25 **ABSTRACT**

26 For organisms that respond to environmental stimuli using taxes, reversal of the tactic
 27 sign should be tightly regulated for survival. The biciliate green alga *Chlamydomonas*
 28 *reinhardtii* is an excellent model for studying reversal between positive and negative
 29 phototaxis. *C. reinhardtii* cells change swimming direction by modulating the balance
 30 of beating forces between their two cilia after photoreception at the eyespot; however, it
 31 remains unknown how they reverse phototactic sign. In this study, we observed cells
 32 undergoing phototactic turns with a high-speed camera and found that two key factors
 33 determine the phototactic sign: which of the two cilia beats stronger for phototactic
 34 turning and when the strong beating starts. We developed a mathematical model to
 35 explain this sign-reversal with a single equation, which suggests that the timing of the
 36 strong ciliary beating is regulated by switching between the light-on and light-off
 37 responses at the eyespot.

41

42 INTRODUCTION

43 The biciliate unicellular green alga *Chlamydomonas reinhardtii* is an excellent model
 44 organism to study how organisms respond to changing light conditions. *C. reinhardtii*
 45 shows a distinct light-induced behavior known as phototaxis, in which cells swim either
 46 toward or away from a light source (in positive or negative phototaxis, respectively).
 47 The direction of phototaxis, referred to here as the sign (either positive or negative), can
 48 be switched. The regulation of this sign reversal is thought to be important for the
 49 viability of photosynthetic algae, but its mechanism is not well understood.

50 In *C. reinhardtii*, the light signal for phototaxis is received by the eyespot
 51 (Foster & Smyth, 1980), an organelle that appears under a microscope as an orange spot
 52 near the cell equator. It consists of carotenoid-rich granule layers, and a small area of
 53 plasma membrane in which channelrhodopsin (ChR) molecules are localized (Fig. 1A).
 54 The carotenoid-rich granule layers (CLs) function as a quarter-wave plate that reflects
 55 light (Foster & Smyth, 1980; Ueki et al., 2016), while ChR molecules are light-gated
 56 ion channels (Nagel et al., 2002; Nagel et al., 2003; Oleg A. Sineshchekov, Jung, &
 57 Spudich, 2002; Suzuki et al., 2003). Because of the relative position of these two
 58 components, the eyespot perceives light with high directionality. When a light signal
 59 arrives from the ChR-facing side, the light signal is amplified by reflection from the

60 CLs; conversely, light signals are blocked by the CLs when coming from the CL-facing
61 direction. In addition, while swimming, the cell rotates around its anterior-posterior axis.
62 Directional photoreception by cells that swim with bodily rotation enables them to
63 accurately detect and move in the direction of light stimuli.

64 Previous studies suggest that the phototaxis pathway in *C. reinhardtii* consists
65 of: 1) photoreception by ChRs, 2) an increase in intraciliary $[Ca^{2+}]$, and 3) a change in
66 the balance of beating between the two cilia – after photoreception, the forces generated
67 by the two cilia of *C. reinhardtii* become imbalanced, changing the cell's swimming
68 direction. These two cilia can be distinguished by their position relative to the eyespot,
69 with the one nearest the eyespot called the *cis*-cilium, and the other called the
70 *trans*-cilium. A currently prevailing model explains the mechanism underlying positive
71 phototaxis as follows: When the eyespot faces a light source during swimming with
72 bodily rotation, ChRs open to allow for Ca^{2+} entry, intraciliary $[Ca^{2+}]$ increases, and the
73 *trans*-cilium starts to beat more strongly than the *cis*-cilium, by increasing beating
74 amplitude and/or frequency (Ritsu Kamiya & Witman, 1984; Rüffer & Nultsch, 1991).
75 The imbalance between the forces generated by the two cilia tilts the cell's swimming
76 direction toward the eyespot-bearing side (i.e., in the direction of the light source). After
77 180° of rotation, the eyespot stops receiving light due to the shielding of CLs, the ChRs

close, intraciliary $[Ca^{2+}]$ decreases due to some ion pumping activity, and the force generated by the *cis*-cilium increases while that of the *trans*-cilium decreases, resulting in the cell's swimming direction tilting toward the light-source. By repeating this process, the cell will swim toward the light source, displaying positive phototaxis (Fig. 1B). However, in contrast to this widespread model, phototactic turns may also be initiated when the eyespot faces away from the light source (i.e., when the eyespot is shaded) (Isogai, Kamiya, & Yoshimura, 2000).

How, then, can the direction of phototaxis be reversed? The following possibilities exist: (i) The *cis*-cilium, rather than the *trans*-cilium, beats stronger when $[Ca^{2+}]_i$ increases upon photoreception; (ii) A light-off stimulus on the eyespot, rather than a light-on stimulus, activates the dominant *trans*-cilium; (iii) The response of cilia to a light-on stimulus on the eyespot is delayed; or (iv) $[Ca^{2+}]_i$ actually decreases upon photoreception, rather than increasing. Among these possibilities, (iv) must be tested using highly sensitive Ca^{2+} indicators, because the $[Ca^{2+}]_i$ regulating the beating of cilia during phototaxis is thought to be at submicromolar levels (Ritsu Kamiya & Witman, 1984), while (i) to (iii) can be tested by observing cell behavior after light stimulation.

Indeed, several factors are known to induce sign-switching of phototaxis in *C. reinhardtii*, including both extracellular factors like light intensity (Feinleib & Curry,

1971) and extracellular Ca^{2+} concentration (Morel-Laurens, 1987), and intracellular factors such as circadian rhythms (Kondo, Johnson, & Hastings, 1991), photosynthetic activities (Takahashi & Watanabe, 1993), and the amount of reactive oxygen species (ROS) (Wakabayashi, Misawa, Mochiji, & Kamiya, 2011). The amount of cellular ROS can be readily changed by applying membrane-permeable ROS reagents or membrane-permeable ROS scavengers to cells, which strongly bias the phototactic sign: cells show positive phototaxis after treatment with ROS and negative phototaxis after treatment with ROS-scavengers (Wakabayashi et al., 2011).

In this study, to test the possibilities (i) to (iii) above, we carried out high-speed observations of cells turning during positive or negative phototaxis, after treatment with either a membrane-permeable ROS or a membrane-permeable ROS scavenger (hereinafter referred to as “ROS-modulating reagents”). Our results support both possibilities (i) and (ii) described above. In support of (i), after photoreception, we observed that positively phototactic cells beat the *trans*-cilium more strongly, whereas negatively phototactic cells beat the *cis*-cilium more strongly. We also developed a mathematical model that can explain the phototactic-sign reversal based on the change in timing at which ciliary dominance takes place after photo-stimulation. In support of (ii), treatment with the ROS-modulating reagents was found to induce a light-off

114 response, which switched the phototactic sign. While it was impossible to distinguish
115 between possibilities (ii) (light-off response) and (iii) (delay of light-on response)
116 through microscopic observation of the wild-type cells alone, our observations of
117 slow-swimming mutants, along with the results of our mathematical model, strongly
118 support possibility (ii).
119

120 **RESULTS**

121 **Two hypotheses to explain the sign change of phototaxis**

122 The mechanism underlying positive phototaxis can be explained as described in the
123 Introduction (shown in Fig. 1B). To elucidate the mechanism of negative phototaxis, we
124 considered two models (Fig. 1C), in which the dominant cilium is a key factor (defined
125 here as the cilium that begins to beat more strongly after photoreception than the other).
126 In the first model (the dominant-arm model), we assume that the relationship between
127 the dominant cilium and $[Ca^{2+}]_i$ is reversed, such that the *cis*-cilium, rather than the
128 *trans*-cilium, becomes dominant when $[Ca^{2+}]_i$ is increased. If the *cis*-cilium beats more
129 strongly than the *trans*-cilium after light perception (which elicits Ca^{2+} influx), the cell
130 will undergo negative phototaxis. In the second model (the off-response model), we
131 assume that the relationship between the dominant cilium and $[Ca^{2+}]_i$ remains the same,
132 but the onset of ciliary dominance (along with $[Ca^{2+}]_i$ increase) occurs when the eyespot
133 faces away from the light source, and senses a light-off stimulus. In this case, the cell
134 will also show negative phototaxis.

135

136 **Dominant cilia differ in strains with opposite phototactic signs**

137 To determine which of these two models was more plausible, we observed the turning
 138 of *C. reinhardtii* cells using a high-speed camera (150 fps) linked to green
 139 light-emitting diode (LED) illumination sources at right angles. This system was an
 140 extension of the right-angle illumination system originally designed for the previous
 141 study (Isogai et al., 2000), which we here improved upon to observe the phototactic
 142 turnings and the eyespot position simultaneously by synchronizing the high-speed
 143 camera and the LED illumination. This allowed us to determine the exact time when a
 144 light stimulus was applied to a rotating cell, and the simultaneous orientation of the
 145 eyespot (visible as a bright spot under a dark-field microscope with an oil-immersion
 146 condenser). With this system, we first induced phototaxis in cells using the weaker
 147 stimulus of Light 1 (Fig. 2A). Then, the stronger Light 2 was illuminated at right angles
 148 to Light 1. When the eyespot in a swimming cell faced the light-source side of Light 2
 149 (or the light side) after its illumination, we considered the cell to have perceived the
 150 light in that time frame (Fig. 2A). Then, from the position of the eyespot and the
 151 swimming path, we assessed which cilium beat more strongly.

152 We observed the eyespot position during phototactic turning in two genetically
 153 different strains, CC-124 (a negatively phototactic strain, here referred to as NP) and
 154 CC-125 (positively phototactic strain, PP) (see Materials and Methods). We analyzed

155 only those cells that showed phototactic turnings of one full self-rotation after
156 photoreception. We found that PP cells usually showed positive phototaxis. Similar to
157 the PP cell after treatment with *t*-BOOH that induces positive phototaxis in Fig. 2A, a
158 typical control PP cell changed its swimming direction immediately after it detected
159 Light 2 (green arrow position). When turning toward the direction of the light source,
160 more than half of the cells performed phototactic turning while the eyespot was located
161 on the light side (i.e., the *trans*-cilium became dominant immediately after
162 photoreception) (Fig. 2B).

163 In contrast, NP cells usually showed negative phototaxis. Similar to the NP cell
164 after treatment with DMTU that induces negative phototaxis in Fig. 2A, a typical
165 control NP cell changed its swimming direction immediately after it detected Light 2,
166 similar to the PP cell. When turning against the direction of the light source, most cells
167 performed turns while the eyespot was located on the light side, i.e. the *cis*-cilium
168 became dominant immediately after photoreception (Fig. 2B). These observations
169 suggest that the difference between PP and NP cells can be explained by the “Dominant
170 arm model.” The cilium that becomes dominant after photoreception is genetically
171 determined. Therefore, if the dominant cilium is the *trans*-cilium, the strain tends to

172 show positive phototaxis, while if it is the *cis*-cilium in another strain, it tends to show
173 negative phototaxis.

174

175 **Reversal of phototactic sign by “off-response” of the dominant cilium**

176 Next, we examined the effect of reagents that change the cellular ROS, affecting the
177 phototactic sign. After treatment with 0.2 mM *t*-BOOH, a membrane-permeable ROS
178 reagent that induces positive phototaxis in both strains, most PP cells made phototactic
179 turns while the eyespot was located on the light side, while most NP cells made
180 phototactic turns while the eyespot was located on the dark side (i.e., the side opposite
181 the light-source) (Fig. 2B). Fig. 2A shows the representative data, and the
182 *t*-BOOH-treated NP cell changed its swimming direction after the cell made a
183 half-self-rotation (magenta arrow). In contrast, after treatment with 75 mM DMTU, a
184 membrane-permeable ROS scavenger that induces negative phototaxis in both strains,
185 most PP cells made phototactic turns while the eyespot was located on the dark side,
186 and most NP cells made phototactic turns while the eyespot was located on the light
187 side. In Fig. 2A, the DMTU-treated PP cell changed its swimming direction after the
188 cell made a half-self-rotation (magenta arrow).

189 Thus, the sign-reversal of phototaxis in both strains can be explained by the
190 off-response model; i.e., *t*-BOOH induces the onset of *cis*-cilium dominance in the dark
191 side in NP cells and DMTU induces that of *trans*-cilium dominance in the light side in
192 PP cells. Simply put, the reversal of genetically determined phototactic signs in a given
193 strain is achieved by reversing the eyespot position relative to the light source (the light
194 or dark side) when its genetically determined dominant cilium starts to show stronger
195 beating than the other after light stimulation. We found that the dominant cilium after
196 photoreception of PP cells was always the *trans*-cilium, while that of NP was always
197 the *cis*-cilium. In each strain, the sign-switching of phototaxis was caused by the onset
198 of strong beating of the dominant cilium on the dark side.

199 Therefore, these phototactic turning events can be categorized into two cases
200 for each sign of phototaxis. For cells displaying positive phototaxis: in (Positive Case 1),
201 phototactic turning occurred while the eyespot was located on the light side. In this case,
202 the *trans*-cilium must have become dominant in response to the light-on stimulus (such
203 as PP cells without the ROS-reagents or with *t*-BOOH). In (Positive Case 2),
204 phototactic turning occurred while the eyespot was located on the dark side. In this case,
205 the *cis*-cilium must have become dominant in response to the light-off stimulus (such as
206 NP cells with *t*-BOOH). For cells displaying negative phototaxis: in (Negative Case 1),

207 phototactic turning occurred while the eyespot was located on the light side. In this case,
 208 the *cis*-cilium must have become dominant in response to the light-on stimulus (such as
 209 NP cells without the ROS-reagents or with DMTU). In (Negative Case 2), phototactic
 210 turning occurred while the eyespot was located on the dark side. In this case, the
 211 *trans*-cilium must have become dominant in response to the light-off stimulus (such as
 212 PP cells with DMTU).

213

214 **Eyespot position in the helical paths**

215 Regarding changes in the balance of beating between the two cilia during phototactic
 216 turning, we first wanted to examine the force balance in unstimulated cells. Under
 217 homogeneous light conditions, *C. reinhardtii* cells swim in a helical path, due to the
 218 imbalanced force generation of the two cilia beating in slightly skewed planes (Fig.
 219 S1A). In previous work, Isogai et al. showed that the eyespot is located on the outer
 220 edge of the helical swimming paths in ~80 percent of positively phototactic cells (Isogai
 221 et al., 2000). In contrast, for negatively phototactic cells, ~50 percent of cells swim with
 222 the eyespot facing inside, whereas ~30 percent of cells swim with the eyespot facing
 223 outside (Isogai et al., 2000). These results suggest that eyespot position in the helical
 224 swimming path is partially correlated with the phototactic sign, but the correlation is not

determinative. We thus investigated whether the eyespot position in the swimming paths is affected by ROS-modulating reagents. Most, but not all, cells swam with the eyespot outside the helix when they showed either positive phototaxis (Fig. S1B, Sign P). However, when cells showed negative phototaxis in the presence of DMTU, directing the eyespot inside the helix was observed almost as frequently as towards the outside (Fig. S1B, Sign N, +DMTU). Thus, we did not observe a strict correlation either between phototactic sign and eyespot position in the helical paths.

232

233 **Photoreceptor currents after treatment with the ROS-modulating reagents**

A possible explanation for how ROS-modulating reagents induce the light-off response is that those reagents delay the response of the dominant cilium by slowing the opening of photo-gated channels (ChRs). If this delay is as long as the time required for a cell to perform a half rotation (~250 msec), then the phototactic sign of the cell would reverse. To test this possibility, we measured the photoreceptor current (PRC) in a population of *C. reinhardtii* cells by the method of Sineshchekov et al. (O. A. Sineshchekov, Govorunova, Der, Keszthelyi, & Nultsch, 1992, 1994) (Fig. S2A). Treatment with *t*-BOOH did not significantly affect the magnitude of PRC produced by a single flash of light stimulation, in either PP or NP cells (Fig. S2B, C). We also measured the time

(delay) required for the generation of PRC after photostimulation, but detected no significant difference between the control and the *t*-BOOH-treated cells (Fig. S2B, C). In contrast, after treatment with DMTU, we found that PRC decreased, while delay time increased, in both strains (Fig. S2B, C). However, the increase in delay time was only ~1 msec. These results suggest that the light-off response is not caused by the delay in PRC generation.

249

250 **Mathematical model to test the experimental data**

Our experimental results suggest that two factors are important for reversal of the phototactic sign in *C. reinhardtii* cells: (1) which of the two cilia becomes dominant after photoreception, and (2) when such a change in dominance takes place. To quantitatively examine these factors, we developed a simple mathematical model that describes the swimming behaviors of *C. reinhardtii*, focusing on the timing of the appearance of ciliary dominance. We also considered whether the ciliary dominance taking place on the dark side might either be caused by the light-off stimulus, or result from a delay in the light-on response with this model.

Our modeling framework is based on previous models of phototaxis in *C. reinhardtii* and the multicellular green alga *Volvox carteri* (Bennett & Golestanian,

261 2015; Drescher, Goldstein, & Tuval, 2010), which we extend by explicitly introducing a
 262 time delay into the ciliary response after a light stimulus (see SI Appendix A for details).
 263 We approximate the cell as a rigid ball and define the body axes of the cell as in Fig. 3A,
 264 where $\mathbf{a}$, $\mathbf{b}$ and $\mathbf{c}$ are unit vectors that are fixed to the body of the cell. We assume that a
 265 cell swims with cilia forward, with a constant speed v_0 in the posterior direction $\mathbf{c}$, i.e.,
 266 $\mathbf{v} = v_0 \mathbf{c}$, and rotates with the angular velocity

$$267 \quad \boldsymbol{\omega}(t) = -\omega_c^{(0)} \mathbf{c} + (\omega_a^{(0)} - p(t))\mathbf{a}, \quad \text{---}[1]$$

268 where $\omega_c^{(0)}$ and $\omega_a^{(0)}$ are constants. p expresses the contribution from the change in
 269 the behaviors of the two cilia: when the *trans*-cilium beats stronger than the *cis*-cilium,
 270 p becomes positive, and vice versa. The data in Fig. 2 indicate that the beating balance
 271 between the two cilia changes depending on the change in the light intensity received at
 272 the eyespot, I , with some delay time. We thus relate p and I as

$$273 \quad p(t) = \gamma_0 \frac{dI(t - \tau_0)}{dt}, \quad \text{---}[2]$$

274 where γ_0 is a constant that takes the value +1 or -1. $\gamma_0 = +1$ means the *trans*-cilium is
 275 dominant (as in PP), while $\gamma_0 = -1$ means the *cis*-cilium is dominant (as in NP). τ_0
 276 is the delay time of the onset of the ciliary dominance after photoreception (around
 277 30-40 msec under normal culture conditions) (Rüffer & Nultsch, 1991; Witman, 1993).
 278 We consider the situation where a parallel light comes from the positive z direction (Fig.
 279 3B), and I is given by $I(t) = I_0 (-\mathbf{e}_{light} \cdot \mathbf{e}_{eyespot} + 1) / 2$, where $\mathbf{e}_{light} = (0, 0, -1)$,
 280 $\mathbf{e}_{eyespot} = (\mathbf{a} + \mathbf{b}) / \sqrt{2}$ and I_0 is the intensity of the light; $\mathbf{e}_{light}$ and $\mathbf{e}_{eyespot}$ represent the

281 direction of the incident light and the eyespot, respectively. The directions of body axes,
 282 **a**, **b**, **c**, are specified by three variables, the Euler angles $(\theta_1, \theta_2, \theta_3)$ (Fig. 3B) (Landau,
 283 1976). This model is described by the variables $(\theta_1, \theta_2, \theta_3)$ and the position of the cell
 284 $\mathbf{r} = (x, y, z)$ (see Appendix A), and their time evolution equations are closed in terms of
 285 the variables.

286 The model has two characteristic steady solutions (Eqs. S5 and S6): one
 287 represents positive phototaxis, where the cell swims in the positive z direction with a
 288 constant speed, drawing a right-handed spiral trajectory. The other represents negative
 289 phototaxis, where the cell swims in the opposite direction in a similar way (Fig. 3D).
 290 Thus the model intrinsically accounts for both positive and negative phototaxis states.
 291 The stability of the two states changes with the parameters involved in the relation
 292 between p and I , (i.e., γ_0 , I_0 and τ_0). To examine how these parameters
 293 determine the steady state (i.e., the final swimming direction), we conducted numerical
 294 simulations with appropriate initial conditions of $(\theta_1, \theta_2, \theta_3, \mathbf{r})$. The results showed that
 295 a cell with the *trans*-flagellum dominant ($\gamma_0 = +1$) shows positive phototaxis when τ_0
 296 $= 0.08$ sec, and negative phototaxis when $\tau_0 = 0.32$ sec (Fig. 3C, D). As one full rotation
 297 of the cell about **c** axis takes 0.5 sec in this simulation ($\omega_c^{(0)} = 4\pi$), a τ_0 value between
 298 0 and 0.25 means that the onset of ciliary dominance occurs on the light side (when the
 299 eyespot faces the light source), whereas τ_0 between 0.25 and 0.50 means that it
 300 occurs on the dark side (when the eyespot faces opposite the light source after
 301 photostimulation). Thus, the simulation results are consistent with our experimental
 302 results of the PP strain (Fig. 2).

Fig. 4 shows the average velocities in the z direction (parallel to the light axis) in the steady state for various values of γ_0 , I_0 and τ_0 . Blue dots are the states where Eq. S5 (positive phototaxis) is realized, while red dots are the states in which Eq. S6 (negative phototaxis) is realized. Black dots represent states other than Eqs. S5 and S6, in which the cell does not draw a simple spiral trajectory but a complex one (Fig. S3), where $v(t)$ oscillates. The following three properties of our model are apparent from Fig. 4: (i) When the sign of γ_0 (representing the dominant cilium) is changed, the sign of $\bar{v}_z$ (representing the phototactic sign) changes. (ii) When τ_0 (the delay time of the onset of ciliary dominance after photoreception) changes, the sign of $\bar{v}_z$ also changes. (iii) When I_0 (the maximum light intensity that the cell senses) increases, the blue and red dot regions decrease and the black dot regions increase. Property (i) validates the Dominant-arm model (Fig. 1C), which agrees with the previous mathematical model (Bennett & Golestanian, 2015). Property (ii) validates the Off-response model (Fig. 1C) as long as $0.25 < \tau_0 < 0.5$, a range that is consistent with the present study. Property (iii) indicates that the increase in I_0 destabilizes Eqs. S5 and S6 (see SI Appendix B and Fig. S3 for details), implying that intense light tends to make the movement of *C. reinhardtii* unstable.

Off-response or delayed response?

In the Off-response model, ciliary dominance starts to occur on the dark side. We interpreted this as an immediate response to a light-off signal. However, it may also be a

324 delayed response to a light-on signal. If the delay time τ_0 is fixed between 0.25 sec
325 and 0.5 sec, a delayed response to a light-on stimulus would just look like a light-off
326 response without a delay. To assess which of these two interpretations is more plausible,
327 we conducted an experiment and a simulation.

328 First, we observed phototaxis in slow-swimming mutants *ida4* (lacking
329 inner-arm dynein subspecies a, c and d) and *oda1* (lacking entire outer-arm dynein)
330 after treatment with ROS-modulating reagents (R. Kamiya, 1988; R. Kamiya, Kurimoto,
331 & Muto, 1991; Takada, Wilkerson, Wakabayashi, Kamiya, & Witman, 2002). As the
332 bodily rotation of the cell is caused by the slightly three-dimensional beating of the two
333 cilia, slow-swimming mutants show bodily rotation with a longer rotation cycle time, as
334 we observed (Table 1). If the delay time is between 0.25 and 0.50 sec, those
335 slow-swimming mutants may differ in phototactic sign from the wild-type PP and NP
336 strains. We found that both *oda1* and *ida4* cells tended to display positive phototaxis
337 under neutral or oxidizing conditions, and negative phototaxis under reducing
338 conditions, similarly to the PP strain of the wild type (Fig. 5). However, the
339 sign-reversal in the slow-swimming mutants was not as clear as in the wild type,
340 especially after treatment with the ROS-scavenger. It is possible that the force
341 generation for steering is weaker under these conditions in the slow-swimming mutants.

342 We also used our mathematical model to simulate the behavior of cells that
 343 self-rotate at a lower-than-normal frequency of 0.67 Hz, a frequency close to that of
 344 *odal* (0.72 Hz; Table 1). Our simulation results indicated that when τ_0 is between 0.25
 345 and 0.5 sec, such cells do not change phototactic signs with a change in τ_0 , unlike the
 346 wild type cells that rotate at higher frequencies of ~2 Hz (Fig. 6). Taken together, these
 347 results suggest that, in the slow-swimming mutants (and most likely in the PP and NP
 348 strains also), it is more likely that the onset of ciliary dominance alteration on the dark
 349 side takes place in direct response to a light-off stimulus, rather than as a delayed
 350 response to a light-on stimulus.

351

352 **DISCUSSION**

353 In this study, we observed phototactic turning of *C. reinhardtii* cells with high-speed
 354 video recording. As previously shown (Wakabayashi et al., 2011), both PP and NP cells
 355 changed the sign of phototaxis when treated with ROS-modulating agents. Our results
 356 demonstrate that the sign of phototaxis is determined by which of the two (*cis*- and
 357 *trans*-) cilia beats stronger after photoreception, and that the sign reverses depending on
 358 whether the dominant cilium begins to beat stronger when the eyespot faces the light
 359 source or away from it (Fig. 7). An important factor that modulates when the onset of
 360 ciliary dominance occurs is the intracellular amount of ROS. Our mathematical model
 361 supports these findings.

362

363 **The cilium that becomes dominant after photoreception**

364 The first key factor that determines the phototactic sign is whether the *cis*- or the
 365 *trans*-cilium is dominant in a given strain. Several previous studies have shown that the
 366 two cilia of *C. reinhardtii* are intrinsically different (R. Kamiya & Hasegawa, 1987;
 367 Ritsu Kamiya & Witman, 1984; Ruffer & Nultsch, 1987, 1998; Ruffer & Nultsch,
 368 1991). Ruffer and Nultsch (1991, 1998) carried out high-speed cinematographic
 369 observation on cells trapped with a suction pipette. They found that, upon

370 photo-stimulation, the *trans*-cilium tended to beat more strongly (with a larger
371 amplitude and at a higher frequency) than the other in positively phototactic strains,
372 whereas the *cis*-cilium beat more strongly than the other in negatively phototactic
373 strains (Ruffer & Nultsch, 1998; Ruffer & Nultsch, 1991). Our results, obtained from
374 observation of free-swimming cells undergoing phototactic turning, are consistent with
375 these studies.

376 How is the dominant cilium determined? The results of the present study, as
377 well as those of Ruffer and Nultsch (1991), indicate that the cilium that becomes
378 dominant after photostimulation is the *trans*-cilium in PP and the *cis*-cilium in NP cells.
379 One would be inclined to assume that the Ca^{2+} sensitivities of the *cis*- and
380 *trans*-axonemes (the inner structure of cilia) are reversed between PP and NP. However,
381 in detergent-extracted and motility-reactivated cell models, the Ca^{2+} -dependent motility
382 of the two axonemes attached to a single cell body was found not to differ between PP
383 and NP strains (Wakabayashi et al., 2011). Therefore, factors other than axonemes may
384 cause differences in ciliary Ca^{2+} -response of PP and NP cells. For example, some
385 detergent-soluble constituents of cilia, or some chemical modification of the axoneme
386 that is not retained after detergent extraction, may be responsible.

387 Previously, we identified the defect that causes the negatively phototactic
388 phenotype in the NP strain (*agg1*) as the loss of a protein that possibly functions in
389 mitochondria (Ide et al., 2016). If this protein functions in the respiratory chain, the
390 redox poise and/or the amount of ROS could differ between PP and NP cells and
391 differentially modulate the activities of membrane proteins, such as Ca^{2+} channels and
392 pumps. Other *C. reinhardtii* mutants, *agg2* and *agg3*, are also known to display
393 negative phototaxis. Although whether the *cis*- or the *trans*-cilium is dominant in these
394 mutants has not been determined, their defects are also caused by mutations in
395 non-axonemal proteins; the causative protein Agg2 is localized to the proximal ciliary
396 membrane, while Agg3 is a flavodoxin that localizes to the ciliary matrix (Iomini, Li,
397 Mo, Dutcher, & Piperno, 2006). Loss of these proteins may modulate the function of the
398 ciliary membrane and could switch the dominant cilium.

399

400 **How is the off-response of the ciliary dominance produced?**

401 The second key factor that determines the phototactic sign is the timing at which the
402 dominant cilium starts to increase power after photoreception. We showed that *t*-BOOH,
403 a membrane-permeable ROS that promotes positive phototaxis, induces the onset of
404 *cis*-cilium dominance on the dark side in NP cells, whereas DMTU, a

405 membrane-permeable ROS-scavenger that promotes negative phototaxis, induces that of
 406 the *trans*-cilium dominance on the dark side in PP cells (Fig. 2A, B). The onset of
 407 ciliary dominance on the dark side could be interpreted as a so-called off response or a
 408 step-down response, which means that cells respond to a light-off stimulus. Initiation of
 409 phototactic turn as an off response has been proposed previously (Isogai et al., 2000),
 410 and the present study provides evidence for this from simultaneous observation of
 411 swimming track and eyespot position while artificially manipulating the phototaxis
 412 direction. Rüffer and Nultsch (1991) showed that the beating in the two cilia
 413 reciprocally changes upon reception of light-on as well as light-off stimuli, and
 414 suggested that cells displaying opposite cilia responses exhibit positive and negative
 415 phototaxis, which our results are in general agreement with.

416 The molecular mechanism of the off response in *C. reinhardtii* is unknown.
 417 Theoretically, a response equivalent to an off-response could be accomplished by an
 418 appropriate delay in the light-on response. However, our observations on
 419 slow-swimming mutants, as well as theoretical considerations, rule out this possibility.
 420 Previous observations by Rüffer and Nultsch (1991) that micropipette-held *C.*
 421 *reinhardtii* cells display on- and off- responses also indicate the presence of a genuine
 422 off-response. Generally, the photoreception by ChR, a light-gated cation channel, is

423 thought to induce depolarization of the cellular membrane. However, the Ca^{2+} influx at
 424 the eyespot may induce activation of Ca^{2+} -activated K^+ channel (Vergara, Latorre,
 425 Marrion, & Adelman, 1998), which would induce an increase in K^+ conductance and
 426 concomitant hyperpolarization of the membrane. If the light causes hyperpolarization, a
 427 light-off stimulus may induce depolarization of the membrane and elicit an off-response.
 428 In addition, recently, ROS-modulating reagents were shown to modulate the
 429 phosphorylation state of ChR1 (Bohm et al., 2019). The activity change of ChR1
 430 according to this phosphorylation state may also lead to the off-response. These
 431 possibilities can be tested by further electrophysiological analyses using
 432 ROS-modulating reagents.

433

434 **Mathematical model results support the experimental data**

435 To mathematically assess the plausibility of the Dominant arm model and the
 436 Off-response model, we developed a simple model that describes the swimming
 437 behaviors of *C. reinhardtii*. The theoretical model and the experimental data both
 438 showed that the Off-response model is not accomplished by the presence of a fixed
 439 delay time in the light-on response, but by the response to a light-off stimulus (Fig. 6, 7).
 440 While several previous models have been presented to explain the photobehavior of

441 green alga, ours is one of the simplest, explaining the switching of the phototactic sign
442 through only one equation with some changes of the system parameters (Bennett &
443 Golestanian, 2015; Drescher et al., 2010).

444 Our model also provides clues to understanding why all the cells of the same
445 strain under the same light conditions do not exhibit the same sign of phototaxis; for
446 example, even when PP cells are treated with H_2O_2 , which elicits positive phototaxis,
447 ~5% of the cells show negative phototaxis (Wakabayashi et al., 2011). This could be
448 explained by the variance of the delay time in the onset of ciliary dominance. Even
449 though our model precludes the fixed delay time after treatment with the
450 ROS-modulating reagents, the delay time may vary between cells. In Fig. 5, when $\gamma_0 =$
451 1 (i.e., the *trans*-cilium is dominant after photoreception) and $I_0 = 0.1$ or 0.5 , cells show
452 positive phototaxis when $\sim 50 < \tau_0 < \sim 300$ msec. The value of τ_0 has been suggested to
453 be longer than 30~40 msec (Rüffer & Nultsch, 1991; Witman, 1993). Thus, if a cell has
454 longer τ_0 than 300 msec, which would be caused by several factors including kinetics of
455 Ca^{2+} influx and cellular ROS amounts, this cell will exhibit negative phototaxis.
456 Furthermore, the τ_0 -vz curves in Fig. 5 will change greatly if the eyespot position
457 somewhat varies and causes a change in the τ_0 -vz curve. If a cell has the eyespot at an
458 irregular position, it may exhibit an opposite sign of phototaxis even with the same τ_0 .

459 In summary, our experimental observations combined with the insights from
 460 our theoretical model showed that phototactic signs of *C. reinhardtii* cells are
 461 determined by two factors: the genetically determined dominant cilium, and the timing
 462 of the onset of strong beating by the dominant cilium after photoreception (Fig. 7). The
 463 timing, either on the light side or the dark side, is modulated by the cellular amount of
 464 ROS, which is a byproduct of photosynthesis. Cells may monitor photosynthetic
 465 activities through ROS amounts, and this regulation mechanism may contribute to
 466 maintaining ideal photosynthetic activities by modifying light conditions through
 467 phototaxis.

468

469 MATERIALS AND METHODS

470 *Cell culture and strains*

471 *Chlamydomonas reinhardtii* strains CC-124 (nit1– (nitrate reductase), nit2–, aggl–,
472 mt– (mating type))(Ide et al., 2016), CC-125 (nit1–, nit2–, mt+), CC-2670 (ida4–, mt+),
473 and CC-2228 (oda1–, mt+) were used. CC-124 and CC-125 were termed PP and NP,
474 respectively. The CC-125 strain maintained in our laboratory appears to have a slight
475 difference in motility characteristics from the same strain available from the
476 Chlamydomonas Resource Center (<http://www.chlamycollection.org/>) (Sato, Sato, &
477 Toyoshima, 2018; Wakabayashi et al., 2011). CC-2670 (*ida4*; lacking inner-arm
478 dyneins a, c, and d) and CC-2228 (*oda1*; lacking outer-arm dynein and the outer-dynein
479 arm docking complex) were used as slow-swimming mutants. Cells were grown in
480 tris-acetate phosphate medium (TAP) medium with aeration at 25 °C, on a 12 h/12 h
481 light/dark cycle (Gorman & Levine, 1965).

482

483 *High-speed observation of phototaxis and measurement of the bodily rotation cycle*

484 Cells were washed with an experimental solution (5 mM Hepes (pH 7.4), 0.2 mM
485 EGTA, 1 mM KCl, 0.3 mM CaCl₂) (Okita, Isogai, Hirono, Kamiya, & Yoshimura,
486 2005) and kept under red light for more than 50 minutes before the assays. To induce

487 positive or negative phototaxis, the cell suspensions were treated with
488 tertiary-butylhydroperoxide (*t*-BOOH; final concentration is 0.2 mM) (Wako Pure
489 Chemical Industries) as a ROS reagent, or dimethylthiourea (DMTU; final
490 concentration is 75 mM) (Sigma-Aldrich) as a ROS-scavenging reagent (Wakabayashi
491 et al., 2011). Cell suspensions were put between a coverslip and a glass slide and placed
492 on the stage of a dark-field microscope with an oil-immersion condenser (BX53;
493 Olympus). The directional light to induce phototaxis was produced with two green
494 LEDs ($\lambda=525$ nm). The setup is shown in Fig. 2A. First, a weak green light ($\sim 5 \mu\text{mol}$
495 $\text{photons m}^{-2} \text{s}^{-1}$) was illuminated (Light 1 in Fig. 2A). Most cells showed either positive
496 or negative phototaxis. Then a stronger green light (Light 2 in Fig. 2A; $\sim 30 \mu\text{mol}$
497 $\text{photons m}^{-2} \text{s}^{-1}$) was illuminated, perpendicular to Light 1. Most of the cells then
498 changed their swimming directions and oriented parallel to the Light 2 beam. The
499 behavior of cells was observed with dim red light ($\lambda > 600$ nm) and videos were
500 recorded with a high-speed camera (HAS-L2M, DITECT) at 150 fps. The LED for
501 Light 2 was linked with the trigger switch of the high-speed camera so that recording
502 was initiated when it was lit. The timing of photoreception was determined as the time
503 when the eyespot faced the Light 2 side (Fig. 2A, 2B). The position of the eyespot in the
504 helical swimming paths was also determined from the same video footage.

505 The measurement of the bodily rotation cycle was carried out with the same
506 experimental setup as above (without sideways illuminations). The time required for
507 one bodily rotation was determined from the position of the eyespot on the swimming
508 trajectories, and the rotation period was calculated.

509

510 ***Phototaxis assay***

511 The phototaxis assay shown in Fig. 5 was carried out by the method described in (Ueki
512 et al., 2016). In brief, cells were washed with the experimental solution and kept under
513 dim red light for 30 min before the phototaxis assays. For dish assays, cell suspensions
514 ($\sim 10^7$ cells/mL) were put in Petri dishes (30 mm in diameter, 10 mm thick), illuminated
515 with a green LED ($\lambda = 525$ nm, ~ 50 $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$) from one side for 5 min, and
516 photographed (DSC-RX100M2; Sony). For single-cell analysis, cells were observed
517 under a dark-field microscope (BX-53, Olympus) under dim red light ($\lambda > 600$ nm) and
518 recorded to video using a CCD camera (1129HMN1/3; Wraymer). The angle (θ)
519 between the light direction and the swimming direction was measured for 1.5 s,
520 following illumination with a green LED for 15 s. Images of swimming cells were
521 auto-tracked using Image Hyper software (Science Eye), and angles were measured
522 from the cell trajectories. t-BOOH (final concentration of 0.2 mM; Wako Pure

523 Chemical Industries) was used as a ROS reagent, and dimethylthiourea (final
524 concentration of 75 mM; Sigma-Aldrich) was used as a ROS-scavenging reagent

525

526 *Electrophysiology*

527 PRCs were assessed in a population of *C. reinhardtii* cells by the method
528 of Sineshchekov et al. (1992) (O. A. Sineshchekov et al., 1992, 1994). In brief, 1 ml of
529 cell suspension in a measuring solution (0.5 mM Hepes, pH 7.3, 0.1 mM CaCl₂) was put
530 in a cuvette (10×10×15 mm), with two electrodes on each side of its rectangular bottom.
531 A 500 nm beam of light was generated with an LED source (NSPE510S, Nichia
532 Chemical) and applied from one side of the electrode. The current was measured with a
533 patch-clamp amplifier (Axoclamp 200B, Axon).

534

535 *Measurement of ciliary beating frequency*

536 Ciliary beating frequency (CBF) was measured based on the method described in (R
537 Kamiya, 2000) with modifications (Wakabayashi & King, 2006). The median frequency
538 was obtained from the power spectra of fast Fourier-transformed cell body vibration
539 signals in microscopy images averaged for ~20 s.

540

541 *Measurement of bodily rotation cycle*

542 Cells were observed under a dark-field microscope with an oil-immersion condenser
 543 (BX-53, Olympus) and recorded to video with a high-speed camera (HAS-L2M,
 544 DITECT) at 150 fps. The bodily rotation cycle was defined as the time it takes for the
 545 eyespot (observed as a bright spot) to return to the same position relative to the cell's
 546 swimming trajectory, and was measured by counting the frames for one cycle.

Table 1. Ciliary beating frequencies and bodily rotation cycles of strains used

	PP	NP	<i>ida4</i>	<i>oda1</i>
Ciliary Beating Frequency (Hz) (Mean $\pm$ SEM, n=3 measurements)	55.0 $\pm$ 0.6	55.5 $\pm$ 1.0	51.6 $\pm$ 2.6	24.3 $\pm$ 0.6
Bodily rotation cycle (Hz) (Mean $\pm$ SD, n=10 cells)	2.11 $\pm$ 0.27	1.89 $\pm$ 0.27	1.25 $\pm$ 0.22	0.72 $\pm$ 0.09

662 **Figure legends**

663 **Fig. 1**

664 **Schematic images of a *Chlamydomonas reinhardtii* cell and its phototaxis.**

665 (A) Schematic image of *C. reinhardtii* cell and the eyespot. The cilium closest to the
 666 eyespot is called *cis*-cilium, whereas the one farthest from the eyespot is called
 667 *trans*-cilium. The eyespot is composed of the carotenoid-rich granule layers that
 668 function as a light reflector, and channelrhodopsin molecules aligned in the plasma
 669 membrane. Channelrhodopsin functions as a light-gated cation channel. The light signal
 670 coming from the outside of the cell is reflected by the carotenoid granule layers and
 671 amplified, whereas that coming through the cell is blocked. (B) The current model to
 672 explain positive phototaxis. After photoreception at the eyespot (yellow arrow), $[Ca^{2+}]_i$
 673 in the cilia increases and the *trans*-cilium (t) becomes dominant. After a half rotation of
 674 the cell around its central axis, the light signal to the eyespot is blocked, $[Ca^{2+}]_i$ in the
 675 cilia decreases, and the *cis*-cilium (c) becomes dominant. (C) Hypothetical models for
 676 negative phototaxis. In the “Dominant arm model”, Ca^{2+} -sensitivities of two cilia are
 677 assumed to be reversed from the positively phototactic cell shown in (B); the *cis*-cilium
 678 becomes dominant after photoreception. In the “Off-response model”, after

679 photoreception, the *trans*-cilium becomes dominant when the eyespot faces opposite to
680 the light source.

681

682 **Fig. 2**

683 **Eyespot position relative to the cell trajectory during phototaxis.**

684 **(A)** Phototactic turnings of PP and NP cells after treatment with t-BOOH or DMTU.

685 Images of a swimming cell, taken at 150 fps, are superimposed every 0.13 sec. First,

686 Light 1 (weak green light from the left) was illuminated to induce positive (top;

687 swimming to the left) or negative (bottom; swimming to the right) phototaxis. After

688 Light 2 (strong green light from the top) was turned on, the cell changed its swimming

689 direction. The timing of the onset of Light 2 was at the white arrows/arrowhead. The

690 eyespot facing Light 2 is shown with green arrowheads, whereas that facing opposite to

691 Light 2 is shown with magenta arrowheads. The former case is classified as “the light

692 side”) and the latter “the dark side” in **(B)**. Yellow arrows show the swimming

693 directions. (The cells whose trajectories intersect with the superimposed cells were

694 removed from the image in the process creating the superimpose. See SI Movies S1-4

695 for the raw data.) **(B)** The proportion of the dominant cilium and the side where the

696 onset of the ciliary dominance occurred. PP cells showing positive phototaxis (control

697 and +*t*-BOOH) or negative phototaxis (+DMTU) and NP cells showing negative
698 phototaxis (control and +DMTU) or positive phototaxis (+*t*-BOOH) were observed
699 (n=8~28 per condition).

700

701 **Fig. 3**

702 **Mathematical model for *C. reinhardtii* phototaxis.**

703 (A) Definitions of the body axes of a *C. reinhardtii* cell. The vectors **a**, **b** and **c** are unit
704 vectors that are fixed to the body of the cell. **a**, **b** and **c** are mutually orthogonal to each
705 other, and **b** and **c** are within the ciliary beat plane. **b** is close to the side of *cis*-cilium.
706 With them, the direction of eyespot is expressed as $\mathbf{e}_{\text{eyespot}} = (\mathbf{b} + \mathbf{c}) / \sqrt{2}$. The directions
707 of **a**, **b** and **c** evolve with time according to Eq. 1. (B) Definitions of the Euler angles
708 that specify the directions of **a**, **b**, **c** for the x, y, z coordinate system that is fixed in
709 space. θ_1 is the angle between the y-axis and the vector **N**, where $\mathbf{N} = \mathbf{z} \times \mathbf{c} / |\mathbf{z} \times \mathbf{c}|$.
710 θ_2 and θ_3 are angles between the z-axis and **c** and between **N** and **b**,
711 respectively. When $\theta_1 = \theta_2 = \theta_3 = 0$, **a**, **b**, **c** axes coincide with *x*, *y*, *z* axes,
712 respectively. (C), (D) Examples of initial trajectories of the cell obeying Eq. 1
713 ($0 \leq t \leq 10$), which indicate positive phototaxis ($\tau_0 = 0.08$ sec, (C)) and negative
714 phototaxis ($\tau_0 = 0.32$ sec, (D)). The parameters are $\gamma_0 = 1$ (the *trans*-cilium becomes

715 dominant after photoreception at the eyespot) and $I_0 = 0.5$, and the initial conditions
 716 are $\mathbf{r}(0) = (0, 0, 0)$, $\theta_1(0) = 0$, $\theta_2(0) = -\pi/2$ and $\theta_3(0) = 0$. Thick orange arrows
 717 show the direction of the light illumination, and thin black arrows show the swimming
 718 direction of the cell.

719

720 **Fig. 4**

721 **Sign-switching of phototaxis in the mathematical model.**

722 The mean velocity $\bar{v}_z$ of the steady-state of the cell after a long-time simulation as a
 723 function of the delay time τ_0 for various values of γ_0 and I_0 . For each set of system
 724 parameters, only one steady state of Eq. 1 realizes, which does not depend on the initial
 725 conditions of θ_1 , θ_2 , θ_3 , $\mathbf{r}$. $\bar{v}_z$ changes with τ_0 ; especially, the sign of $\bar{v}_z$ (=the
 726 sign of phototaxis) changes with γ_0 and τ_0 . Blue dots are the states where solution S5
 727 realizes, while red dots are the states where solution S6 realizes. Black dots with bars
 728 are the states where solutions other than Eqs. S5 or S6 are achieved, in which $v_z(t)$
 729 oscillates in time. The bars indicate the standard deviation of v_z of the steady-state.

730 The parameter values used are $v_0 = 120$ [$\mu\text{m/s}$], $[1/\text{s}]$ and $\omega_a^{(0)} = 2\pi$ [$1/\text{s}$]. The initial
 731 conditions are: $\mathbf{r}(0) = (0, 0, 0)$, $\theta_i(0) = \delta_i$ with random numbers $\delta_i \in [0, 2\pi]$ for
 732 $i = 1, 2, 3$, and $dI(t)/dt = 0$ for $0 \leq t \leq \tau_0$. For the discretization of Eq. S1, the Euler

method was used ($\Delta t = 1/10000$). The model suggests that, when $\gamma_0 = 1$ (i.e. the *trans*-cilium is dominant), the cell shows positive phototaxis (i.e. γ_0 is positive) when the dominant cilium beats stronger than the *cis*-cilium with the delay (τ_0) 50~260 ms. Similarly, when $\gamma_0 = -1$ (i.e. the *cis*-cilium is dominant), the cell shows negative phototaxis under the same conditions.

Fig. 5

Phototaxis assay of the slow-swimming mutants.

(A) PP, NP, *oda1*, and *ida4* cell suspensions put in Petri dishes with or without ROS-modulating reagents (0.2 mM *t*-BOOH or 75 mM DMTU) were illuminated by green LED ($\lambda = 525$ nm, $30 \mu\text{mol photons m}^{-2} \text{s}^{-1}$) from the right (green arrows) for 5 min from the right. Cells showing positive phototaxis are accumulated in the right halves of the dishes (orange boxes with “P”) and those showing negative phototaxis are accumulated in the left halves of the dishes (blue boxes with “N”). (B) Polar histograms depicting the percentage of cells moving in a particular direction relative to light illuminated from the right (green arrows), with or without treatment with ROS-modulating reagents (12 bins of 30° ; $n = 30$ cells per condition).

751 **Fig. 6**

752 **Sign-switching of phototaxis in a slow-swimming mutant in the mathematical**

753 **model.**

754 The plot of the mean velocity $\bar{v}_z$ of the steady-state of the mathematical model (Eqs.

755 S3 and S4) concerning the delay time τ_0 for cells rotate at 0.67 Hz, three times slower

756 than typical wild-type cells (~2.0 Hz). The parameter values used here are the same as

757 those used in Fig. 4 except for $\omega_a^{(0)}$ representing the bodily rotation cycle. The

758 meanings of blue, red, and black dots and bars in this figure are the same as those in Fig.

759 4.

760

761 **Fig. 7**

762 **Schematic model of sign-reversal in phototaxis suggested by this study.**

763 To make a phototactic turning, *cis*-dominant strain beats the *cis*-cilium (C) stronger than

764 the *trans*-cilium (T), whereas *trans*-dominant strain beats the *trans*-cilium stronger than

765 the *cis*-cilium. The *trans*-dominant strain, such as PP in this study, shows positive

766 phototaxis when the strong beating occurs upon light-on response (i.e. when the eyespot

767 faces the light side) and negative phototaxis when it occurs upon light-off response (i.e.

768 when the eyespot faces the dark side). The *cis*-dominant strain, such as NP in this study,

769 shows negative phototaxis when the strong beating occurs upon light-on response and
770 positive phototaxis when it occurs light-off response.
