Summary: Whether glial cells use a particular metabolism to support axonal metabolism and function remains controversial. We show here that the deletion of PKM2, an enzyme essential for the Warburg effect, in mature myelinating Schwann cells (mSC) leads to a deficit of lactate
30 in these cells and in peripheral nerves, and to motor defects despite no alteration of the myelin sheath. When electrically stimulated, peripheral nerve axons of mSC-PKM2 mutant mice failed to maintain lactate homeostasis, resulting in an impaired production of mitochondrial ATP. Action potential propagation was not changed but axonal mitochondria transport was altered, muscle axon terminals retracted and motor neurons showed cellular stress. Further reducing
35 lactate availability through dichloroacetate treatment definitely aggravated axonal malfunction in mutant mice. Thus, cancer-like Warburg effect is essential in mSC for the long-term maintenance of peripheral nerve axons physiology and function.

INTRODUCTION:

Energetic metabolism is an essential parameter of neurons' function and survival (Harris &
40 Attwell, 2012; Attwell & Laughlin, 2001; Alle *et al*, 2009). Indeed, the nervous system consumes a large amount of glucose mainly to allow synapses to function but also organelles and vesicles transport along axons and action potentials firing (Harris & Attwell, 2012). In the peripheral nervous system (PNS), axons grow far from their cell bodies to reach distant targets such as muscles. Maintaining metabolic homeostasis on such a long distance is a real challenge
45 for large axons that are extensively covered by a myelin sheath (Waxman, 1997).

This insulating sheath, resulting from several turns of compacted plasma membrane, is produced by myelinating Schwann cells (mSC). The ionic and electronic insulation forces action potentials

to “jump” from one node of Ranvier to the next, accelerating the nerve conduction velocity up to 120m/s (Waxman, 1980). Unfortunately, this insulation also mechanically hinders the diffusion of metabolites in the axonal environment and prevents the metabolic supply of myelinated axons. On the other hand, glial cells may be a solution to provide trophic support to the axons they surround. Evidence for a metabolic coupling between glial cells and neurons has been provided in the CNS. Indeed, astrocytes and oligodendrocytes play a critical role in this process by metabolizing glucose into lactate and exporting it to the axon as a fuel for axonal mitochondria, a process known as the lactate shuttle theory (Magistretti & Allaman, 2015; Fünfschilling *et al*, 2012; Lee *et al*, 2012). Recently, mitochondrial respiration was shown to be dispensable for myelinating oligodendrocytes suggesting these cells can use glycolysis for ATP production and produce lactate (Della-Flora Nunes *et al*, 2017; Fünfschilling *et al*, 2012). Moreover, the disruption of monocarboxylate transporters (MCT), which mediate the traffic of metabolites in these cells, induces axonal damages and the degeneration of neurons *in vivo* (Lee *et al*, 2012), suggesting lactate export from oligodendrocytes is required for axons maintenance (Bouçanova *et al*, 2021; Jha & Morrison, 2020). In the PNS, mSC do not remain without mitochondrial respiration (Fünfschilling *et al*, 2012), but lactate has been detected in the extracellular space of nerves and shown to be effective in supporting nerve function *ex vivo* (Brown *et al*, 2012). However, the cellular origin of the released lactate and its relevance as an energy substrate for axons remains largely unclear (Stassart *et al*, 2018).

Lactate production in aerobic conditions has been well studied in cancer cells. Indeed, many type of cancer cells use aerobic glycolysis, also called the Warburg effect, to produce ATP as well as other metabolites required for cell survival and proliferation (Vander Heiden *et al*, 2009). This metabolic shift to the Warburg effect relies on the expression of Pyruvate Kinase M2 (PKM2)

isoform instead of PKM1 (Israelsen *et al*, 2013, 2). PKM2 is a master regulator of glycolysis cumulating metabolic and non-metabolic functions as a protein kinase and transcriptional coactivator (He *et al*, 2017, 2). How PKM2 expression leads to more lactate is not clear. However, as PKM2 slows down pyruvate synthesis compared to PKM1, this may allow lactate dehydrogenase to metabolize pyruvate into lactate (Hanahan & Weinberg, 2011; He *et al*, 2017; Frezza & Gottlieb, 2009).

Recently, cases of reversible peripheral neuropathy have been observed following treatment with Dichloroacetate (DCA), a chemical compound acting on lactate level in cells (James & Stacpoole, 2016; Tataranni & Piccoli, 2019). Indeed, DCA is indirectly activating pyruvate dehydrogenase (PDH) and increasing the mitochondrial uptake of pyruvate, depleting cellular lactate. While the use of this compound to prevents cancer cells growth in several tumors is controversial (Stacpoole, 1989; Tataranni & Piccoli, 2019), it is also indicated to treat acute and chronic lactic acidosis and diabetes (James *et al*, 2017). DCA side effects suggest the importance of lactate balance in the PNS function. Here, we investigated the role of lactate in the physiology and function of axons and mSC of the PNS through the deletion of PKM2 in mSC (mSC–PKM2). Our results reveal the delicate equilibrium of lactate homeostasis in myelinated fibres of peripheral nerves and the critical trophic role of mSC in the support of axonal function in PNS.

RESULTS:

PKM2 expression promotes Warburg effect in mSC

Firstly, to investigate the metabolic status of SC, we examined the expression and localization of PKM1 and PKM2 isoforms in mouse sciatic nerves using RT-qPCR and immunohistochemistry. PKM1 mRNA was downregulated during sciatic nerve maturation from

postnatal day (P) 2 to P28 while PKM2 expression increased at the same time (**Fig. 1A**). At non
 95 mature ages of SC, P4 and P15, PKM1 and PKM2 were both expressed in mSC (E-cadherin) that
 surrounded axons (2H3, **Fig. 1B a,b,c,d**). When SC were mature and formed myelin, at P30 and
 5 months, PKM2 replaced PKM1 in mSC (**Fig. 1B e,f,g,h**), in particular in the perinuclear region
 (**Fig. S1**), suggesting mSC enters the Warburg effect metabolic mode when the myelinated fibers
 are mature.

100 **PKM2 deletion in mSC leads to a reorganization of the metabolism in the nerve**

mSC expressed PKM2, suggesting they were producing lactate, which raised the
 possibility that they provided a trophic support to axons. To test this hypothesis, we first
 performed a specific and conditional deletion of PKM2 isoform in myelinating glia of mice,
 crossing a mouse strain expressing floxed PKM2-specific exon 10 alleles (Israelsen *et al*, 2013)
 105 with a strain expressing the Cre recombinase under the inducible and myelinating cell-specific
 promoter PLP1-ERT (Doerflinger *et al*, 2003). Injecting tamoxifen in Cre positive/*PKM2*^{fl/fl}
 (mutant) and Cre-negative/*PKM2*^{fl/fl} (control) littermates at 1 month postnatal resulted in a
 significant decrease of PKM2 expression in sciatic nerves of mutant as seen in immunoblotting,
 quantitative RT-PCR and immunostaining (**Fig. 1C,D,E**). The same experiments indicated that
 110 PKM1 was re-expressed in PKM2-deleted mSC (**Fig. 1D,E**), suggesting a compensatory
 mechanism to maintain energy production.

Next, we expressed a lactate-detecting fluorescent probe (Laconic, **Fig. S2**, San Martín et
 al., 2013) in mSC of the mouse sciatic nerve *in vivo* using an AAV9 vector (Gonzalez *et al*,
 2014). Mutant and control mice expressing the probe were then anesthetized and their nerves
 115 imaged using a multi-photon microscope to measure the relative amount of lactate in mSC of
 living mice. Cells of mutant mice showed significantly less lactate than mSC of control mice

(**Fig. 1F**). In addition, biochemical measurements showed that this deficit of lactate in mSC resulted in a global reduced amount of lactate in mutant mice nerves compared to control ones (**Fig. 1G**).

To analyze on a broad way the influence of PKM2 deletion in mSC on the metabolic status of the nerve, we performed a targeted metabolomic screen on mutant and control mouse nerves. We observed a decrease of some acylcarnitines in mutant mice (**Fig. S3**), without modification of the acylcarnitine/carnitine ratio (0.2707 vs 0.2739 in control and mutant respectively, $P=0.77$ two –tailed Student T-test). These acylcarnitines are involved in the transport of fatty acids across mitochondrial membranes before their degradation in carnitine and acetyl-CoA (Indiveri *et al*, 2011). Therefore, the maintenance of the ratio coupled to the decrease of acylcarnitines indicated a higher turnover, suggesting an increase of the mitochondrial activity. Moreover, as mitochondrial dysfunction following deletion of TFAM1 in mSC of mice has been shown to dramatically increase acylcarnitines (Viader *et al*, 2013), our data suggested the opposite effect in mutant mice, i.e. the upregulation of mitochondrial activity.

Lactate homeostasis and ATP production are impaired in axons of PKM2-SCKO mice

According to the lactate shuttle theory, this decrease of lactate should also result in a shortage of axonal lactate. We investigated this assumption by expressing Laconic in peripheral axons using an AAV9 vector injected intrathecally in young pups (**Fig. S4A**). After tamoxifen recombination, we performed live imaging of probe-labeled axons that cross the saphenous nerve in anesthetized mice (**Fig. S4A**). While in resting conditions no difference could be seen between genotypes (**Fig. S5A**), when nerves were challenged with electrical stimulations to generate action potentials in type A fibers, axonal lactate increased shortly after the stimulation in control

but dropped in mutant (**Fig. 2A**). In the long term, control mice axons were able to maintain their
 140 lactate homeostasis while mutant mice axons could not (**Fig. 2A**, red line).

Beside lactate, another way axons may feed their mitochondria is glucose-derived
 pyruvate. Thus, we used a glucose-specific probe (FLII12Pglu-700uδ6, **Fig. S4B**) (Takanaga *et*
al, 2008) to investigate glucose level in axons in the same conditions. While in resting axons a
 similar amount of glucose was found in both genotypes (**Fig. S5B**), upon electrical stimulations
 145 glucose increased in axons of mutant mice while it remained stable in control mice (**Fig. 2B**),
 suggesting that axons of mutant mice mobilized glucose instead of lactate upon stimulations. We
 finally investigated the production of ATP by axonal mitochondria *in vivo* using a mitochondria-
 targeted fluorescent probe detecting ATP (ATeam, **Fig. S4C**) (Tsuyama *et al*, 2013). Again, no
 difference could be seen in resting conditions (**Fig. S5C**). However, when axons were stimulated
 150 mutant mice mitochondria failed to increase ATP production while this production increased in
 control mice (**Fig. 2C**). Thus, in absence of the Warburg effect in mSC, lactate homeostasis and
 mitochondria ATP production are impaired in electrically active axons, despite the mobilization
 of glucose.

155 **Behavior impairment and neuromuscular junction loss in PKM2-SCKO mice are not due to demyelination**

Since we observed a deficit in energy production in axons, we tested whether this had an
 impact on motor capacities of mutant mice. A longitudinal analysis revealed a significant deficit
 in both Rotarod and grip tests in mutant mice (**Fig. 3A,B**), suggesting a direct influence of the
 160 metabolic changes observed in mutant mice axons on their motor abilities. We also measured the
 nerve conduction velocity of sciatic nerves, and noticed it was not altered in mutant mice (**Fig.**

3C) indicating that the myelin sheath was not affected. Accordingly, electron microscopy analyses showed correctly myelinated axons and a regular g-ratio in mutant mice (**Fig. S6**). The conduction of action potentials along myelinated axons was also not altered as the electrophysiological properties of sciatic nerve axons *ex vivo* were maintained even at very high firing frequencies (**Fig. S7, Table S**). Motor neuron number did not change in the spinal cord (**Fig. 3D**) but they displayed a higher expression of cleaved Caspase 3 (**Fig. 3E and S8**), a marker of neuronal stress and axonal degeneration (Mukherjee & Williams, 2017). Indeed, tracking axonal mitochondria *in vivo* revealed a decrease of their movements in mutant mice both before and after electrical stimulation (**Fig. 3F**). In addition, mutant mice showed significantly more denervated neuromuscular junctions with intact postsynaptic structures (**Fig. 3G,H**) in the gastrocnemius muscle, suggesting the retraction of axon terminals. Taken together, these data indicated that PKM2 deletion did not affect the maintenance of the myelin sheet but resulted in a motor distal neuropathy in mice. This indicated that the Warburg effect in mSC is required for the maintenance of axonal trafficking and neuromuscular junctions.

Long-term maintenance of axons function rely on lactate feeding by SC

To investigate further the role of lactate intake in axons' long term maintenance , we treated mutant and control mice with dichloroacetate (DCA), a drug that promotes mitochondrial consumption of pyruvate and decreases the availability of lactate (**Fig. 4A**) (Stacpoole, 1989). DCA treatment has been considered for patients suffering from congenital lactic acidosis and for cancer treatment but it can lead to a reversible peripheral neuropathy primarily affecting axons in humans and rodents (James & Stacpoole, 2016). Over the seven weeks of treatment, Rotarod performance decreased in treated mice independently of the genotype (**Fig. 4B**) with no effect on

the myelin sheath as the nerve conduction velocity did not significantly change (**Fig. 4C**). However, when the treatment stopped, control mice recovered over 3 weeks on the Rotarod while mutant mice did not (**Fig. 4B**). This indicated that axonal function was definitely damaged in these mice, confirming that Warburg effect in mSC is required for the long-term maintenance of peripheral axons' physiology.

DISCUSSION:

While the role of the lactate in the metabolic crosstalk between axons and the surrounding glia has been recognized for a long time in the CNS (Harris & Attwell, 2012), it remains unclear in the PNS. The presence of this compound in peripheral nerves had been detected and *ex vivo* experiments had shown that it could support action potentials propagation along axons (Brown *et al*, 2012). However, the origin of this nerve lactate remained unclear. By deleting PKM2 in mSC *in vivo*, we showed that part of this nerve lactate is provided by mSC using aerobic glycolysis and this lactate is required for axons to maintain their metabolic homeostasis and functions over time.

Unexpectedly, and to the opposite of cancer cells, preventing mSC performing aerobic glycolysis had very little impact on its own physiology and biology. Indeed, no defect could be detected in the myelin sheath of PKM2 mutant mice and the nerve conduction was not affected. A slight but significant shift occurred in the amount of some acylcarnitines without any alteration of the carnitine/acylcarnitine ratio, suggesting a higher turnover of these compounds that shuttle lipids into mitochondria for β -oxidation. According to the literature, we interpreted these data as the sign of a higher metabolic activity of mSC mitochondria. This is consistent with the upregulation of PKM1 expression we observed in mutant mice nerves as the higher enzymatic

activity of this isoform promotes pyruvate production and its use in the mitochondrial citric acid cycle and respiration. In the absence of PKM2, mSC metabolism probably shifted to more oxidative phosphorylation. As mSC cannot be dispensed of mitochondrial respiration (Della-Flora Nunes *et al*, 2017; Fünfschilling *et al*, 2012), this shift is likely to be mild for the cell which is still able to produce myelin and maintain it. However, as evidenced by our results the shutdown of aerobic glycolysis in mSC is clearly deleterious for axonal maintenance. Therefore, we conclude that mSC use simultaneously both mitochondrial respiration for myelin production and maintenance and Warburg effect to support axons survival.

The challenge in the analysis of metabolic crosstalk in a tissue is to distinguish between the metabolisms of the different cell types. In addition, nerve injury or section immediately modifies both axonal and glial mitochondria physiology (Kerschensteiner *et al*, 2005). To overcome these challenges, we chose to use the genetically encoded fluorescent probes delivered specifically to axons or mSC *in vivo* to follow a few critical metabolites in real time in physiological conditions. These probes such as lactate sensor *Laconic*, the glucose sensor *FLH12Pglu-700u86* and the ATP sensor *ATeam* have been extensively characterized in several *in vitro* and *in vivo* models and we confirmed that variations could be observed in the nerve *in vivo*. Although this gave us a limited view of all the metabolic changes that may have occurred in mutant cells, we could nevertheless draw some decisive conclusions.

Firstly, we observed that the metabolic homeostasis is efficient in peripheral nerves. While electrically activated axons show radical alterations in mutant mice in just a few dozens of minutes in particular for lactate, no change could be detected in resting axons of anesthetized animals disregarding the genotype. In this regard, axonal homeostasis is much more efficient than mSC homeostasis as lactate levels remained significantly lower in these cells in mutant

mice than in control mice. However, axonal homeostasis was not sufficient to buffer the metabolic changes that occur following physiological stimulations. Indeed, while axonal lactate remained apparently unaltered after stimulations in control mice, it sharply and steadily dropped in mutant mice axons. This revealed that actually the maintenance of lactate levels in control mice axons is due to a significant uptake of mSC lactate to compensate for a severe consumption during axonal activity (Rich & Brown, 2018). Therefore, lactate produced by mSC is a critical fuel for mitochondria of actively firing myelinated axons. Indeed, even the mobilization of glucose in stimulated axons was not sufficient to sustain an adequate ATP production in mitochondria. The involvement of the mSC lactate was definitively confirmed by the DCA treatment. Mutant mice were unable to recover their performances on the Rotarod following the draining of lactate supplies, while mice that could produce lactate in their mSC through aerobic glycolysis recovered. This underlines the dependence of myelinated axons to mSC lactate as all the other sources of energy substrates such as glucose, glycogen or glutamine are not directly altered by DCA. The reason for this dependence is puzzling but one possibility could be the swift accessibility of this glial lactate pool and its readiness for mitochondrial respiration while using glucose may require more time and enzymatic resources in the axons to generate pyruvate.

The main macroscopic phenotype resulting from PKM2 deletion in mSC is a motor weakness observed through Rotarod and grip test in the absence of demyelination. This was not significantly detectable before 6 months suggesting a late onset of the distal motor neuropathy. Taken together, this is characteristic of axonal CMT diseases in mice. Moreover, this neuropathy did not result from motor neurons death but from an axonal dysfunction illustrated by a decreased mitochondrial motility and retracted neuromuscular terminals. This retraction is likely to be the main cause of the motor weakness. Mitochondrial migration, which is essential for the

maintenance of the synapses, in particular in motor neurons (Marinković *et al*, 2012), relies on the ATP produced in mitochondria. In a previous work we showed that shutting down ATP synthase activity steadily slowed down mitochondrial movements in mSC *in vivo* (Gonzalez *et al*, 2015). Taken together, our results suggest that, the failure of mutant mice axonal mitochondria to increase their ATP production following physiological activity is the likely initial cause of the axonal dysfunction.

However, axonal firing properties were not significantly altered by this mitochondrial failure. This was unexpected because a largely accepted idea is that axonal ATP, and therefore axonal mitochondria, are required to maintain the membrane negative potential that allows depolarization. Actually, more recent analysis of neuronal energetics indicates that the energy cost of maintaining axon membrane potential is not that important, especially in myelinated fibers (Harris & Attwell, 2012). Therefore, the production of ATP by mutant mice axonal mitochondria may be sufficient to support this cost. Nevertheless, our data clearly indicate that mitochondrial ATP production and adaptation to the axon activity is critical for axonal maintenance.

Meeting the energy demand of axons is critical to ensure the long-term maintenance of the nervous system. Indeed, increasing evidences indicate that an unbalanced energy supply to axons is a capital factor of neurodegenerative diseases such as ALS (Vandoorne *et al*, 2018), Parkinson and Alzheimer diseases (Camandola & Mattson, 2017) or leprosis *Mycobacterium Leprae*-induced peripheral neuropathy (Medeiros *et al*, 2016). However, the molecular basis of this support remains unclear. The present data show that axonal dysfunction may be a direct result of perturbed metabolic support by supporting glial cells such as mSC. In this regard, the dramatic effect of DCA treatment on control and mutant mice motor performances is striking and

the inability of mutant mice to recover from this treatment is challenging. Indeed, DCA is proposed as a long-term treatment for several cancers and other diseases such as acute and chronic lactic acidosis and diabetes. Our data suggest that drugs targeting aerobic glycolysis metabolism as a treatment for these diseases may have a singular and deleterious effect on the nervous system and in particular on the PNS. Therefore, further and finer characterization of the axon/glia metabolic crosstalk is required in particular in neurodegenerative diseases. In this regard, the cancer-like nature of this glial metabolism constitute a risk for the nervous system regarding the deleterious effects of anticancer drugs that affect cell metabolism.
