Abstract

Reptiles are the most species-rich vertebrate group with a broad diversity of life history traits. Biotelemetry is an essential methodology for reptiles as it compensates for several limitations when studying their natural history. We evaluated trends in reptile spatial ecology studies focusing upon quantifying home ranges for the past twenty years. We assessed 290 English-language reptile home range studies published from 2000-2019 via a structured literature review investigating publications’ study location, taxonomic group, methodology, reporting, and analytical techniques. Substantial biases remain in both location and taxonomic groups in the literature, with nearly half of all studies (45%) originating from the USA. Snakes were most often studied, and crocodiles were least often studied, while testudines tended to have the greatest within study sample sizes. More than half of all studies lacked critical methodological details, limiting the number of studies for inclusion in future meta-analyses (55% of studies lacked information on individual tracking durations, and 51% lacked sufficient information on the number of times researchers recorded positions). Studies continue to rely on outdated methods to quantify space-use (including Minimum Convex Polygons and Kernel Density Estimators), often failing to report subtleties on decisions that have substantial impact on home range area estimates. Moving forward researchers can select a suite of appropriate analytical techniques tailored to their research question (dynamic Brownian Bridge Movement Models for within sample interpolation, and autocorrelated Kernel Density Estimators for beyond sample extrapolation). Only 1.4% of all evaluated studies linked to available and usable telemetry data, further hindering scientific consensus. We ultimately implore...
herpetologists to adopt transparent reporting practices and make liberal use of open data platforms to maximize progress in the field of reptile spatial ecology.

**Keywords:** home range, reptiles, open science, reproducibility, biotelemetry, space use, spatial ecology

**Introduction**

There are at least 11,242 described reptile species worldwide (Uetz, Freed & Hošek, 2020; accessed 2020-04). Reptiles typically have narrower niche requirements and smaller ranges than other vertebrates such as birds and mammals, leaving them increasingly susceptible to threats (Böhm et al. 2013). Nearly one in five reptilian species are threatened with extinction, and almost one in four assessed species are Data Deficient (Böhm et al. 2013). Data deficiency in reptiles (21%) is higher than that of bird and mammal species (<1% and 15%, respectively; Stattersfield, Bennun, & Jenkins, 2004; Schipper et al. 2008); in particular for tropical reptiles and those with fossorial habits. Recent collapses of snake diversity have been reported with rippling effects to the ecosystem (Zipkin et al. 2020), but baseline data is often unavailable to properly evaluate these events and is likely understating the cascading effect of disappearing species (Roll et al. 2017). Targeted conservation action requires information and knowledge that is lacking for many reptile species (Tingley, Meiri, Chapple, 2016; Etard, Morrill & Newbold, 2020).

Efforts to collect baseline data are frustrated by reptiles’ nature history – often small, rare, and cryptic – limiting detection probabilities during visual count surveys. Telemetry studies can counteract low detection probability (or at least provide baseline detection estimates; Boback et al., 2020), as we know exactly the number, identity, and location of radio-marked individuals in the study site—with many potential applications (Refsnider et al., 2011). By tracking animal movement, we gain valuable insight into habitat requirements, foraging strategies, and behaviour (Kingsbury & Robinson 2016).

Radio-telemetry (VHF) is common in reptile research, whereas the use of GPS and other automated telemetry technology in terrestrial reptiles is still relatively rare (e.g., Hart et al. 2015, Smith et al. 2018) when compared to other taxa (Joo et al. 2020). Using novel technologies and the resulting increased data volume in telemetry studies should also increase the analytical method...
complexity and encourage greater uptake of movement-based methods. However, the field of movement ecology has stagnated as the proportion of studies using movement-based methods is not matching the available software tools and methods (Joo et al. 2020).

The term “home range” is frequently and irrespectively applied to two distinct concepts: 1) the Burt (1943) home range definition, i.e., the area an animal uses for all of its lifetime activities, 2) within sample “space-use” (still commonly referred to as a “home range”), i.e., an area used by an animal throughout the study period duration. While both concepts have biological value, the chosen research question should govern choice of concept, and thus the space-use estimation methods researchers should use to answer their question. Researchers often use terms like “seasonal home range” to estimate animal space-use within the study period (Viana et al., 2018), delineating boundaries of interest based on season (Korbelová et al., 2016). Many studies improperly use the term home range (which by definition will include areas the animal will use outside the study period, i.e., beyond sample), when they intend to estimate overall space-use of their animals during the study period.

We treat reptile home range studies as any study intending to quantify space-use, regardless of whether the intent was to estimate areas used outside of the study or bounded by the study period. Initially, geometric methods such as the Minimum Convex Polygon (MCP) were the norm, but subsequently researchers have turned towards statistical techniques incorporating underlying probabilistic models, such as Kernel Density Estimators (KDE; Worton 1989). The autocorrelated nature of movement data violates traditional KDEs assumptions lead to the development of movement-based methods: autocorrelated KDEs (Fleming et al. 2015), and Brownian Bridge Movement Models (Horne et al. 2007; Kranstauber et al. 2012). Although researchers have continued to expand and develop analytical methods within movement and spatial ecology (Laver & Kelly 2008), the proportion of studies using movement-specific methods has not increased (Joo et al. 2020). Biotelemetry driven home range work has the potential to fill many gaps in reptile natural history information, and is a precursor to robust population estimates, but it is fraught with difficulty. Macartney, Gregory, & Larsen (1988) summarized the landscape of snake home range studies and suggested developing useful baseline data for comparative purposes requires longer-term studies and standardized data collection, analysis, and presentation.
In 1990, a general review found most studies focused on mammals and used MCPs to estimate home ranges (Harris et al. 1990). By 2008, the same patterns were still present, with mammalian and ornithological home range studies most prevalent, and with 96 out of 141 studies still utilizing MCPs (51% utilizing both MCPs and KDEs; Laver & Kelly 2008). Goldingay (2015) reviewed home-range studies for Australian terrestrial vertebrates between 2001-2012, and only 19% out of 150 papers pertained to reptiles, even though Australia has over 860 native reptile species; in comparison, 68% of studies were on mammals, which only correspond to 16% of Australian’s land species. As for home range estimators, the MCPs appeared in 84% of these studies, followed by KDEs (45%), illustrating a lack of methodology advancement despite a growing field.

Here, we reviewed reptile telemetry literature to assess whether the field showed a similar trajectory of increasing data volume and shifts in collection methods (e.g., GPS and satellite tags), and a continuing stagnation in home range estimation techniques. We also sought to reveal underlying reptile home range study biases, both geographically and taxonomically, to determine future limitations in undertaking global syntheses and analyses. As most home range estimates are sensitive to study design and data collection protocol (e.g., number of locations and duration), we also evaluated reptile telemetry studies within the framework of open, reproducible, and comparable science, to determine the number of available datasets from our review. Finally, we make recommendations for improving reporting standards to aid in making reptile home range studies more broadly applicable and reproducible.

**Survey methodology**

We performed a comprehensive literature review by searching in Google Scholar, Web of Science, and Scopus on January 30th, 2020 for articles relating to reptile spatial ecology using the terms (“reptile” OR “tortoise” OR “crocodile” OR “alligator” OR “snake” OR “lizard”) AND (“home range” OR "home-range" OR "space use" OR "spatial ecology"). We limited the search to papers from 2000-2019 published in peer-reviewed journals. Following Haddaway et al., (2015) we only included the first 300 results from Google Scholar.

Our aim was solely terrestrial/semi-terrestrial reptile home range studies, so we excluded studies on marine species (e.g., sea turtles, sea snakes). However, we did include studies from semi-aquatic or typically range-limited to waterway species (e.g., crocodilians, freshwater turtles). We excluded studies lacking home range or space-use estimates, such as those that only used...
movement measurements. As multiple field sampling techniques can generate home ranges, we defined our inclusion criteria as only studies using an attached telemetric device (e.g., VHF transmitters, GPS). We further excluded clear re-analyses of previously published datasets to avoid pseudoreplication. In these cases, we included only the oldest published article returned from the systematic search for review. We did however include studies pooling previous data with newly collected data.

When studies included multiple species, we considered the overall methodology rather than for each species individually to avoid pseudoreplication. We only collected multiple values for a study's methodology if researchers used two different tracking devices (e.g., both VHF and GPS), as different tracking devices are subject to different limitations in data recording. We used the distinct biotransmitter type to review tracking protocols (e.g., sample frequency, number of locations) and trends in biotransmitter selection (e.g., VHF vs GPS), but used study level effort to review geographic and taxonomic patterns. From each included paper, we collected basic study information (country, year, species, number of individuals tracked) as well as more detailed information about the data sampling regime and home range estimation methods. To assess the field sampling protocols, we collected data concerning the reporting of tracking duration, number of locations, and tracking frequency (number of fixes per day) for studied individuals.

Regular temporal sampling is an assumption in several movement analyses, so we also identified whether studies conducted regular sampling. We defined two cases of regular temporal sampling: (1) whether individuals were located at least once per day consistently throughout the study, (2) whether sampling occurred at an equal hourly sampling rate (e.g., one fix every 2 hours, one fix every 15 min). We converted the reported tracking methodology into the number of tracks per day, recording both the minimum possible and maximum possible frequency. In cases where authors used ambiguous language (e.g., biweekly), or provided insufficient detail, we classified the tracking frequency as "not reported". We also documented whether the study used multiple regular tracking regimes (e.g., tracking once per day in the summer months, and only weekly during the winter).

We coded each article’s adherence to two key reporting characteristics that can impact space-use and home range estimates: tracking time duration, and number of fixes. Tracking time duration differs from study duration, and refers to the period of time over which researchers tracked an
individual. In contrast, study duration is the overall study period, and thus represents a study-level characteristic, while tracking duration represents an individual-level characteristic. We scored articles on a scale of zero to three. For example, zero indicated reporting only study duration/study-level number of fixes (e.g., “...tracked individuals from 2018-01-01 to 2018-09-23...” or “...collected a total of 356 fixes...”) while failing to report the exact data quantity per individual (See Table 1 for details).

Table 1. Scoring category definitions for both number of location and study durations.

For each included study, we also recorded the method for estimating home range area. Kernel Density Estimation is a common technique but is highly dependent on the smoothing factor ($h$) selection method. To address this, we collected the method used to determine the $h$-value for KDEs (when reported). We recorded whether the authors reported a movement metric based on time (e.g., mean daily displacement), as field sampling regime can also affect such metrics. Finally, we recorded if the study attempted to "validate" the home range estimation — i.e., included any form of analysis that assessed the relationship between number of locations and the home range estimation (e.g., linear regressions, bootstrapped asymptotes).
Data and software availability

We use R v.3.6.3 (R Core Team, 2020) and RStudio v.1.4.1029 (RStudio Team, 2020) to summarise all data. We summarised data with dplyr v.1.0.2 (Wickham et al., 2020), raster v.3.4.5 (Hijmans, 2020), forcats v.0.5.0 (Wickham, 2019a), reshape2 v.1.4.4 (Wickham, 2007), and stringr v.1.4.0 (Wickham, 2019b) packages, and visualised data with cowplot v.1.1.0 (Wilke, 2019), ggplot2 v.3.3.2 (Wickham, 2016), ggpubr v.0.4.0 (Kassambara, 2018), ggrepel v.0.8.2 (Slowikowski, 2018), ggridges v.0.5.2 (Wilke, 2018), and scico v.1.2.0 (Pedersen & Crameri, 2018). We have included all data and summary code to create manuscript materials at Zenodo (We have included all data and summary code to create manuscript materials at Zenodo (http://doi.org/10.5281/zenodo.4303643). Data file “reptileHRReview_References.csv” includes the results of the stages of systematic review alongside article information, the data file “reptileHRReview_LiteratureReview.csv” contains the raw data from the literature review process, metadata file “reptileHRReview_Metadata.csv” includes full descriptions of all columns in both main data files. An additional file from Reptile Database (Uetz, Freed & Hošek, 2020; accessed 2020-04) “reptileChecklist_2020_04.csv” includes the information used for genus- and clade-based summaries. We created the reptile diversity using Global Assessment of Reptile Distributions (GARD) data (Roll et al., 2017) and functionality from sf v.0.9.6 (Pebesma, 2018) and fasterize v.1.0.3 (Ross, 2020) packages. We counted terms used and produced the word cloud using pdftools v.2.3.1 (Ooms, 2019) and quanteda v.2.1.2 (Benoit et al., 2018).

Results

Data collection

From 1,028 unique articles returned from the literature searches (Figure S1), our exclusion criteria produced a final sample of 290 reptile spatial ecology studies consisting of 303 tracking subsets (accounting for multiple tracking protocols, i.e., GPS and VHF, within each study) involving 7,897 individual animals. However, one study failed to report the number of animals tracked. The majority of studies used VHF telemetry devices (278), with only 22 using GPS, and a further three instances of ultrasonic or satellite tracking. Regardless of the tracking method used, tracking frequency varied dramatically (Figure 1): ranging from 480 (24 if automated VHF is excluded) to 0.0328 tracks per day for VHF, and 144 to 0.143 per day for GPS. In other words, tracking 0.0328 times per day is equivalent to tracking approximately once a month (i.e., 1/30.5), and 0.143 times...
per day is the equivalent to tracking once per week (i.e., 1/7). Ninety-two tracking subsets (30.4%) had consistent tracking frequencies throughout the study (i.e., minimum and maximum tracking frequency are the same, with no seasonal variation or multiple tracking regimes). The number of tracks/fixes per day was not always reported ($n = 26$), or reported ambiguous maximum and minimum number of tracks per day (e.g., “bi-weekly”, “at least”); this number increases to 79 tracking subsets that failed to clearly report one extreme of the tracking frequency. Such reporting is key when measurements of movement capacity are calculated, and 189 out of 290 studies reported a movement metric.
Figure 1. Reported number of tracks per day. A) Density and boxplot plot showing the distribution of all reported tracking frequencies, x-axis is square-root transformed. Shaded grey area highlights instances of < 1 track per day. Text labels show the minimum, median, mean, and max numbers of tracks per day. B) The variation per study between the maximum and minimum tracking frequencies, provided both are < 1 per day. Both plots exclude all unreported tracking frequencies.

Despite the extensive field effort expended tracking 7,897 animals, we identified serious gaps in basic reporting that undermine understanding basic study characteristics. In addition to the 26 instances of incomplete tracking frequency data, 162 studies provided very limited or missing descriptions of tracking duration (135 scored 0, 27 scored 1), and number of fixes obtained (95 scored 0, 52 scored 1, sum 147). Reporting standards of 2 and higher (i.e., likely sufficient to enable meta-analyses inclusion) were reached in 128 studies for durations and 143 for the number of fixes. Location reporting was further hindered by ambiguous terms, we found 34 different terms describing how many times an animal was tracked: studies largely used terms stemming from locat*, but even within a single study we often found multiple terms used to describe when researchers located animals (Figure S2). Providing raw data could mitigate reporting deficiencies; however, we found only 24 studies included links to external data and only 4 of those links led to raw tracking data.

Estimation methods

Between 2000-2019 the number of studies per year increased from 6 in 2000 to 18 in 2019, with a low of 4 in 2001 and a peak of 25 in 2017 (Figure 2A). Minimum Convex Polygons (MCP) and Kernel Density Estimations (KDE) use has dominated reptile home range studies for the past 20 years (272/290 studies; Figure 2B) and were present in over 75% of studies each year (Figure 2B). Frequently, studies include estimations from both methods, and rarely use KDEs without including MCPs (Figure S3). A minority of studies (n = 19) used “other” methods without pairing to estimations via MCPs and KDEs. These methods included: alpha-hull methods, harmonic means, linear home ranges, Brownian Bridge kernels among others (for full list see Table S1). Of all other methods listed, only dynamic (and standard) Brownian Bridge Movement Models directly incorporate movement to estimate space-use (i.e., movement models).
Figure 2. Changes in the field from 2000 to 2019. A) Number of articles over per year and the telemetry devices used: dark grey = only VHF used, middle grey = GPS was used exclusively or in conjunction with VHF, light grey = other device used (ultrasonic and satellite). B) The percentage of studies using Minimum Convex Polygon (MCP), Kernel Density Estimations (KDE), both or other estimation methods. “Other” only includes studies that did not use either MCPs or KDEs. Lower text labels highlight the year select papers were published aiming to guide, or enable new, space-use estimation.

Studios using MCPs largely made use of high % contours (100 and 95%; Figure S4). KDEs used a greater diversity of contour values (5 to 100%), but with clear concentration towards 95% and 50%. Studies more frequently (n = 97/270 studies using MCPs) failed to report the contour used with MCPs than other methods, potentially connected to the assumption that MCPs default to 100%.

For studies using KDEs, we found 14 smoothing factor selection methods, but researchers primarily used Least Squares Cross-validation (LSCV; 73/159; Figure S5). Similar to basic reporting, we show that 27 (17.4%) studies failed to report a smoothing factor, either by omission or by only stating the “default” for a software.
Geographic and taxonomic biases

The United States of America is a clear hotspot with 133 of 290 studies. All other countries are dramatically lower (<8 studies, 30 countries with a single study), with only Australia (35), Canada (22), and South Africa (12) breaking the trend. Despite high reptile diversity, Africa exhibited a dearth of reptile home range papers (Figure 3).

![Reptile diversity and Number of studies](Image)

**Figure 3.** Number of studies undertaken in each country. Insert map bottom left, shows the distribution of reptile species globally, ranging from zero species (black) to 182 species (yellow); the heatmap was generated using GARD data (Roll et al., 2017). Insert density plot bottom right, shows the distribution of per country study counts. Count of studies is shown on a log scale to help differentiate between countries with fewer studies. Smaller territories are highlighted with a label denoting the number of studies.

The 7,897 tracked individuals, 303 tracking subsets, and tracking subset sample sizes were not split evenly across the major clades of Crocodylia (mean individuals per subset = 9.32 ± 1.48), Serpentes (22.3 ± 1.61), Sauria (28.4 ± 3.53), and Testudines (35.4 ± 6.80; Figure 5). Serpentes was the most studied clade and with the most tracked individuals, whereas Crocodylia was the lowest. However, in terms of percentage of genera studied, Crocodylia leads with 44.4% (4/9; Testudines 27/94, 28.7%; Serpentes 40/522, 7.66%; Sauria 28/564, 4.96%).
Overall, of the 1,210 reptile genera (Uetz, Freed & Hošek, 2020; accessed 2020-04), 99 (8%) have been tracked (but there are genera untrackable with current telemetry equipment, e.g., *Amphisbaena* and *Ramphotyphlops*). Two genera (*Crotalus* & *Gopherus*) stand out having been studied 22 and 23 times (Fig S6), whereas 45 genera had only a single study.

**Discussion**

We identified key issues limiting study comparability. Study design decisions on tracking frequency and duration are critical considerations when attempting to produce biologically relevant space-use estimates (Girard et al., 2002; Börger et al., 2006; Silva et al., 2020). These decisions determine total individual sampling effort; an individual with 12 locations over a single day is unequal to one with 12 locations over an entire year. Reporting solely the study duration (e.g., stating that tracking occurred between X and Y date) would then obscure individual variation—further hindering our ability to generalize across the study population. By reporting at the individual level, researchers can highlight potential sources of heterogeneity between studies (e.g., tracking an animal once every week while tracking others twice a week would hinder daily movement comparisons) (Alexander & Maritz, 2015; Riotte-Lambert & Matthiopoulos, 2019). As
we found a wide range of tracking frequencies throughout reptile spatial ecology studies, it limits our ability to conduct large inter-study comparisons and undermines their validity.

Our review also reveals major biases in the study of reptile home ranges. Geographically, nearly 50% of studies originated from a single country, the United States of America. We found a stark mismatch between reptile diversity and reptile home range study locations (Roll et al., 2017), reflecting similar gaps seen in reptile abundance studies (Doherty et al., 2020); in particular, the Middle East and Central Africa. Taxonomically, we observed less severe biases, but should still be considered in evaluating the patterns in the available data. Only 8% of genera have been studied and the groups studied are far from a random sample; a relatively small number of genera dominate the available reptile spatial ecology data (e.g., Gopherus, Crotalus, Pituophis). Efforts to synthesise reptile home range or movement must recognize that any results may be biased towards patterns in temperate western hemisphere species, rather than global trends. Global syntheses may be inhibited by the drastic differences in seasonal climate between well-studied temperate areas and neglected tropical regions, which is likely key to reptiles as ectotherms (Shine and Madsen, 1996).

Many of the issues that we revealed in the reptile spatial ecology literature can be mitigated with greater transparency, adopting open science and reproducible analyses (i.e., code-based analysis avoiding language ambiguities by being, and describing, the exact analytical procedure performed; Ince, Hatton & Graham-Cumming, 2012; Archmiller et al., 2020). Open science presents a vital resource for replication efforts and can facilitate better meta-analyses. It also benefits the original researchers by increasing citations, boosting publication chances, and creating more potential for collaborations (Piwowar & Vision, 2013; Markowitz, 2015; Allen & Mehler, 2018). The disparity between reptile data and other taxa on prominent movement data repositories re-emphasizes our review findings (when searching either “reptilia” or “reptile”, 24 reptile studies have available movement data on MoveBank as of 12.02.2020, and only 11 of those studies focus on terrestrial species). Ecology journals (and herpetology journals especially; Marshall & Strine, 2020) should redouble efforts to enforce data availability statements (Roche et al., 2015), making data availability the default and refusing to accept “on request” statements (Aalbersberg et al., 2018). Researchers can make use of free data repositories (movement specific like MoveBank, or generic like Zenodo or OSF) to ease this process. We hope the opening of reptile movement data can
facilitate broader studies similar to those undertaken in avian and mammalian fields (e.g., Tucker et al., 2019; Noonan et al., 2020).

Researchers often justify using KDEs and/or MCPs to compare with the wider reptile spatial ecology literature. However, methodological choices in reptile space-use studies hinder inter-study comparisons, as KDEs and MCPs are sensitive to differences in sampling effort (e.g., number of locations, tracking duration and frequency) (Mitchell, White, & Arnold, 2019; Silva et al. 2020). Reptile studies also used a wide range of smoothing factors for KDEs, which can also result in considerable home range over- or underestimations (Bauder et al. 2015; Silva et al. 2020). For example, two widely used smoothing factors, \( h_{\text{ref}} \) and LSCV, produce dramatically different area estimations. Failure to report or account for smoothing factors is thus a major concern, as it would significantly alter meta-analysis patterns. Although Row & Blouin-Demers (2006) suggested MCPs over KDEs for home range size comparisons across groups or time periods, MCP and KDE comparability is unreliable rendering their use generally inappropriate for most ecological studies (Nilsen, Pedersen, & Linnell, 2008; Silva et al. 2020).

There is a growing body of work demonstrating the versatility of newer analytical methods (Noonan et al., 2018), and how they can be applied to the coarser and zero-inflated radio-telemetry data (Averill-Murray, Fleming, & Riedle, 2020; Hromada et al. 2020; Silva et al. 2020). Reptile spatial ecology so far has largely failed to capitalise on the wealth of analytical options available, namely integrating movement information explicitly into estimations of space-use. Unlike traditional estimation methods (KDEs and MCPs), movement-based models do not operate under the assumptions breached by tracking data (independence of points) and guard better against under- and overestimation (Fleming & Calabrese 2017; Silva et al. 2020). One of the common solutions to autocorrelation is the thinning of data; this procedure is inherently wasteful and inefficient, defeating the purpose of collecting high temporal-resolution data and reducing the biological significance of telemetry datasets (Fleming et al. 2015; Calabrese et al. 2020). With low temporal-resolution data, analytic approaches will not necessarily reveal the correct home range patterns and need to be applied with caution; in these cases, it may be necessary to reconsider our research questions or re-evaluate study design for additional data collection.

Researchers should aim to explore the estimation sensitivity choices (Signer & Fieberg, 2020), while ensuring that their method matches their question. Conceptualizing home range as within
sample versus beyond sample space-use requires distinguishing between occurrence distribution versus range distribution methods (Fleming et al. 2015; Horne et al. 2019; Figure 5). While occurrence distributions (e.g., dBBMMs) allow us to answer research questions regarding the actual movement trajectory of an animal (and its confidence region), range distributions (e.g., AKDEs) consider the processes underlying animal movements and long-term space-use (Horne et al. 2019). Some research questions investigated in the reptile home range literature are actually targeting within sample space-use, requiring no extrapolation beyond the sampling period. In many cases, the sampling duration was too short to confidently identify range stability, which is a prerequisite for beyond sample home range estimates. To help unify the terminology used in reptile spatial ecology studies we draw attention to definitions from existing literature and reiterate them in Figure 5.

**Figure 5.** A breakdown of the two complimentary conceptualisations of animal space-use. Displayed alongside are examples of the 99% contour derived from dynamic Brownian Bridge Movement Models (Kranstauber, Smolla & Scharf, 2016) and autocorrelated Kernel Density Estimators (Calabrese, Fleming & Gurarie, 2016; Fleming & Calabrese, 2020). Data used is from Marshall et al. (2020) and can be found in Supp File 4.

Ambiguous language further compounded reporting issues. Failing to report estimation methods (or reporting with ambiguous or ill-defined acronyms) and associated smoothing parameters completely undermines computational reproducibility and inter-study comparability. Relatively few studies failed to attempt reporting their tracking frequency; many of our 79 failures to determine minimum or maximum tracking frequency were a direct result of ambiguous language,
such as using words with multiple definitions (e.g., “bi-weekly”) or using imprecise summaries (e.g., “at least”). We also found semantic ambiguity when describing locations. Studies used a wide range of terms to refer to locations, relocations, fixes, datapoints, etc., yet are selecting contrasting or overlapping definitions for these terms. The key distinction for the definition of location is whether it refers each time researchers documented the animal’s spatial position or whether it refers only to a unique spatial position (a movement from the previously recorded location) used by the study animal (often referred to as “relocations”). Standardising and unifying terminology is essential for creating widely useful methods and comparable databases (Schneider et al., 2019).

Answering specific questions requires appropriate protocols and, to draw broad inferences among a single study, those protocols must remain consistent. Between study comparisons also require consistency (or at least clear reporting on inconsistencies). The compound effect of geographical, taxonomical and methodological biases leads to inappropriate generalizations when ignored. Recent macroecological investigations have failed to account for varying tracking regimes and different estimation methods (Slavenko et al. 2016; Todd & Nowakowski 2020). To facilitate detailed reporting of tracking datasets, we have supplied an example report based on an existing tracking dataset (Marshall et al., 2020; Supp. File 2). This example aims to provide a foundation for transparent reporting of sample size, study duration, number of datapoints, as well as important aspects used to describe the tracking regime: namely plots that describe individual tracking durations (while highlighting deviation from proposed tracking protocols), and distribution of time lags between tracks. We have supplied the code (as an .Rmd file, Supp. File 3) and data (as a .csv, Supp. File 4) used to generate the report as supplementary material.

Conclusion

The past 20 years have seen a growing number of reptile home range studies and continued reliance on traditional but outdated methods, Kernel Density Estimations (KDEs) and Minimum Convex Polygons (MCPs), for home range and space-use estimations, despite more appropriate available methods. Scientific conventions can be slow to shift, and often require substantial interdisciplinary research to move towards better alternatives (Smaldino & O’Connor, 2020). We appeal to researchers focusing on reptiles to engage with quantitative ecologists to ease the uptake of more complex and appropriate statistical methods and thus maximize the value of hard-won field data.
The best way to facilitate broader engagement is to adopt more transparent practices by sharing and fully reporting collected data.

Acknowledgements

We thank Suranaree University of Technology, Institute of Science and Institute of Research and Development for logistic support and facilitating our research. We also thank King Mongkut’s University of Technology Thonburi for support and particularly the Petchra Pra Jom Klao Scholarship. Also, we thank Aubrey Alamshah for her patience and support during several intensive reviewing and writing gatherings. We thank Supunnee Potijun Strine for suffering through the loss of her husband during long writing weekends and for providing much-needed sustenance during these times.

Author contributions

All authors contributed equally to the manuscript.

Conceptualization, M.C., I.S., B.M.M., and C.T.S.;
Methodology, M.C., I.S., B.M.M., and C.T.S.;
Investigation, M.C., I.S., B.M.M., and C.T.S.;
Visualisation, B.M.M.;

All authors read and approved the final manuscript.
