Abstract Deforestation rates in the Brazilian Amazon have been steadily increasing since 2007. Recent government policy, projected growth of agriculture, and expansion of the cattle industry is expected to further pressure primates within the Amazon basin. In this study, we examined the anthropogenic impact on the widely distributed black-headed night monkey, *Aotus nigriceps*, whose distribution and population status have yet to be assessed. We 1) modeled species distribution in *A. nigriceps*; 2) estimated impact of habitat loss on population trends; and 3) highlight landscape-based conservation actions which maximize potential for their long-term sustainability. We found the black-headed night monkey to be restricted by several biotic and environmental factors including forest cover, elevation, isothermality, and precipitation. Over the last two decades, over 132,908 km² of tree cover (18%) has been lost within their documented range. We found this species occupies only 49% of habitat within in their range, a loss of 19%

from their estimated 2000 distribution, and just over 34% of occupied areas were in protected areas. Projected deforestation rates of *A. nigriceps* equates to an additional loss of 23,084 km² of occupied habitat over the next decade. This study suggests that although classified as a species of Least Concern, *A. nigriceps* may have a much smaller range and is likely more at risk than previously described. The future impact of continued expansion of mono-cultured crops, cattle ranching, and wildfires is still unknown. However, expanded use of participatory REDD+, sustainable agroforestry in buffer zones, secured land tenor for indigenous communities, wildlife corridors, and the expansion of protected areas can help ensure viability for this nocturnal primate and other sympatric species throughout the Amazon Basin.

Keywords Amazon, *Aotus nigriceps*, Peru, deforestation, MaxEnt, primate

Introduction

Deforestation rates in the Amazon rainforest are at their highest levels since 2007 due to expansion of mono-cultured agriculture (e.g., palm oil and soy), cattle ranching, wildfires, and urban expansion (Davidson et al., 2012; PRODES 2020); with models predicting up to 40% of all Amazonian forests will be lost by 2050 (Gomes et al., 2019). These at-risk areas overlap with many neotropical primate species whose populations may suffer large declines. This includes the black-headed night monkey, *Aotus nigriceps* (Dollman 1909), one of eleven currently recognized species of night monkey found in Central and South America (Hershkovitz 1983; Defler and Bueno 2007; Plautz et al. 2009; Babb et al. 2011; Ruiz-Garcia et al., 2011).

Aotus nigriceps is a wide-ranging nocturnal monkey species found across much of the central and upper Amazon, including degraded forest, agroforested landscapes, and areas in close proximity to humans (Helenbrook et al., 2020). Nevertheless, while night monkeys are adaptable and persist in degraded landscapes, they still require connective forest cover, access to seasonally available fruiting trees, sleeping sites, and are restricted by environmental conditions (Aquino & Encarnación 1994; Helenbrook et al., 2020). Although thought to be a common species, it is currently listed as Appendix II of CITES, and the impact of anthropogenic disturbances on the long-term viability of *A. nigriceps* remains unknown.

Aotus nigriceps is found in Southern Peru, northern Bolivia, and central-western Brazil. However, discrepancies remain regarding the extent of their eastern distribution in the state of Rondonia and additional taxonomic analysis is needed from the area (e.g., Pieczarka et al. 1993; Plautz et al. 2009; Menezes et al. 2010; Babb et al. 2011; Ruiz-Garcia et al., 2011). The species is not considered under threat due to an extensive range, suspected large and sustained population size, presumed low risk of extinction throughout the species range (Shanee et al.

2018), and high density estimates ranging from 19-50 individuals/km² (Helenbrook et al., 2020).

70 However, no known population size estimates or trends have been described. This is concerning since large portions of its range overlap with areas experiencing some of the highest deforestation rates in the world (Estrada et al., 2018). Besides habitat loss, their long-term viability is also projected to be further impacted by altered phenology and increased average maximum temperatures from climate change, which will force species to adapt their distribution or face increased risk from extinction (e.g., Raghunathan et al., 2014; Cohn et al., 2019; 75 Carvalho et al., 2019a).

Assessing the population status of *Aotus nigriceps*, and any species in general, requires accurately describing their distribution, baseline population size, and predicting future population growth or loss. This information can be used to build predictive models that can indicate priority 80 regions for conservation action. Species distribution modeling is a well-known approach, which predicts a species distribution across a landscape based on the environmental conditions necessary for species occupancy (e.g., Bett et al., 2012; Kamilar & Tecot 2015; Rabelo et al., 2018). The MaxEnt program is especially suited for this task and is considered the most accurate maximum entropy machine learning model, achieving high predictive accuracy without true 85 absence data, incomplete data, and small sample sizes (Phillips & Dudik 2008; Merow et al. 2013). Maxent has recently been used in primate studies to determine current and future distribution of snub-nosed monkeys (Wong et al. 2013; Luo et al. 2014; Nüchel et al., 2018), habitat suitability of Sichuan golden monkeys (e.g., Liu et al. 2017), potential distribution of Caatinga howler monkeys (Filho and Palmeirim 2019), and conservation efforts for the brown- 90 headed spider monkey (Peck et al. 2011). However, it is typically not used for species of Least Concern and only after a species is considered under threat.

For this study, we used species distribution modeling with MaxEnt to estimate *A. nigriceps* distribution and then projected density measurements across their predicted distribution. The objectives of this study are to: 1) develop baseline distribution models on the occupancy of *A. nigriceps* utilizing ecological, biogeographical, and environmental data; 2) project population losses due to habitat loss and degradation; and 3) identify priority conservation actions needed to sustain black-headed night monkey populations.

Methods

Species occurrence and environmental data

We constructed an occurrence data set (N=75) of *Aotus nigriceps* observations throughout their range (10.13140/RG.2.2.33456.58886) (Fig. 1). We used several available sources, including published manuscripts (Wright 1996; Helenbrook et al. 2020) and field records provided by the Wildlife Conservation Society and iNaturalist (Lopez-Strauss et al., 2016) (Fig. 2a). To ensure accuracy, we only included data which had confirmed species identity and accurate geographic location. All points were confirmed to ensure coordinates aligned with described distributions and associated habitat. All records were then plotted in QGIS (3.12.1) and created a polygon layer that included all records and followed major river barriers. The polygon represented the maximum species' extent of occurrence described by several peer-reviewed sources (e.g., Plautz et al. 2009; Babb et al. 2011).

115 FIG. 1: Currently described *Aotus nigriceps* range based on biogeographical limitations and literature.

FIG. 2: a) *Aotus nigriceps* predicted distribution based on the maximum test sensitivity plus specificity

120 threshold in a) 2000 and b) 2018. Darker areas represent lower probability. a) Includes presence data used
in Maxent models.

We used bioclimatic variables as environmental predictors based on their presumed
ecological or physiological relationship to black-headed night monkey suitability as previously
125 used in other neotropical primate studies (e.g., Booth et al., 2014; Holzmann et al., 2014; Rabelo

et al., 2018). Climatic variables were downloaded from WorldClim dataset and included annual mean temperature, annual temperature range, annual precipitation, and isothermality (defined as mean diurnal range [mean of monthly (max temperature – min temp)] divided by temperature annual range) (Fick & Hijmans 2017). For elevation, we used the Shuttle Radar Topographic Mission elevation dataset (SRTM 2020). We also obtained percent forest cover data from 2000, forest gain from 2000-2012, and forest loss between 2000-2018 from Earth Engine Partners (Hansen et al. 2013). Autocorrelated variables greater than 0.7 were removed from the analyses to avoid overfitting. To calculate the most current cover percentage for the year 2018, the cumulative gain and loss between 2000 and 2018 were added and subtracted from the 2000 cover layer within their range, respectively. We calculated protected area within *A. nigriceps* range and predicted distribution using polygons obtained from Protected Planet (UNEP-WCMC & IUCN 2020). All layers utilized in the study were in 30 seconds (1 km) spatial resolution.

Distribution models

We used MaxEnt (Version: 3.4.1) to develop a correlative species distribution model for *Aotus nigriceps*, relating known geographic occurrences to available environmental variables to estimate suitable habitat (Phillips & Dudík, 2008; Franklin 2013). To model their predicted distribution, we used 2000 and 2018 forest cover layers to predict their most current distribution. We used 70% of known species' localities as training data and 30% of the localities were set aside as test data. A bootstrap method was used with a maximum of 5,000 iterations, 10,000 randomly selected background points, a prevalence of 0.75, and 15 replicates with a random seed. Since there was a spatial sampling bias with many of the observations, a kernel density analysis was conducted using QGIS (3.12.1), and this raster layer representing the intensity of points was then used as a bias file in Maxent (Brown 2014). A regularization multiplier of 3 was

also added to further constrain the model and avoid overfitting, reduce complexity, and generate
 150 less localized predictions (Anderson & Gonzalez, 2011; Merow et al., 2013; Shcheglovitova &
 Anderson, 2013; Morales et al., 2017).

To assess model discriminatory power and compare performance of species distribution
 models, we measured the area under the receiver operating characteristic curve (AUC) (Fielding
 & Bell, 1997; Babar et al., 2012; Phillips & Dudík, 2008; Stohlgren et al., 2011). To measure
 155 variable importance and determine which variables contributed most to the model, we performed
 a Jackknife analysis with and without each variable in isolation. Habitat was considered suitable
 enough to be occupied based on the maximum specificity and sensitivity threshold which has
 been found to produce the most accurate results (Liu et al. 2005, Jimenez-Valverde and Lobo
 2007). We then calculated total area of suitable habitat using QGIS.

160 *Population Size Estimates and Threat Assessment*

To estimate loss of habitat over time we 1) calculated tree cover loss within their
 documented range from Global Forest Watch data layers (Hansen et. al. 2013), and 2) calculated
 the area of their occurrence between 2000 and 2018 using the MaxEnt modeled species
 distribution. We then used upper and lower population density estimates obtained from
 165 Helenbrook et al. (2020) to extrapolate across projected habitat using area of occurrence
 calculations. Future deforestation projections in the Brazilian Amazon were based on rates
 calculated by Butler (2020). We highlight management practices needed to minimize habitat
 loss, maintain connectivity, and restore populations regionally.

Results

170 *Species Distribution Modeling*

MaxEnt models showed fair support for predicting observed distribution (AUC = 0.688), representative of generalized species. Mean temperature and annual temperature range were removed from the final models due to high correlation with other variables. Occupancy increased with greater forest cover (range 0 - 100%) and precipitation (range 819 – 4,797mm), decreased with isothermality (range 6.4 - 8.7%) and elevation (range 1 - 3,062 m) (Fig. 3a). Cover and isothermality had the highest permutation importance (Table 1). Cover and elevation were the most effective variables for predicting the distribution of the occurrence data set aside for training, cover for testing, and cover, isotherm, and precipitation when predictive performance was measured using AUC (Fig. 3b). The largest contributing environmental variable when omitted in all jackknife tests was elevation, isothermality, and precipitation, suggesting that they contribute the most information not found in the other variables.

TABLE 1: Relative contribution estimates of environmental variables to the MaxEnt model predicting *Aotus nigriceps* occupancy. For percent contribution, the increase in regularized gain for each iteration of the training algorithm is added to the contribution of the corresponding variable or subtracted if the change to the absolute value of lambda is negative. For permutation importance, the values of the environmental variable on training presence and background data are randomly permuted. The model is reevaluated on the permuted data, and the resulting drop in training AUC is normalized to percentages. Values shown are averages over replicate runs.

Variable	Percent contribution	Permutation importance
Forest cover	58.9	59.6
Elevation	23.5	1.7
Isothermality	16.4	32.8
Precipitation range	1.9	5.9

FIG. 3a. The predicted probabilities of *Aotus nigriceps* occupancy of each environmental variable, keeping all other variables at their average sample. The curves represent the mean response of 15 replicate MaxEnt runs (red) and +/- one standard deviation (blue). FIG. 3b. Jackknife tests for variable importance for regularized training gain, test gain, and AUC averaged over 15 replicate bootstrap runs for predicting *Aotus nigriceps* distribution modeling.

The estimated current extent of *Aotus nigriceps* was 1,591,711 km² based on the available literature (Hershkovitz 1983; Defler and Bueno 2007; Plautz et al. 2009; Babb et al. 2011; Ruiz-Garcia et al., 2011: Fig. 1). We calculated a loss of 18% of forest cover between 2000-2018 satellite imagery data (Fig 4a). Protected areas represented 14% of forest cover within their range in 2000 and exhibited forest cover loss of 5% over the past decade. Their predicted distribution based on the maximum test sensitivity plus specificity threshold indicated they occupied 49% (779,938 km²) of their known range (Fig. 2b), a loss of 19% from the predicted 60% in 2000 (Fig. 2a). Of their predicted distribution only a third (34%) was in protected areas (Fig. 4b).

210 FIG 4: a) Forest loss between 2000-2018 based on satellite imagery obtained from Earth Engine Partners. We calculated a loss of 18% of forest cover between 2000-2018 satellite imagery data b) Protected areas in gray. Lighter gray areas have higher probability of occupancy.

Current population estimates using modeled viable habitat coupled with density estimates
 215 from previous studies (i.e., 19-50 individuals per km²) range from 14,818,822 to 38,996,900 individuals (Helenbrook et al., 2020). Based on contraction of suitable habitat between 2000-

2018, we estimate a loss of 3,326,672-8,754,400 individuals. Current extrapolated deforestation rates across present-day modeled distribution of *A. nigriceps* equates to an additional loss of 23,084 km² of habitat over the next decade.

220 Discussion

This is the first study to assess the species distribution, population status, and conservation management implications for the black-headed night monkey. Although considered Least Concern due to their adaptability to a variety of habitat types including the moist forests of the Southwest Amazon, Jurua-Purus, Purus-Maderia, and Maderia-Tapajos, *A. nigriceps* distribution appears restricted by biotic and environmental factors. In particular, they were more likely to occupy habitats represented by low altitudes, low isothermality, higher precipitation, and high forest cover. We found that although not considered a species of concern due to its broad distribution across several Amazon Basin ecoregions, they currently occupy a much smaller distribution than the previously described extent of their range would suggest. Even two decades ago, their distribution was only half of their presumed extent of occurrence.

Furthermore, we estimate that between 2000 and 2018, this species has been reduced by at least 3 million individuals. Although this species is currently considered common, they will likely continue to decline significantly due to widespread anthropogenic pressures, especially since less than a quarter of their suitable habitat is within protected areas.

235 This study provides evidence that *A. nigriceps* has experienced sharp declines in forest cover in portions of their range over the last couple of decades and will continue to experience habitat loss and degradation resulting in population decline over the coming decade. Deforestation rates have surged recently in Brazil driven by heavy pressure from cattle ranching and mono-cultured agriculture (Gomes et al., 2019; IMAZON 2020). Some of the highest

deforestation rates in the Amazon occur in the Brazilian States of Pará, Rondonia, and Mato Grosso where this nocturnal species occurs. Systematic conservation planning based solely on the black-headed night monkey appears premature at this time due to the broad distribution of the species and without a thorough analysis of underlying taxonomy and molecular variability throughout its range. However, the expansion of several existing conservation strategies would benefit *A. nigriceps* and contribute to overall biodiversity conservation.

Although extensive protected areas and indigenous territories exist in Peru, Bolivia, and Brazil, though level of protection varies widely (Amazonia Socioambiental 2019; Paiva et al. 2020). Forest loss and degradation still occurs within protected and indigenous lands, though the degree to which these areas is impacted depends on the type of protected area and management (e.g., indigenous, federal, or state: Herrera et al., 2019). Regardless of governance, primates clearly benefit from protected areas (e.g., Paim et al. 2018). Continued support for participatory and jurisdictional REDD+ programs also appears effective though this approach requires realistic expectations among local communities regarding benefits and participation, secured land tenor, and a mix of intervention strategies including incentives, disincentives, and introduction of alternative livelihoods (e.g., Davis and Goldman 2017; Simonet et al., 2019; Dupuits & Cronkleton 2020). Agroforestry research related to night monkey species is limited, though a study in the northern Andes suggests that coffee plantations can benefit night monkeys while also providing farmers with income (Guzmán et al., 2016). We have previously documented that the black-headed night monkey is quite common in secondary forest and that they make use of orchards (Helenbrook et al., 2020). The main issue would appear to be whether connected canopy is maintained in order for night monkeys to traverse a complex matrix with forest fragmentation and diverse land uses.

Here, we presented an assessment of the current state of forest degradation and loss in the Amazon, coupled with an analysis of the associated anthropogenic impact on a common primate species. Our goal is not to suggest that the black-headed night monkey is under threat of extinction but to show that even widely distributed primates face extensive risks. More specialized sympatric primate species likely face a far greater threat of habitat loss and plummeting population size. By using the black-headed night monkey species as an indicator of landscape and forest health, solutions that mitigate their decline would also favor those that are much more vulnerable – either because they are more sensitive to habitat disturbances, have far smaller numbers, or have yet to even be discovered. There is also the issue of *A. nigriceps* taxonomic uncertainty. There may very well be undescribed conservation management units across this widely distributed species – or currently unrecognized subspecies driven by riverine barriers. This species is distributed across the Amazon but could potentially include units that are each under their own unique stresses and face reduced viability compared to the whole. The range of *A. nigriceps* is also likely to change with continued molecular and morphological analysis. Nevertheless, this study provides critical information of areas highly likely to have black-headed monkeys which can be used for future conservation monitoring and planning. This species has experienced extensive habitat loss over the past couple of decades and there will likely be continued habitat loss and degradation, threatening this relatively common species. A regional landscape-level conservation plan that maintains forest connectivity and minimizes habitat loss would benefit not only the black-headed night monkey but the many other sympatric species who are under increasing threat in the region.
