26 discovery, DOCKoalent, COVID-19, SARS-CoV-2

27 **Abstract**

28 Designing covalent inhibitors is a task of increasing importance in drug discovery. Efficiently
29 designing irreversible inhibitors, though, remains challenging. Here, we present *covalentizer*, a
30 computational pipeline for creating irreversible inhibitors based on complex structures of targets
31 with known reversible binders. For each ligand, we create a custom-made focused library of
32 covalent analogs. We use covalent docking, to dock these tailored covalent libraries and to find
33 those that can bind covalently to a nearby cysteine while keeping some of the main interactions of
34 the original molecule. We found ~11,000 cysteines in close proximity to a ligand across 8,386
35 protein-ligand complexes in the PDB. Of these, the protocol identified 1,553 structures with
36 covalent predictions. In prospective evaluation against a panel of kinases, five out of nine predicted
37 covalent inhibitors showed IC₅₀ between 155 nM - 4.2 μM. Application of the protocol to an
38 existing SARS-CoV-1 M^{pro} reversible inhibitor led to a new acrylamide inhibitor series with low
39 micromolar IC₅₀ against SARS-CoV-2 M^{pro}. The docking prediction was validated by 11 co-crystal
40 structures. This is a promising lead series for COVID-19 antivirals. Together these examples hint
41 at the vast number of covalent inhibitors accessible through our protocol.

42

43 Introduction

44

45 Covalent irreversible inhibitors have become increasingly popular over the last decade as
46 chemical probes and drugs. Most often these inhibitors target a cysteine residue to form the
47 covalent bond. Several rationally-designed irreversible inhibitors targeting cysteines were
48 approved by the FDA in recent years, with notable examples such as Ibrutinib¹, Afatinib² and
49 Osimertinib³. Irreversible binding offers a variety of advantages, including prolonged residence
50 time⁴ and an ability to compete with high-affinity natural substrates⁵⁻⁷. Another important
51 advantage of covalent inhibitors is their improved selectivity when targeting non-conserved
52 cysteine residues^{8,9}. Moreover, covalent binding can enable targeting of especially challenging
53 targets such as the G12C oncogenic K-Ras mutation¹⁰⁻¹².

54 Historically, most covalent inhibitors were designed by the addition of an electrophile to
55 an already known reversible inhibitor that suitably binds next to a cysteine residue¹³⁻¹⁸. More
56 recently, covalent inhibitors are also being discovered by empirical screening of covalent fragment
57 libraries¹⁹⁻²⁵ and by covalent virtual screening^{10,26-32}. While covalent fragment and virtual
58 screening can potentially discover new scaffolds, the binding affinity of primary hits may be
59 relatively low, and often require laborious medicinal chemistry to reach suitable potency.

60 Covalent derivatization of an already known reversible binder, can endow the compound
61 with added benefits of irreversible binding such as time dependent inhibition, longer duration of
62 action, improved selectivity towards proteins that contain the target cysteine compared to
63 homologs without a cysteine at that position, and possibly improved potency. Still, this approach
64 is far from trivial. Three crucial questions have to be answered: 1. Which electrophilic moiety to
65 use? 2. What is the optimal vector on the scaffold to attach through? 3. What linker, if any, would
66 optimize the placement of the electrophile with respect to the binding mode of the scaffold and the
67 position of the target cysteine residue? There are numerous possible answers for these questions.
68 Furthermore, the “*covalentized*” (derivative containing the electrophile) version of the reversible
69 inhibitor should be synthetically accessible. Therefore, tools that would enable to address this
70 design problem algorithmically, would significantly simplify covalent inhibitor design and has the
71 potential to discover many potent covalent binders for a large variety of targets.

72 Computational approaches to address this challenge are scarce. DUckCov²⁹ a covalent
73 virtual screening method, begins with non-covalent docking of a library of covalent compounds,
74 while using pharmacophoric constraints for hydrogen bonds, as well as for the covalent warhead.
75 This is followed by covalent docking of the ligands with the strongest non-covalent affinities.
76 CovaDOTS³³ uses a set of synthetic schemes and available building blocks, to create covalent
77 analogs of existing non-covalent ligands, but was only assessed retrospectively. Cov_FB3D³⁴
78 constructs *de novo* covalent ligands and was retrospectively assessed on recapitulation on known
79 covalent inhibitors.

80 Here we present a computational pipeline to identify potential existing reversible binders
81 for *covalentization* (creation of a covalent analog). Given a complex structure or model of a ligand
82 in the vicinity of a cysteine residue, we elaborate the ligand or its substructures with various

83 electrophiles. This *ad hoc* library of covalent analogs is covalently docked to the target protein and
84 the original (non-covalent) structure is used as a filter to identify high-confidence covalent
85 candidates. We applied this protocol - *covalentizer* - to the entire PDB to identify thousands of
86 potential candidates amenable for irreversible inhibition, and made both the protocol and the
87 database of pre-computed candidates publicly available to the community
88 (<https://covalentizer.weizmann.ac.il>). We have prospectively synthesized and tested several
89 predictions of various covalent kinase inhibitors proposed by the protocol and succeeded in five
90 out of nine designs with IC₅₀'s of 155 nM - 4.2 μM.

91 In early February 2020, the COVID-19 pandemic started to spread globally^{35,36}. We turned
92 to the pre-compiled database of *covalentizer* results, to look for possible candidate inhibitors for
93 SARS-CoV-2 proteins. The search found a reversible small molecule inhibitor designed against
94 the main protease of the SARS-CoV-1 virus (PDB: 3V3M³⁷), which has 96% sequence identity to
95 the main protease of SARS-CoV-2, with a promising covalent prediction. We synthesized the
96 prediction and validated irreversible binding to the SARS-CoV-2 main protease (M^{Pro}). We further
97 optimised the non-covalent affinity of the compound, resulting in improved analogs. Co-crystal
98 structures confirmed the computational model. This example highlights the strength of our method
99 - the design was already available, and enabled very rapid development. The database suggests
100 that hundreds more such examples await testing.

101

102 Results

103

104 *The covalentizer pipeline*

105

106 For a given complex structure with a reversible ligand in the vicinity of a target cysteine
107 residue, the pipeline (Fig. 1) comprises four consecutive steps: fragmentation, electrophile
108 diversification, covalent docking and RMSD filtering.

109

110

111 **Figure 1. An overview of the covalentizer computational protocol.**

112 The protocol comprises four consecutive steps. **A. Fragmentation:** the molecule is broken and divided into fragments
113 (red arrows) using synthetically accessible bonds³⁸. Murcko scaffolds³⁹ of the fragments (blue arrows) are also added
114 to the list of fragments. **B. Electrophilic diversification:** for each substructure, a library of potential electrophilic
115 analogs is generated, a few hundred compounds in size. We used four kinds of nitrogen-based electrophiles ranging
116 in reactivity: vinyl sulfones, chloroacetamides, acrylamides and propynamides. We also considered various linkers
117 between the fragment and the electrophile. **C. Docking:** The target structure is then docked against its appropriate
118 analog library using all available cysteine rotamers. Finally, RMSD calculation: For each docked compound, an
119 RMSD is calculated between the MCS (maximal common substructure) of the reversible compound and the new
120 covalent analog. We show examples of predictions with increasing RMSDs, for binders of 1. Nitrate reductase from
121 *Ulva prolifera* (PDB: 5YLY) 2. Human mineralocorticoid receptor (PDB: 5HCV) and 3. Human progesterone receptor
122 (PDB: 1A28).

123

124 **A. Fragmentation:** In this step, the ligand is broken-down and divided into two parts via
125 synthetically accessible bonds³⁸. Doing this recursively, results in a list of substructures (Fig. 1A).
126 For each substructure, we augment the list with its corresponding Murcko scaffold³⁹ (the naked
127 ring system, without any decoration) to allow more exit vectors from which the electrophile can
128 be added next. The motivation for this fragmentation step is three-fold. First, as mentioned,
129 fragmenting the molecule exposes new vectors on which to install the electrophile (see Fig. 1C
130 example 2). Second, the additional constraint of forming the covalent bond might cause a slight
131 shift to the molecule's binding mode from the original crystal structure. Such a shift may propagate
132 and cause a steric clash between the protein and a ligand moiety distal to the electrophile. Since
133 adding the covalent bond is expected to increase the overall potency, we 'sacrifice' parts of the

134 molecule to enable the addition of an electrophile. The final ranking of candidate covalent analogs
135 relies on covalent docking which is sensitive to sub-Å shifts. Hence, occasionally, a truncated
136 version of the ligand will dock well, while the full ligand will not. Thus, including the sub-
137 structures and their scaffolds maximizes the number of candidates. Since covalent docking
138 accuracy was shown to deteriorate with ligand size and number of rotatable bonds²⁶, we filter the
139 final list of substructures, to those with 8-25 heavy atoms and up to five rotatable bonds.

140
141 **B. Electrophile diversification:** For each substructure or scaffold, we generate a library of potential
142 electrophilic analogs, typically resulting in a few hundred analogs (Fig. 1B). We consider four
143 kinds of electrophiles ranging in reactivity: vinyl sulfonamides, chloroacetamides, acrylamides
144 and propynamides, that can all be installed in one step onto a free amine. We add these
145 electrophiles to the substructures using simple connection rules which, however, do not guarantee
146 synthetic accessibility (see methods section for more details). We also consider various linkers
147 between the fragment and the electrophile. In our application below, we considered either a
148 methylene linker or various di-amine linkers (Supp. Fig. 1).

149
150 **C. Covalent docking:** The structure of the complex is prepared for docking, using all available
151 cysteine rotamers. We use DOCKoValent²⁶ to dock the electrophile library we described above
152 against the protein (after removing the crystallographic ligand).

153
154 **D. RMSD filtering:** Compounds that are able to form a covalent bond with the target cysteine while
155 still maintaining the same binding mode of the original reversible ligand are likely candidates for
156 covalent analogs. To assess this, we evaluate the RMSD (root mean square deviation) between
157 each docking prediction and the crystallographic ligand. Due to the fact that RMSD is calculated
158 between two sets of matching atoms, and the reversible ligand is different from the irreversible
159 one, it was calculated based on the maximal common substructure (MCS) between the two
160 molecules. Figure 1C exemplifies predictions with varying RMSDs. For a PDB wide application
161 of the pipeline, we focused on covalent analogs with a docking position of < 1.5 Å RMSD from
162 the crystallographic ligand.

163
164 *Covalent kinase inhibitors benchmark*

165
166 To benchmark the pipeline, we wanted to test whether it is able to find known covalent inhibitors,
167 given only their reversible part as input. To achieve this, we used the kinase subset of a recently
168 published covalent docking benchmark³⁰. This set included 35 kinase covalent inhibitor complex
169 structures with either acrylamides, chloroacetamides or vinyl sulfonamides (after excluding seven
170 inhibitors with uncommon electrophiles). To form the input for *covalentizer*, we removed the
171 electrophiles while leaving only a free amine. For substituted acrylamides we removed β-
172 substitutions as well.

173 Out of the 35 structures, the pipeline identified the crystallographic covalent inhibitor in
174 14 (40%) of the cases, with a threshold of 1.5 Å MCS-RMSD (Fig. 2; Supp. Table 1).
175

176
177 **Figure 2. *Covalentizer* successfully recapitulates known covalent kinase inhibitors.**
178 Examples of covalent kinase inhibitors (green) for which *covalentizer* was able to find a substructure match (magenta)
179 under the 1.5 Å threshold. **A.** ERK2, PDB: 4ZZO. **B.** EphB3, PDB: 5L6P. **C.** EGFR (T790M), PDB: 4I24. **D.** JAK3,
180 PDB: 5TOZ. The electrophiles span acrylamides (A,D), a substituted acrylamide (C) and chloroacetamide (B).
181

182 *Covalentizing the PDB*

183
184 Encouraged by the results in recapitulating known covalent kinase inhibitors we aimed to
185 apply our protocol to the entire PDB. We started from the set of all the protein-small molecule X-
186 ray structures (< 3.0 Å resolution) that contained a small molecule with a molecular weight greater
187 than 300 Da, and no DNA/RNA chains. As of the date of the search (July 4th, 2019) this resulted
188 in 44,990 structures. We filtered these to structures in which a ligand has one of its atoms within
189 6 Å of the sulphur atom of a free cysteine residue. Disulfides or covalently modified cysteines
190 were excluded. After applying this filter, we ended up with 8,386 such structures, and ~11,000
191 cysteines.

192 These structures, which constitute the target space for our protocol, contain significant
193 redundancy. Clustering them with a threshold of 90% sequence identity, results in 2,227
194 representatives. 38% of the structures are of human proteins and the rest span many other
195 organisms including rodents, bacteria and yeast. They also span seven different enzyme classes,
196 with the most prevalent being transferases (41.4%). 928 structures (11.1% of the entire dataset)

197 are kinases. These ~8,400 proteins contain 3,673 different ligands, each binding next to a cysteine.
198 The ligand that is most abundant in this database is Flavin-Adenine Dinucleotide occurring in 504
199 structures, whereas 3,058 ligands (83% of the compounds) occur only in a single structure. The
200 most common ligands were nucleotide or nucleotide-like molecules.

201 After running the aforementioned algorithm against the ~8,400 structures that passed our
202 filtering (Fig 3A), 1,553 structures produced at least one candidate below the 1.5 Å RMSD cutoff.
203 These structures represent roughly 380 proteins (representative set at 95% sequence identity).
204 1,051 structures are of human proteins, 338 are structures of kinases. 80 of the structures had
205 produced a covalent analog prediction that was docked < 0.5 Å from the original ligand,
206 representing very high-confidence candidates (Fig. 3B). The distribution of selected electrophiles
207 is almost uniform (Fig. 3C). All of the predictions are made available through a public website
208 (<https://covalentizer.weizmann.ac.il>) which is automatically updated weekly with new PDB
209 entries.

210

211
212 **Figure 3. PDB wide application of *covalentizer* identifies candidate irreversible inhibitors for more than 1,500**
213 **structures.** **A.** We filtered the protein data bank (PDB) for structures that had only protein chains (no DNA/RNA),
214 and contained a small molecule of at least 300 Da. This threshold was set to ensure some minimal initial fit/binding
215 affinity to the target, as well as to filter out non-ligand small molecules like crystallization reagents. We used a pymol
216 based script to filter only the structures in which at least one ligand atom is < 6 Å away from the sulfur atom of a
217 cysteine residue. This cysteine also has to be free (no disulfide or other covalent modifications). After running the
218 *covalentizer* protocol and filtering only for results with < 1.5 Å RMSD of the maximal common substructure (MCS)
219 between the reversible ligand and the covalent analog generated by *covalentizer*, there were 1,553 structures for which
220 at least one such prediction was obtained. **B.** The top 1% of results have an RMSD under 0.5 Å. 23% are between 0.5
221 Å and 1 Å, and 76% are between 1 Å and 1.5 Å. **C.** The distribution of the four electrophiles used is balanced, with
222 29% chloroacetamides, 27% acrylamides, 24% vinylsulfones, and 20% propynamides.

223

224 *Exploring additional linkers*

225

226 As mentioned above, the entire database was processed using direct attachments of the
227 electrophiles to atoms of the sub-structures, as well as with a methylene linker. The use of longer
228 and more diverse linkers for the addition of an electrophile would allow the targeting of cysteines
229 further from the ligand thus increasing the available target space, as well as diversifying the
230 introduced chemistry. To investigate this further, we searched the covalent inhibitor discovery
231 literature⁴⁰⁻⁴³ for the most common di-amine linkers used in the last decade which led to the

232 selection of 7 aromatic linkers and 17 aliphatic linkers (Supp. Fig. 1). Since including all of these
233 linkers increases the computational demands of the pipeline, we restricted its application to the
234 subset of liganded kinase structures in the PDB. Since these linkers can enable ligands to reach
235 further cysteines at extended distances, the search criteria was extended to a distance of up to 10
236 Å from the ligand (instead of 6 Å, previously).

237 The final subset includes 1,880 PDB structures that contain a Cys residue of up to 10 Å
238 away from one of 1,398 various ligands. The size of the custom-made libraries of electrophilic
239 analogs for a particular reversible ligand, containing these linkers, now extends to a few thousand
240 compounds. Overall, we generated *in silico* over 3 million electrophilic compounds with di-amine
241 linkers for the kinase subset. The results show candidates of < 1.5 Å MCS-RMSD between the
242 original reversible ligand and the electrophilic candidate for 411 protein structures. 186 of these
243 structures (45%) were not found in the previous run, showing the potential of using these more
244 sophisticated linkers to reach farther cysteines and to *covalentize* more ligands.

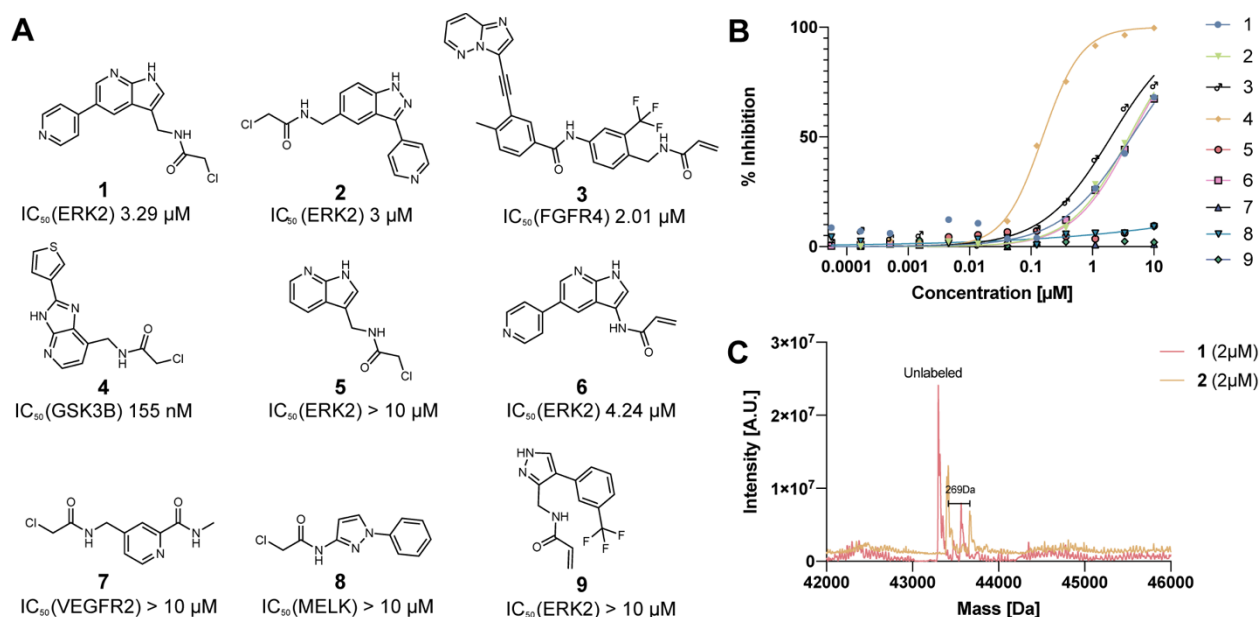

245

246 *Novel covalent inhibitors for various kinases*

247

248 Kinase inhibitors comprise 22% of the *covalentizer* results. We selected a subset of these
249 for prospective validation. We chose the candidates based on three features: 1. Low RMSD relative
250 to the parent reversible ligand. 2. The addition of the electrophile is not predicted to interfere with
251 the kinase hinge binding region. 3. Ease of synthesis. This required manual inspection of pre-
252 selected low RMSD results. Overall, we made and tested nine compounds (Fig. 4) targeting five
253 different kinases. In some cases, addition of the electrophile required removal of large parts of the
254 parent reversible ligand (Supp. Fig. 2). The compounds were each tested in a kinase activity assay
255 against the target kinase in the structure from which the *covalentizer* result was derived. The assay
256 was performed at ATP concentration equal to the K_m of the kinase in question, with a 2 h pre-
257 incubation of the inhibitor at 25 °C.

258

259
 260 **Figure 4. Prospective prediction identifies novel irreversible kinase inhibitors.** **A.** Chemical structures and in vitro
 261 kinase activity assay IC_{50} s for nine prospective *covalentizer* predictions. See Supp. Fig. 2 for the parent compounds,
 262 pose predictions and RMSD values. **B.** Dose response curves for each of the nine compounds (see additional
 263 repetitions for **1** and **2** in Supp. Fig. 3). Each compound was tested against its corresponding target kinase. **C.**
 264 Deconvoluted mass spectra obtained by intact protein LC/MS of recombinant ERK2 (2 μM) incubated with equimolar
 265 **1** or **2** for 1 h at room temperature, identifies significant irreversible binding by both compounds.
 266

267 Four of the nine compounds did not show inhibition under the assay conditions (IC_{50} > 10
 268 μM). Three compounds targeting ERK2 showed IC_{50} values of 3 - 4.24 μM . For two of these
 269 inhibitors, **1** and **2**, we assessed irreversible binding to ERK2 by intact protein mass spectrometry
 270 (2 μM ERK2, 2 μM compound, 1 h incubation at 25 $^{\circ}\text{C}$). The expected protein-compound adducts
 271 were detected (25% and 33% labeling respectively; peak-to-peak Δm 265-270 Da for both
 272 compounds; Fig. 4B) with no additional adducts derived from multiple reactions, highlighting the
 273 moderate reactivity of the designed α -chloroacetamides. The remaining *covalentizer* hits included
 274 a 2.01 μM inhibitor (**3**) of FGFR4 derived from the non-selective kinase inhibitor ponatinib, and a
 275 155 nM inhibitor (**4**) of GSK3 β .
 276

277 *A covalent SARS-CoV-2 main protease inhibitor*

278
 279 Upon the release of the first structure of the new SARS-CoV-2 M^{pro} protease (PDB:
 280 6LU7⁴⁴) we noticed that the active site is nearly identical to that of SARS-CoV-1. The entire
 281 protein is highly conserved with 96% sequence identity. This prompted us to search the database
 282 for covalent versions of SARS-CoV-1 M^{pro} ligands. One such prediction was available based on a
 283 reversible inhibitor ML188 (IC_{50} = 4.8 \pm 0.8 μM , racemate; 1.5 \pm 0.3 μM , (*R*)-enantiomer) of the
 284 SARS-CoV-1 main protease (PDB: 3V3M³⁷; Fig. 5A). We re-synthesized and tested racemic
 285 ML188 against SARS-CoV-2 M^{pro} which showed an IC_{50} of 3.14 μM (Supp. Fig. 4A), similar to
 286 what has been reported for SARS-CoV-1. ML188 was synthesized using the Ugi four-component

287 reaction (4-CR), and the covalent prediction was easily accessible by replacing one reactant (2-
288 furoic acid to acrylic acid) to give **10**, synthesized and isolated as the racemate (Fig. 5D). We
289 initially assessed irreversible binding of **10** towards recombinant SARS-CoV-2 M^{pro} using intact
290 protein mass spectrometry (2 μ M protein, 1.5 h incubation with electrophile at 25 °C; Fig. 5F).
291 The expected adduct was detected with 19% labeling at 2 μ M compound, and up to 88% labeling
292 at 200 μ M compound (Fig. 5F).

293 Despite the irreversible binding, this initial compound did not show strong inhibition in a
294 fluorescence-based enzymatic assay ($IC_{50} > 99 \mu$ M, 13% inhibition at 20 μ M; 15 min pre-
295 incubation; Fig. 5H). However, it was a promising starting point for additional optimization. Due
296 to the modular nature of the Ugi 4-CR procedure, it was possible to synthesize and test large
297 libraries of analogs by systematically varying each reactant to target different pockets. We
298 designed those libraries based on computational modelling of *in silico* generated Ugi products, as
299 well as an exhaustive screen of commercially available isocyanides (see Supp. Dataset 1). A few
300 of the early combinatorial synthetic results, which had low biochemical potency (comparable to
301 our starting Ugi compound), allowed for crystallographic analysis in the presence of M^{pro}. In these
302 cases, the expected binding mode was recapitulated experimentally and showed low deviation
303 from the non-covalent starting point (Fig. 5B, 5C, Supp. Fig. 5), thus proving the *covalentizer*
304 prediction to be correct. In all crystal structures, the electrophile formed the expected covalent
305 bond with the catalytic cysteine residue.

306 To optimize **10**, we have made and tested close to 140 analogs (Supp. Dataset 1; Fig. 5.
307 Supp. Fig. 7,8), exploring all three components of the Ugi reaction while keeping the acrylamide
308 fixed. We explored a variety of replacements for the initial *p-tert*-butylphenyl motif protruding
309 into the S2 pocket (Fig. 5), most of them did not result in improved potency (Supp. Fig. 7C).
310 Similarly, independent optimization of binding to the S1 pocket only led to the identification of
311 one beneficial change (**23**, $IC_{50} 65.58 \mu$ M), with a *meta* chloro-substitution of the pyridine (Supp.
312 Fig. 7A). Other substituents (-Br, -OMe, -OEt, -CF₂CH₃) led to inactive compounds.

313 Beyond further optimization of the S1 and S2 pocket binding it was clear that extension of
314 the ligand towards the S3 and S4 pockets should prove fruitful. For example, a reversible-covalent
315 α -ketoamide inhibitor⁴⁶ (biochemical $IC_{50} 0.67 \mu$ M \pm 0.18 μ M) probes the S3/4 region with an
316 additional hydrogen bond to the backbone of Glu166. In a large scale fragment screen, numerous
317 fragments were able to bind in these pockets⁴⁷. In this case, we exhaustively synthesized analogs
318 of **10**, using 34 available isocyanides. Starting from **10**, simple alkyl chain extension resulted in
319 compounds with improved potency (Fig. 5D). In particular compound **11**, harboring a
320 phenethylamide motif, was particularly potent with an IC_{50} of 2.95 μ M (Fig. 5G) and K_{inact}/K_i of
321 18.4 M⁻¹s⁻¹ (Supp. Fig. 6).

322

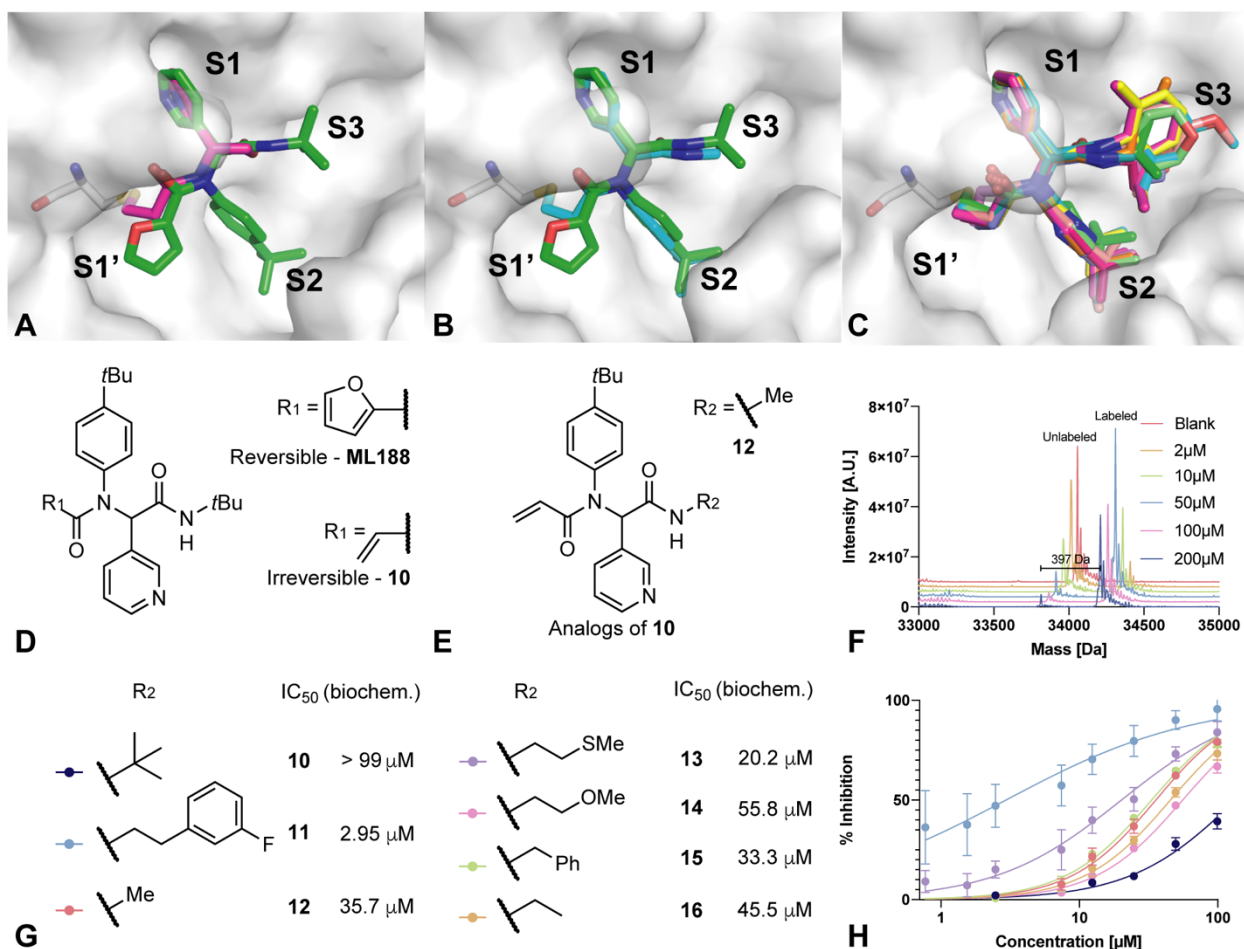

Figure 5. Computational prediction and experimental validation of an irreversible SARS-CoV-2 M^{pro} inhibitor.

A. The *covalentizer* prediction of **10** (magenta) overlaid on the non-covalent compound it is based on (ML188⁴⁵; green; PDB:3V3M). The protocol suggested to substitute the furanyl moiety of ML188 with an acrylamide to bind the catalytic cysteine. The RMSD between the covalent fragment and the original reversible inhibitor is 0.65 Å. **B.** The crystal structure of one of the covalent analogs of **10** (PDB: 5RH5; cyan) overlaid on ML188 (green). **C.** Overlay of all the 11 crystal structures of compound **10** analogs, all exhibiting the same predicted binding mode. PDBs: 5RGT, 5RH5, 5RH6, 5RH7, 5RH9, 5RL0, 5RL1, 5RL2, 5RL3, 5RL4, 5RL5. For individual structures see Supp. Fig. 5. **D.** The chemical structures of ML188 and **10**. **E.** Chemical structure of Ugi compounds exploring the S3 pocket, with the R group that is shown in the crystal structure in (B). **F.** Deconvoluted mass spectra obtained by intact protein LC/MS of recombinant SARS-CoV-2 M^{pro} 2 μM incubated with 2 μM - 200 μM **10** for 1.5 h at room temperature. **G.** Further analogs of **10** with their associated biochemical potencies. **H.** The dose response curves for the seven compounds shown in G.

It appears that relief of steric strain around the amide nitrogen also plays a part, since change to a methyl amide (in **12**, relative to **10**) also resulted in increased potency. Opposed to our initial assumption of independent optimization of S1-3 pocket binding, the combination of beneficial structural motifs in a third generation of Ugi products led to inhibitors with diminished potency compared to **11** (see Supp. Fig. 7B; Supp. Dataset 1). One explanation for this behaviour is the high plasticity of M^{pro}, leading to induced fit effects.

343 Removal of the furanyl in ML188 and replacement with an electrophile in **10** initially led
344 to a loss in potency, which in this case was overcome by optimization of the non-covalent affinity
345 in the S3 region to give compound **11**. Re-installing the furanyl ring in combination with the S3-
346 optimized phenethylamide motif led to compound **17** with a similar IC₅₀ (2.72. μM; Supp. Fig.
347 4B), suggesting that the marked improvement of this side-chain is particular to the covalently
348 bound conformation.

349 In conclusion, we successfully executed a mode of action change towards irreversible
350 targeting of the catalytic cysteine residue in M^{pro} which may have improved activity in cells as
351 well as long-term strategic benefits to safeguard against viral evolution.

352

353 Discussion

354

355 Designing new covalent inhibitors is challenging. Here we leveraged the subset of protein
356 targets for which a structure of a known binder is available, to computationally enumerate and
357 evaluate exhaustive sets of covalent derivatives. Automating the protocol allowed us to apply it to
358 the entire PDB and assess the applicability of this approach. Prospective testing against six real-
359 world targets demonstrated that irreversible ligands can be reached with little synthesis, and
360 structures validated the binding-pose prediction.

361

362 A main advantage of our work is the wide exploration of X-ray structures which produced
363 an extensive list of candidates waiting to be explored. This allowed us to quickly find a promising
364 lead series against SARS-CoV-2 M^{pro}. This prediction, which was based on a historic non-covalent
365 SARS-CoV-1 M^{pro} inhibitor⁴⁵ was pre-calculated, and ready for synthesis at a moment's notice.
366 We have made thousands of such predictions available through a public website
367 (<https://covalentizer.weizmann.ac.il>) which updates weekly with the release of new structures to
368 the PDB. It also allows *covalentizing* of user uploaded structures. We believe this would enable
369 wide application and experimental testing of new covalent inhibitors.

370

371 Despite the success of our protocol, several caveats remain. First is the fact that currently
372 the protocol does not take into account the synthetic feasibility of the proposed designs. When
373 selecting candidates for prospective evaluation, we found that some of the molecules required
374 complicated synthesis. Incorporating into our pipeline a strategy such as DOTS^{33,48}, other
375 retrosynthesis algorithms⁴⁹⁻⁵¹ or even the use of synthetic feasibility scores⁵²⁻⁵⁴, can significantly
376 improve the quality of proposed candidates in the future.

377

378 Another point for improvement is the relatively weak potency of our prospective designs
379 in comparison to their parent compounds. One likely explanation for these lower affinities is the
380 removal of non-covalent affinity elements which are not sufficiently compensated by the gains
381 from covalent bond formation. For example, in compound **2** (derived from PDB: 4QTA) more
382 than 350 Da of the original compound⁵⁵ is removed (Supp. Fig. 2), resulting in three orders of
383 magnitude loss in potency. However the remaining covalent fragment still shows significant
384 inhibition of ERK2. Another example is compound **1**, its parent compound (PDB: 4QP9) has an
385 IC₅₀ of 71 nM, however the propyl-pyrazole group we have omitted in order to accommodate the
386 electrophile (Supp. Fig. 2) improved the parent reversible binder by more than 150-fold. Lastly
387 the loss of a hydrogen bond between the M^{pro} backbone NH of Gly143 and the furanyl oxygen of
388 ML188 (PDB: 3V3M), decreased potency, under our assay conditions of 15 min. pre-incubation,
389 by more than 30-fold. These results suggest that a careful examination of the binding energy
390 contribution is required for the parts that are omitted in order to accommodate the new electrophile.

391

392 However, as we saw for both ERK2 (**1** vs. **5**) and M^{pro} (**10** vs. **11**), improving reversible
393 recognition is able to improve potency, and even to surpass the parent compound in the case of **11**.
394 For this series we believe that further structure-based optimization of binding to the S3 pocket,
395 including H-bonding to Glu166 and chiral separation of the active enantiomer can pave the way
396 for sub-micromolar Ugi-type covalent M^{pro} inhibitors. Thus, in many cases where irreversible
397 binding is needed our protocol can provide a promising starting point for optimization.

398
399 Another possible explanation for the relatively low affinity of the irreversible binders are
400 slight inaccuracies in the covalent warhead positioning which results in sub-optimal covalent bond
401 formation. Perhaps due to the fact that the docking program does not take into account the actual
402 formation of the covalent bond, and ignores for instance the transition state energy of the rate-
403 determining step of the organosulfide bond formation, but rather evaluates the binding energy of
404 the adduct. Better understanding of the steric and electronic constraints of the covalent bond
405 formation, and hence a better docking software should improve the results.

406
407 The docking software also ignores the intrinsic reactivity of the proposed designs. It is
408 interesting to note in this regard the similar activity of a methylene-chloroacetamide (**1**), compared
409 to its acrylamide analog (**6**). Such electrophile replacements can be very useful in rational design
410 of irreversible inhibitors, especially if they prove to work across various scaffolds. Geometrically,
411 the additional methylene before the chloroacetamide makes the distance from the ring to the thiol
412 similar to that of the acrylamide (Supp. Fig. 2). In terms of reactivity, however, the acrylamide,
413 conjugated to the azaindole is activated⁵⁶ and thus is likely closer in reactivity to the
414 chloroacetamide. Indeed, a methylene linker would be the minimal linker element required to
415 insulate against π -conjugation, allowing easier prediction of intrinsic reactivity. No-linker designs
416 connected to extended π -systems such as heteroarenes often exhibit a range of intrinsic
417 reactivities^{20,56} which remain challenging to predict computationally⁵⁷⁻⁵⁹ and thus require careful
418 evaluation.

419
420 Many additional designs remain to be discovered beyond the more than 1,500 we made
421 available through the *covalentizer* server. New electrophiles and linkers which will enable new
422 geometric trajectories between the cysteine and the molecule, can considerably expand the design
423 space. We tested this idea computationally using a library of linkers curated from the literature
424 (Supp. Fig 1), on a subset of kinases from our database, showing an increase in the number of
425 structures that can be *covalentized*. New covalent ‘warheads’, including reversible covalent
426 warheads, such as cyanoacrylamides⁶⁰, and chloroacetamides⁶¹ become available, both for
427 cysteine residues⁶², but also for other amino acids⁶³⁻⁶⁵. These can be incorporated with little effort
428 into the *covalentizer* pipeline. Since cysteine is one of the least abundant natural amino acids,
429 additional covalent chemistries will significantly expand the number of ligands that can be
430 potentially addressed.

431

432 In summary, we show that using covalent docking we were able to make irreversible
433 analogs of ligands for which a complex structure is available. We made our discoveries public in
434 the form of a database of the results we obtained by running our protocol on the entire PDB which
435 is automatically updated weekly with newly released entries, as well as a web-tool for applying
436 the protocol on new targets given by users. Using the protocol, we discovered new covalent kinase
437 inhibitors and optimised a potent covalent COVID-19 protease inhibitor, with a low-cost, modular
438 and fast synthesis. We hope our results will encourage researchers to apply covalent inhibitors for
439 a wide range of targets.
440

441 **Methods**

442

443 *Programs and libraries*

444 RDKit was used for 2D molecular handling, conformation generation and RMSD
445 calculation. RDKit: Open-source cheminformatics; [RDKit.org](https://rdkit.org). Marvin was used in the process of
446 preparing the molecules for docking, Marvin 17.21.0, ChemAxon (<https://www.chemaxon.com>).
447 DOCKoValent²⁶ was used for virtual covalent docking.

448

449 *Curating target structures from the PDB*

450 Using pymol scripts (The PyMOL Molecular Graphics System, Version 2.0.4 Schrödinger,
451 LLC), we filtered only the structures that have a ligand in which one of its atoms is within 6 Å
452 cysteine residue. We further filtered the list to include only cysteines with a free thiol group
453 (defined as a sulfur atom that is only connected to the residue's Cβ). By doing this, we discarded
454 any disulfides, as well as cysteines that are already covalently attached to a ligand. We further
455 removed any ligands which had more than one copy per chain in the structure, and ligands on
456 which processing of the ligand's SMILES failed.

457

458 *Enumerating substructures for covalentization*

459 Fragmentation and scaffold extraction was done using RDKit's implementation of the
460 Recap algorithm³⁸ and the MurckoScaffold³⁹ functionality respectively.

461

462 *Covalentizing a substructure*

463 For each substructure or scaffold, we generated a library of potential electrophilic analogs
464 using SMARTS based reactions. The reaction rules were: 1. Adding an electrophile (including the
465 nitrogen) to any non-substituted aromatic carbon, as well as all aliphatic carbons with one or two
466 bonded atoms, excluding carbons which are already connected to nitrogen. 2. Adding an
467 electrophile to a free amine, either primary or secondary. In this case the nitrogen is completed
468 with the rest of the electrophile. The first rule will usually require more complicated synthesis,
469 whereas the second rule, will allow to use the same ligand as a starting material for a nucleophilic
470 substitution of the acyl form of the electrophile with the free amine.

471

472 *Docking and RMSD calculation*

473 RDKit and Marvin were used to create 250 conformations for each electrophilic analog.
474 Covalent docking was done using DOCKoValent – a virtual screening program. We docked the
475 appropriate analog library for each target, while saving 10 structures for each analog to increase
476 the number of final candidates. When docking the larger linker based libraries we only used the
477 top scoring structure for each analog, due to the large number of structures for analysis. Alternative
478 rotamers for the cysteine residue were generated with pymol based scripts. We used RDKit to filter
479 only for results with a MCS that has an RMSD of less than 1.5 Å to the original ligand.

480

481 *Computational optimisation of the M^{pro} inhibitor*

482 We used the RDKit reaction functionalities, as well as OpenBabel
483 (http://openbabel.org/wiki/Main_Page) to prepare virtual libraries of analogs of compound **10**. The
484 Ugi reaction has three reactants: amine, isocyanide, aldehyde and carboxylic acid. The carboxylic
485 acid is set constant to acrylic acid, since we didn't want to change the electrophilic component. In
486 the virtual libraries, we left it as the reversible furan moiety for convenience in modeling. We thus
487 created three such libraries, each one by replacing one of the three other Ugi reactants with
488 commercially available building blocks. Using RDKit, we generated up to 100 constrained
489 conformations of each molecule, by fixing the conformation of three components as in the crystal
490 structure, and changing only the conformation of the variable part. We then used the Rosetta
491 modeling suite in order to choose the best conformation for each compound, when bound to the
492 protease. For each molecule, we then defined this set of constrained conformations as an extra
493 residue for Rosetta, and used Rosetta Packer⁶⁶ to choose the best conformation, while allowing
494 side-chain flexibility. Eventually, we chose analogs only for the amine and the isocyanide
495 components, as the aldehyde component was highly optimised already. We chose 9 isocyanide
496 replacements and 14 amine replacements (one of them was not based on docking). Most
497 combinations of these components were made by Enamine and tested as part of the Covid-
498 Moonshot effort^{47,67}.

499

500 *Intact protein LC/MS*

501 M^{pro} was incubated for 90 minutes in 50 mM Tris pH 8 300 mM NaCl in room temperature.
502 ERK2 was incubated for 60 minutes in 10 mM Hepes pH 7.5 500 mM NaCl and 5% glycerol in
503 room temperature. The LC/MS runs were performed on a Waters ACUITY UPLC class H
504 instrument, in positive ion mode using electrospray ionization. UPLC separation used a C4 column
505 (300 Å, 1.7 µm, 21 mm × 100 mm). The column was held at 40 °C and the autosampler at 10 °C.
506 Mobile solution A was 0.1% formic acid in water, and mobile phase B was 0.1% formic acid in
507 acetonitrile. The run flow was 0.4 mL/min with gradient 20% B for 4 min, increasing linearly to
508 60% B for 2 min, holding at 60% B for 0.5 min, changing to 0% B in 0.5 min, and holding at 0%
509 for 1 min. The mass data were collected on a Waters SQD2 detector with an m/z range of
510 2–3071.98 at a range of 1000–2000 m/z. The mass data were collected on a Waters SQD2 detector
511 with an m/z range of 2–3071.98 at a range of 900–1500 m/z for ERK2 and 1000–2000 m/z for
512 M^{pro}. The desolvation temperature was 500 °C with a flow rate of 1000 L/h. The voltages used
513 were 0.69 kV for the capillary and 46 V for the cone. Raw data were processed using openLYNX
514 and deconvoluted using MaxEnt (20 - 60 kDa window, 1 Da/channel resolution).

515

516 *Kinase activity assays*

517 Biochemical Kinase inhibition assays were carried out at Nanosyn, Santa Clara. Test
518 compounds were diluted in 100% DMSO using 3-fold dilution steps. Final compound
519 concentration in assay ranged from 10 µM to 0.0565 nM. Compounds were tested in a single well
520 for each dilution, and the final concentration of DMSO in all assays was kept at 1%. Reference

521 compound, Staurosporine, was tested in an identical manner. Compounds were preincubated in
522 25C for 2 hours before the measurements, and the kinase reactions were then performed for an
523 additional 3 hours. For ERK2, the kinase concentration was 0.25-0.35 nM, the ATP concentration
524 was 25 μ M. For MELK, the kinase concentration was 0.06 nM, the ATP concentration was 30
525 μ M. For VEGFR2, the kinase concentration was 0.25 nM, the ATP concentration was 80 μ M. For
526 GSK3B, the kinase concentration was 0.09 nM, the ATP concentration was 10 μ M. For FGFR4,
527 the kinase concentration was 0.17 nM, the ATP concentration was 250 μ M.

528

529 *Biochemical M^{pro} inhibition assay*

530 Compounds were seeded into assay-ready plates (Greiner 384 low volume 784900) using
531 an Echo 555 acoustic dispenser, and DMSO was back-filled for a uniform concentration in assay
532 plates (maximum 1%). Reagents for M^{pro} assay were dispensed into the assay plate in 10 μ l
533 volumes for a final of 20 μ l. Final reaction concentrations were 20 mM HEPES pH=7.3, 1mM
534 TCEP, 50 mM NaCl, 0.01% Tween-20, 10% glycerol, 5 nM M^{pro}, 375 nM fluorogenic peptide
535 substrate ([5-FAM]-AVLQSGFR-[Lys(Dabcyl)]-K-amide). M^{pro} was pre-incubated for 15
536 minutes at room temperature with compound before addition of substrate. Protease reaction was
537 measured continuously in a BMG Pherastar FS with a 480/520 ex/em filter set. Data was mapped
538 and normalized in Genedata Screener.

539

540 *M^{pro}*

Crystallography

541 M^{pro} protein was expressed and purified as discussed previously⁴⁷. Apo M^{pro} crystals were
542 grown using the sitting drop vapour diffusion method at 20 °C by adding 150 nl of protein (5
543 mg/ml in 20 mM Hepes pH 7.5, 50 mM NaCl) to 300 nl of crystallisation solution (11% PEG 4K,
544 6% DMSO, 0.1M MES pH 6.7) and 50 nl of seed stock prepared from initial crystal hits. 55 nl of
545 a 100 mM compound stock solution in DMSO was added directly to the crystallisation drops using
546 an ECHO liquid handler (final concentration 10% DMSO) and drops were incubated for
547 approximately 1 hour prior to mounting and flash freezing in liquid nitrogen. Data were collected
548 at Diamond Light Source on beamline I04-1 at 100K and processed using XDS⁶⁸ and either xia2⁶⁹,
549 autoPROC⁷⁰ or DIALS⁷¹. Further analysis was performed with XChemExplorer⁷²: electron
550 density maps were generated with Dimple⁷³; ligand-binding events were identified using
551 PanDDA⁷⁴ (both the released version 0.2 and the pre-release development version
552 (<https://github.com/ConorFWild/pandda>)); ligands were modelled into PanDDA-calculated event
553 maps using Coot⁷⁵; restraints were calculated with GRADE⁷⁶; and structures were refined with
554 BUSTER⁷⁷. Coordinates, structure factors and PanDDA event maps for all data sets are deposited
555 in the Protein Data Bank under PDB IDs 5RGT, 5RH5, 5RH6, 5RH7, 5RH9, 5RL0, 5RL1, 5RL2,
556 5RL3, 5RL4 and 5RL5. Data collection and refinement statistics are summarised in Supplementary
557 Table 2. The ground-state structure and all corresponding datasets are deposited under PDB ID
558 5R8T.
