS, the last common ancestor of the Abl and Src kinase families) into progressively more

11

promiscuous descendants (ANC-S1 followed by modern Src). In fact, the particular
 lineage leading from ANC-AST to modern Src appears to involve both mechanisms.

342 In the toxin-antitoxin signaling systems of bacteria, Aakre et al.⁵⁷ found that the 343 evolution of some enzymes passes through promiscuous intermediates before 344 developing strong substrate specificity. Our results suggest that eukaryotic protein 345 kinases similarly evolve through waves of promiscuous and specific effectors. Periods of 346 increased promiscuity may allow kinases to access new substrates while maintaining their 347 current function, which could explain the redundancy of kinase networks²⁴. To insulate 348 individual pathways from others, sometimes this promiscuity may be selected out. In other 349 cases, the overlap may provide a fitness advantage resulting in modern protein kinases 350 with overlapping substrates.

351 The present work has addressed one component of kinase substrate specificity – the intrinsic specificity of the kinase domain - but it is important to emphasize the rich 352 353 literature about the crucial role of the additional regulatory domains found within most 354 NRTKs for kinase specificity. Proteins containing SH2 or SH3 domain binding sites are 355 more likely to be phosphorylation targets for NRTKs, due to the selective activation of the kinases^{7,20,58-60}. SH2 and SH3 domains have their own unique specificity⁶¹⁻⁶⁵, and bring 356 357 the kinases to their target substrates. Studies using kinase domains in isolation have not 358 identified all the known substrates that are found in databases like PhosphoSitePlus. For 359 example, Shah et al. limited their library to only known phosphorylation sites, yet they 360 could not see a preference for all known kinase substrates for a given kinase¹⁷. We fully agree with their discussion¹⁷ that intrinsic kinase domain specificity^{13,14,25} acts in concert 361 362 with the selective activation and localization provided by the SH2 and SH3 domains in a cellular context ^{4,7,8,12,20,21,64,66-70} to provide the full specificity of the NRTKs. 363

369 Materials and Methods

370 Kinase Specificity in Whole Cell Lysate Experiment

371 HEK293 cells were grown in CytoOne 150X20mm TC dishes with DMEM (High 372 Glucose, No Glutamine; Fisher Sci) containing HyClone bovine growth serum (Fisher 373 Sci), glutamine (Fisher Sci), fungizone (Fisher Sci), and penicillin-streptomycin (Fisher 374 Sci). At ~90% confluency, cells were washed with 5mL of PBS before being harvested. 375 Cells were centrifuged at 4500g for 6 minutes to pellet. PBS was then decanted from the 376 pellet. Pelleted cells were washed by repeating the previous step. The pellet was then 377 resuspended in ~3 mL of assay buffer (20 mM Tris, Fisher; 500 mM NaCl, Fisher; 1 mM 378 MgCl₂, Fisher; 1mM TCEP, Fisher; pH 8) per 10 plates harvested. Cells were lysed by 379 sonication followed by centrifugation at 30,000g. The supernatant was pipetted from the 380 pellet and 20 mM 5'-(4-Fluorosulfonylbenzoyl)adenosine hydrochloride (FSBA; Sigma 381 Aldrich) was added to the supernatant. The lysate was incubated with FSBA at 25 °C for 382 2 hours. Lysate was dialyzed in 2 L of assay buffer for 5 hours at room temperature 383 followed by a second dialysis at 4 °C overnight in 2 L of assay buffer. The protein 384 concentration in the lysate was then calculated with BCA assay Kit (~9 mg/mL; Pierce).

Wilson et al.²⁹ previously published the construction of an alignment and 385 386 phylogenetic model using BAli-Phy⁷¹, which was used to resurrect ancestral protein sequences with PAML⁷². The robustness of these ancestral kinases have been previously 387 388 tested by investigating activities of alternate sequences of the same nodes²⁹. Ancestral and modern kinases were expressed and purified as previously reported²⁹. The reaction 389 390 was setup with 10 µM kinase, 20 mM MqCl₂, 10 mM ATP, Phosphatase Inhibitor Cocktail 391 #2 (Cal Biotech), and ~1.3 mL of lysate (~12 mg of protein). Reaction went for up to 4 392 hours at 25 °C. This was repeated three times for each kinase along with a background 393 sample where no kinase was added. For the western dot blot time course of Src, 5 µL of 394 sample was guenched with 15 µL of 8 M urea (Fisher Sci) to make the 4-fold dilutions. 395 Other dilutions were made accordingly for 2-fold and 8-fold dilution samples. 1µL samples 396 were loaded directly onto a nitrocellulose membrane (GenScript). The protocol was 397 followed for the iBind Automated Western Systems (ThermoFisher) with Phosphotyrosine 398 antibody (P-Tyr-1000 MultiMab[™] Rabbit mAb mix; Cell Signaling Technology) as the 399 primary antibody (1:2000 dilution) and ScanLater anti-rabbit antibody (Molecular Devices) 400 as the secondary antibody (1:5000 dilution). The western dot blot was then imaged on a

401 SpectraMax i3x Multi-Mode Microplate Reader with a ScanLater Western Blot cartridge402 (Molecular Devices).

403 Mass Spectrometry of Phosphorylated Kinase-Inactive Lysate

404 For analysis of phosphorylated peptides, ~1 mL of lysate (~10 mg of protein) which 405 has been reacted with the kinase previously was guenched with a 1:1 ratio of 8 M urea 406 (Fisher). Followed by digestion with MS grade trypsin protease (Pierce) as instructed by 407 the manufacturer. The reaction was then quenched with 10% trifluoroacetic acid (TFA, 408 Sigma) bringing the final concentration to 0.5% TFA. Samples were desalted under 409 vacuum using Sep Pak tC18 cartridges (Waters). Each cartridge was activated with 1 mL 410 80% acetonitrile (ACN)/0.1% TFA, then equilibrated with 3 x 1 mL of 0.1% TFA. Following 411 sample loading, cartridges were washed with 4×1 mL of 0.1% TFA, and samples were 412 eluted with 4 × 0.5 mL 50% ACN/0.25% formic acid (FA). 20 µg of each sample was kept 413 for protein abundance measurements, and the remainder was used for phosphopeptide 414 enrichment. Samples were dried by vacuum centrifugation. The digested peptides were 415 enriched for phosphopeptides using ion metal affinity column (IMAC). FeCl₃-NTA beads 416 were prepared from Ni-NTA super flow slurry beads (QIAGEN) by first stripping the beads 417 by incubating with 100 mM EDTA in a vacuum manifold three times. The beads were then 418 washed with water before incubating with 15 mM FeCL₃ (Sigma) for one minute three 419 times. Excess FeCl₃ was washed with water before rinsing the beads with 0.5% formic 420 acid (FA). A slurry was prepared by adding water to the beads. 60 µL of slurry was added 421 into a C18 NEST column that had been equilibrated with 150 µL of 80% ACN, 0.1% TFA. 422 100 µL of 50% ACN was added to the lyophilized lysate pellet to dissolve it. 100 µL of 423 100% ACN and 3 µL of 10% TFA was added after lysate was dissolved. 1 mg of peptide 424 is added to Fe-NTA beads in the desalting tip and then incubated for 1-2 minutes followed 425 by mixing and incubation for another 1-2 minutes. After incubating liquid is drained. Then 426 200 µL of 80% ACN and 0.1% TFA was used to wash the beads 3 times. 200 µL of 0.5% 427 FA is used twice to wash the beads. the beads are incubated for 2-3 minutes with 200 µL 428 of 500 mM phosphate buffer pH7 before eluting peptides to C18 column. This is repeated 429 one more time to fully elute the peptides from the beads. The beads are incubated for 15 430 seconds with 200 µL 0.5% FA before the C18 column is used in a centrifuge to elute the

431 phosphorylated peptides with 75 µL of 50% ACN and 0.1% TFA twice before the mass
432 spectrometry run.

433 The LC/MS/MS was performed on all the samples prepared with phosphopeptide 434 enrichment and a background sample with no enrichment. We used a 90-minute 435 separation by nano reversed-phase HPLC gradient over a 75-um ID X 25-cm precolumn 436 packed with Reprosil C18 1.9-µm (Waters). The sample was run on a Q-Exactive Plus 437 mass spectrometer (ThermoFisher) and the top 20 ions were selected for MS2 438 sequencing. Resulting data was then searched with MaxQuant⁷³ to against the human 439 proteome to identify phosphorylated peptides. The mass spectrometry proteomics data 440 have been deposited to the ProteomeXchange Consortium via the PRIDE partner 441 repository⁷⁴ with the dataset identifier PXD020299.

442 **Specificity Calculations**

The results from MaxQuant⁷³ were analyzed with an in-house script written in 443 444 python. For each kinase, a set of substrate sequences was generated from the 445 phosphorylated peptides found in at least one of the three trials. To generate the set of 446 substrates, first the substrate peptides would be extended or shortened to 7 residues on 447 each side of the phosphorylation site. If the sequence was too close to the beginning or 448 end of a protein it would be rejected immediately. Next, if the sequence is already in the 449 set of substrate sequences or was found in the control experiment, where no kinase was 450 added, it would be rejected. Lastly, the localization probability must be greater than or 451 equal to 70% and the MS intensity must be greater than 0. A background dataset was 452 generated by applying the same rules to tyrosine containing peptides, from samples that 453 were not enriched for phosphorylation. The background sequence logo was generated 454 using WebLogo⁷⁵.

Heatmaps were calculated by taking the log frequency of an amino acid occurring at a specific position minus the log of the frequency in the background. Each position and amino acid pair were tested using the logs odd ratio estimate used in pLogos and any significant value was marked with a black square in the heatmap.¹⁰ This allows for intensities of significant residues to be compared between data sets accurately. Residues below a 1.3-fold effect size were masked even if significant to focus only on residues

15

which have the largest effect on specificity. Using the amino acid frequencies for each
 position the sequence entropy was calculated using the SciPy stats module⁷⁶.

463 Activity Assay

Initial rates were measured by a continuous colorimetric assay⁷⁷. The reactions contained 20-100 nM of purified kinase along with 20 mM MgCl₂ (Fisher), 525 μ M β-Nicotinamide adenine dinucleotide (Sigma), 4 mM phosphoenolpyruvate (Sigma), 2.5 μ L of PK/LDH (PK 600 U/mL – 1000 U/mL, LDH 900 U/mL-1400 U/mL; Sigma Aldrich), 0.3 mg/mL Bovine Serum Albumin (Fisher), and substrate peptide (GenScript). Reactions were initiated with 5 mM ATP, by pipetting the solution up and down, and then the absorbance was read at 340 nm for the course of the reaction (20 minutes) at 25 °C.

471 Homology Model of Bound Peptide

An initial homology model was created from a crystal structure of Abl bound to an ATP-peptide conjugate (PDB: 2G2I). Using PyRosetta⁷⁸, the initial structure was mutated to the sequence for either Src or Anc-S1. The bound peptide was then mutated to the sequence of Srctide. The backbone of the protein and peptide was set to be constrained before running the Fast Relax protocol using the ref2015 score function.

Concentration of pY Peptide (mM)

Analysis of the evolution of non-receptor tyrosine kinase specificity with HEK lysate based approach. (A) Phylogenetic tree of non-receptor tyrosine kinase domains constructed with Bali-Phy (Suchard et al. 2006). The reconstructed nodes and modern kinases used herein are marked with stars. For complete tree, sequences, testing of alternate sequences, and statistics see (Wilson et al. 2015). (B) Crystal structure of Abl (PDB ID: 2G2I; Levinson et al. 2006) with peptide substrate (vellow) and ADP (orange) bound. The additive differences in primary sequence between Anc-AST and Anc-AS (purple; 87.3% identity), Anc-S1 (dark blue; 85.8% identity), Src (blue; 65.2% identity), and Abl (red; 67.0% identity) are shown. (C) Flow chart displaying how cell lysate was prepared and used for kinase specificity assays. See methods for a detailed description. (D) Western dot blots using anti-pY1000 antibody to detect phosphorylated tyrosine in proteins. (Top) Cell lysate incubated without Src does not show any phosphorylation, whereas lysate treated with the kinase does. Dilutions of the 60-minute and 240-minute time points illustrate that measurements are in the linear range of the dot-blot. (Bottom) Control of phosphorylated peptide blotted at a range of concentrations, diluted 4-fold. (E) Phosphorylation of the cell lysate over time by Src kinase.

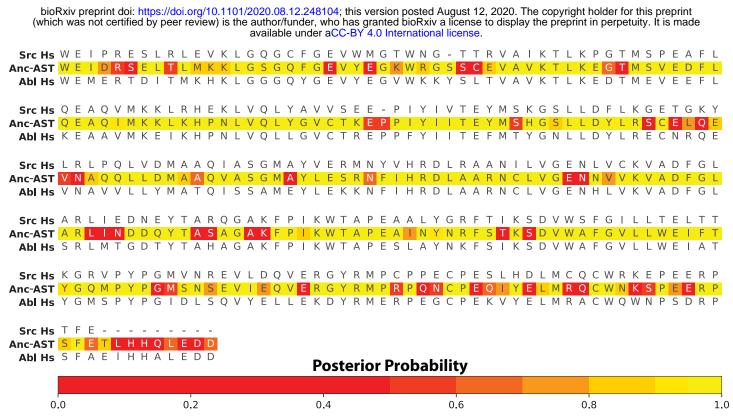

Figure 1 — figure supplement 1: **Posterior probabilities for Anc-AST reconstruction aligned with Src and Abl from** *Homo sapiens.* Wilson *et al.* (2015) performed ancestral sequence reconstruction using PAML (Yang *et al.* 2007) and reported all other ancestral statistics and alignments. Here we report the Anc-AST sequence which has an average posterior probability of 0.86 across all positions. Anc-AST is aligned to the Src and Abl kinase domains and each position displays the given residue's posterior probability from PAML.

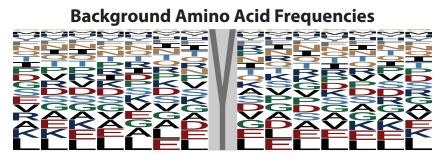

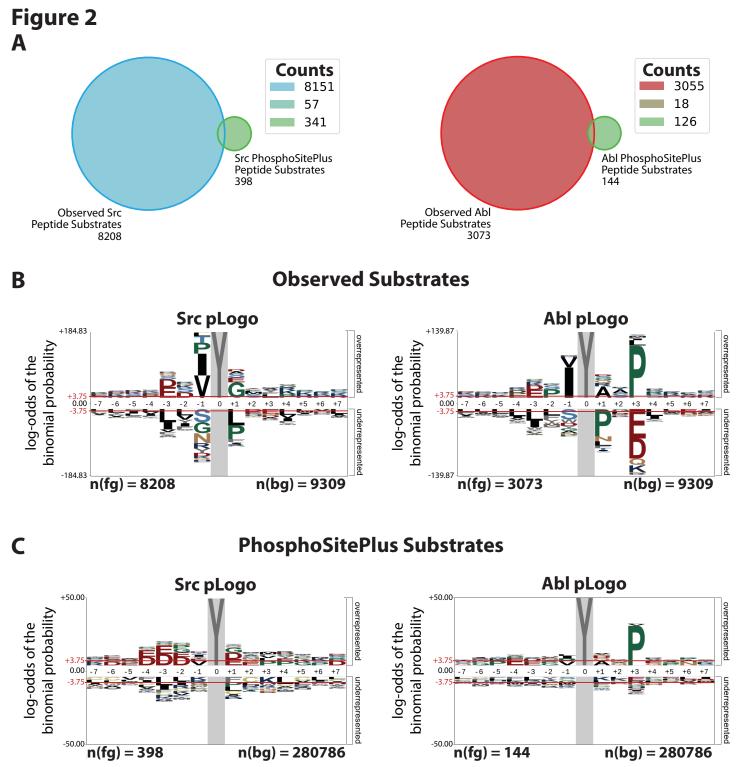

Figure 1 — figure supplement 2: **Frequencies of each amino acid from the unenriched background sample.** Sequence logo generated by WebLogo (Crooks *et al.* 2004) displaying frequency of amino acids in peptides containing a phosphotyrosine from an unenriched sample, that was also not treated with any target kinases.

Figure 1 — figure supplement 3: **BackgroundUnenrichedProteomics.csv** MaxQuant (Cox *et al.* 2008) results from a sample that was not enriched for phosphotyrosine. This data set was used to create the background amino acid frequencies.

Figure 1 — figure supplement 4: **ControlPhosphoproteomicsData.csv** MaxQuant (Cox *et al.* 2008) results from phosphoproteomics experiment where no kinase was added.

HEK cell lysate library approach finds large number target substrates and recapitulates known specificities of Src and Abl with improved statistics. (A) Venn diagrams of sequences that were observed in our Src and Abl kinase specificity experiments compared to the substrates listed in PhosphoSitePlus (Hornbeck *et al.* 2015) for the respective kinase. (B) pLogo's for the prevalence of each amino acid in Src and Abl's individual set of substrates (8208 and 3073 sequences, respectively) relative to the background experiment (9309 sequences). (C) In comparison, pLogo's generated from the list of human substrates on the PhosphoSitePlus database (Hornbeck *et al.* 2015). Statistical significance level is shown as red line in B and C.

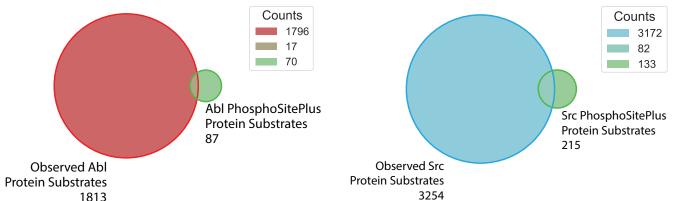

Figure 2 — figure supplement 1: **Natural protein substrates found in phosphoproteomics experiments.** Venn diagrams of proteins that were observed in our kinase specificity experiments compared to the proteins listed in PhosphoSitePlus (Hornbeck *et al.* 2015) for the respective kinase.

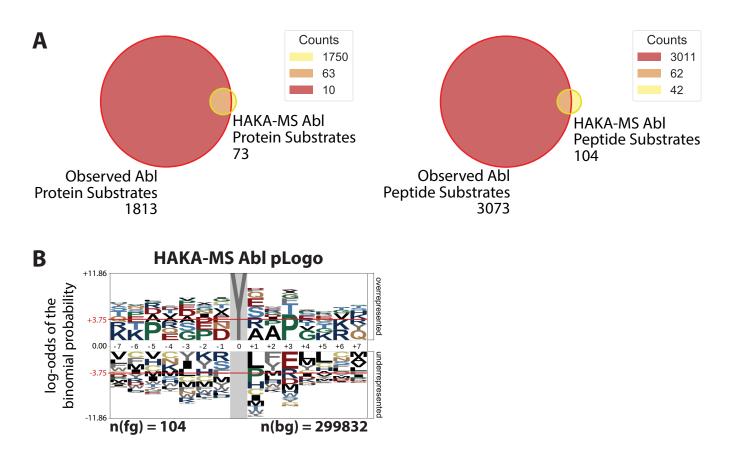

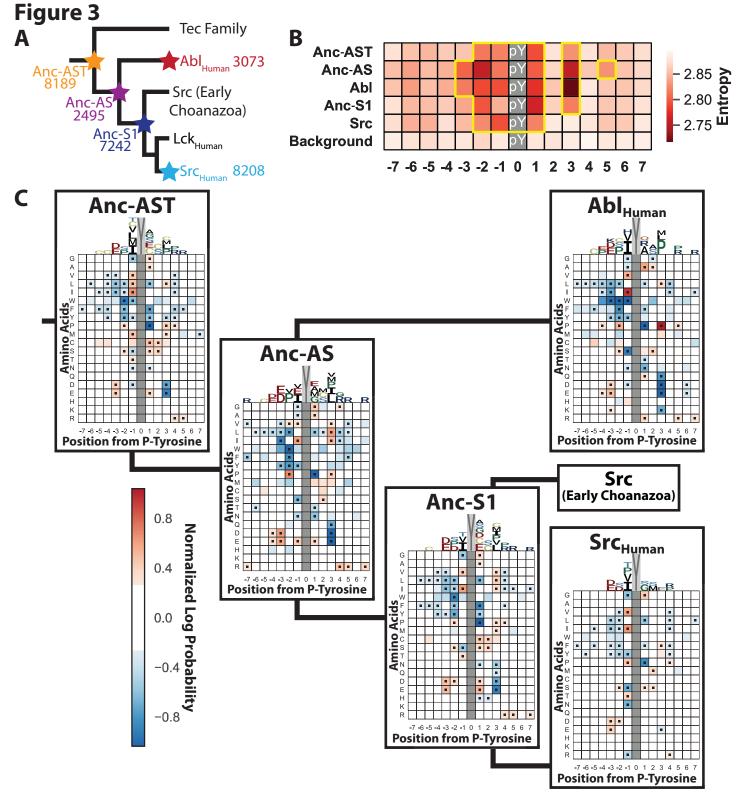

Figure 2— *figure supplement 2:* **Comparison of our results with published data from the HAKA-MS experimental procedure (Muller** *et al.* **2016). (A)** Comparison of how many substrates (proteins and peptide fragments) were found in either our whole cell lysate assay or the HAKA-MS method. **(B)** pLogo showing the preference of Abl based on the peptides from the HAKA-MS method. The background used in their study was all tyrosines in the human proteome. Only $P_{_{+3}}$ was found to be statistically significant.

Anc-AST and Anc-S1 are promiscuous, but are bridged by a relatively specific Anc-AS. (A) Total number of phosphopeptides found for each of the five kinases are plotted onto the gene tree. (B) Positional entropy description for each kinase, where a lower entropy indicates higher specificity. Highlighted in yellow are values below the ~30th percentile for sequence entropy, illustrating the positions with the highest specificity. (C) 20x15 positional/amino acid heatmap displaying the normalized log probability of each amino acid at a given position for modern and ancestral kinases. Significant residues at each position are marked with black squares (p<0.05). The sequence logo above the heatmap displays positions with positive values only, and the height of the character is equal to the normalized log probability.

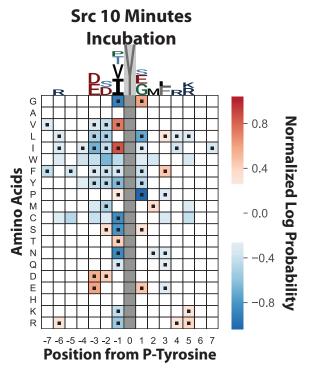

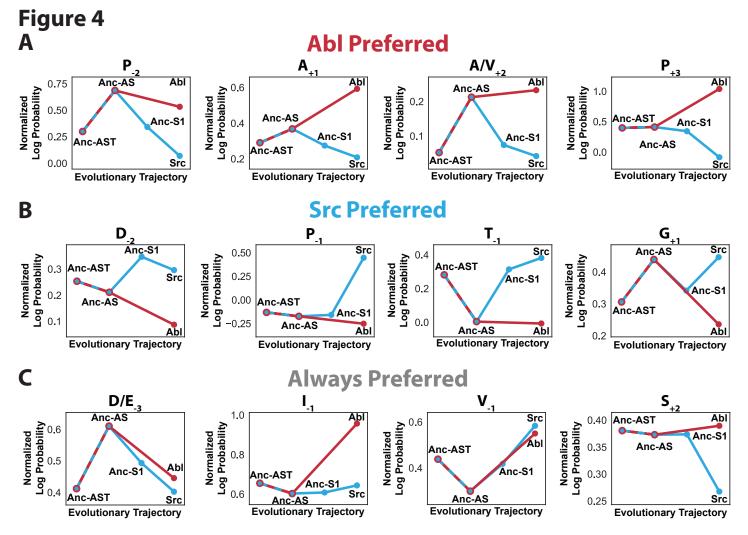

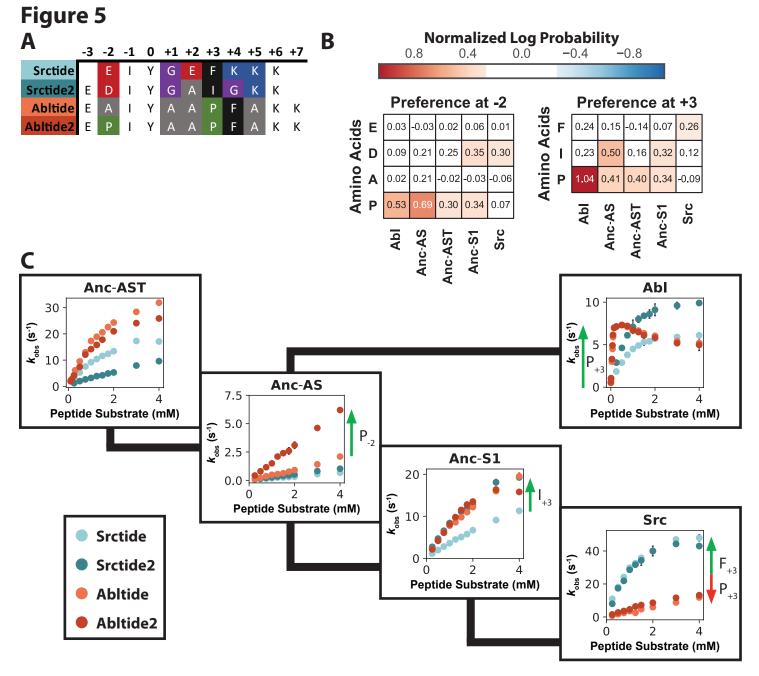

Figure 3 — figure supplement 1: **Substrate specificity is not affected by saturation phosphorylation.** Heatmap displaying enrichment of amino acids at each position in a set of Src substrates after only 10 minutes of incubation. This short time point retains all major features of the heatmap from Src's 4-hour time point in Figure 2C.

Figure 3 — figure supplement 2: **PhosphoproteomicsData.csv** MaxQuant results from phosphoproteomic experiments where kinase was added for the 4-hour incubation.

Figure 3 — figure supplement 3: **PhosphoproteomicsSrcShortTimePoint.csv** MaxQuant results from the phosphoproteomic experiment where Src was added for only 10 minutes.

Evolutionary trajectories of sequence specificity show both subfunctionalization and neofunctionalization. The normalized log probability of an amino acid occurring in a pool of substrates demonstrates the evolutionary progression for (A) Abl specific residues, (B) Src specific residues, and (C) residue determinantscommon to all all kinases in this study.

Specificity of kinases correlate with individual peptide turnover parameters. (A) Sequence alignment of the substrate peptides used with differences between peptides highlighted. Coloring of the peptides are used in the Figure 5C. (B) Normalized log probability of amino acid preferences for -2 and +3 positions for the five ancestral and modern kinases determined from the cell lysate experiments, see also Fig. 3C. (C) Michaelis-Menten curves of phosphorylation for the four peptide substrates and the five different kinases measured with a coupled assay for detecting ADP production (see methods). While it is not possible to saturate and measure accurate K_M values for many of the substrates, it is possible to observe how the rates are affected under k_{cat}/K_M conditions. Each kinase was assayed at 20-200 nM, and error bars represent the standard deviation from three measurements. Green arrows indicate the key primary sequence determinants in the different substrates responsible for the large changes in observed rates.

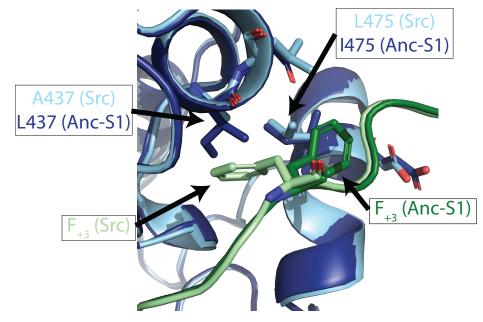

Figure 5 — figure supplement 1: Homology modelling of protein/substrate complexes suggests amino acid differences between modern and ancestral proteins responsible for the differing substrate specificity in the +3 position. A crystal structure of Abl containing a peptide bound to the active site (PDB: 2G2I; Levinson *et al.* 2006) was used to build homology models of Src and Anc-S1 bound to Srctide. The bound peptide in PDB 2G2I already contained F_{+3} , but the rest of the Srctide sequence was modelled in. A Fast Relax protocol was ran in Rosetta with full constraints on the backbone. The zoom-in indicates how the L475I and A437L substitutions in Anc-S1 could prohibit to bind F_{+3} in the same pocket as Src.
